Received ★★; accepted ★★

Abstract. We present and discuss broad band CCD $UBV(I)_C$ photometry and low resolution spectroscopy for stars in the region of the open cluster NGC 6996, located in the North America Nebula. The new data allow us to tightly constrain the basic properties of this object. We revise the cluster size, which in the past has been significantly underestimated. The width of the Main Sequence is mainly interpreted in terms of differential reddening, and indeed the stars’ color excess $E_{B-V}$ ranges from 0.43 to 0.65, implying the presence of a significant and evenly distributed dust component. We cross-correlate our optical photometry with near infrared from 2MASS, and by means of spectral classification we are able to build up extinction curves for an handful of bright members. We find that the reddening slope and the total to selective absorption ratio $R_V$ toward NGC 6996 are anomalous. Moreover the reddening corrected colors and magnitudes allow us to derive estimates for the cluster distance and age, which turn out to be $760 ± 70$ pc ($V_0 - M_V = 9.4 ± 0.2$) and $≈ 350$ Myr, respectively. Basing on our results, we suggest that NGC 6996 is located in front of the North America Nebula, and does not seem to have any apparent relationship with it.

Key words. Galaxy: open clusters and associations: individual: NGC 6996 – open clusters and associations: general
1. Introduction

Galactic open clusters are fundamental tools to probe the global properties and evolution of the Galactic disk. The determination of their fundamental parameters (age, distance, reddening pattern, size) allows us not only to better understand the properties and evolution of the Galactic open cluster system as a whole, but in many cases to put constrains on large structures like super-clusters, complexes, H II regions and molecular clouds systems, which they might be part of or not.

This is the case of NGC 6996 = C2054+444 ($l = 85.47^\circ, b = -0.48^\circ$), which is believed to lie in front of the North America Nebula (NGC 7000) HII region, precisely near its western edge (see Fig. 1), where an important dust cloud separates this nebula from the nearby Pelican Nebula.

NGC 6996 is a sparse and moderately young open cluster ($\sim 10^8$ Myr, Zdanavicius & Straizys 1990). However, its basic parameters, in particular distance and reddening, are not much well known, and this was the main motivation driving this study.

Previous investigations carried out in this area include the photographic studies by Muller (1936) and Barkhatova (1958). Later, a more detailed study has been conducted by Zdanavicius & Straizys (1990), who obtained photoelectric measurements of several bright stars in the region of NGC 6996 in the Vilnius system. More recently, Subramaniam et al. (1995) catalogued this cluster as a probable binary one together with the twin cluster Collinder 428. This latter object is located in the opposite (the eastern) border of the North America Nebula, and indeed both clusters might be related with the H II region.

The entire area belongs to the Cygnus region, which has been studied rather intensively. In fact this region (from $l \sim 74^\circ$ to $l \sim 85^\circ$) has the singular property that stars present an anomalous, with a larger slope, interstellar reddening law (see Straizys et al. 1999 and references therein). In particular, the visual absorption distribution in this region was studied by Goudis & White (1979) with the $H_\alpha$ surface brightness technique, by Bally & Scoville (1980) by using $^{12}$CO observations and, finally, by Cambrésy et al. (2002) from 2MASS data. These latter authors by the way discovered some new possible star clusters toward this area, which might be physical objects and as a consequence deserve further investigation.

In an attempt to derive better estimates of the NGC 6996 basic parameters (reddening, distance and age), to study the reddening law in this region and to understand whether some relations exist between the cluster and the North America Nebula, we performed CCD $UBV(I)_C$ photometry covering most of the cluster region, and complement it with...
Fig. 1. A map of the North America Nebula region. The region of NGC 6996 covered by our study is marked by a dashed square (see also Fig. 3). North is up, East on the left.

low resolution spectroscopic observation of bright stars in this region. Our data were also cross-correlated with near infrared ($JHK_s$) data from the 2MASS catalogue and with astrometric information available from the Tycho-2 catalogue (Høg et al. 2000) for the brightest stars.

The layout of the paper is as follows. In Sect. 2 we describe our observations and the reduction procedure. In Sect. 3 we present the data analysis. Sect. 4 deals with the cluster basic parameters determination. Sect. 5 is finally devoted to a brief discussion of the outcomes of this study.

2. Observations and data reduction

2.1. Photometry

CCD $UBV(I)_C$ data were obtained during three observational runs. Two of them were carried out with the AFOSC camera at the 1.82m Copernico telescope of Cima Ekar (Asiago, Italy), in the photometric nights of November 8, 2002 and September 18, 2003. AFOSC samples a $8\times14 \times 8\times14$ field in a $1K \times 1K$ nitrogen-cooled thinned CCD and this camera was used to take a central and a south frame in the cluster area. The other run was conducted at Teramo Observatory (Italy) using a $512 \times 512$ CCD onboard the 0.72m Teramo Normale Telescope (TNT). Teramo observations were

\end{align*}
\]

Details of the observations are listed in Table 1, where the observed fields are reported together with the exposure times, the typical seeing values and the air-masses. The data has been reduced with the IRAF\(^\dagger\) packages CCDRED, DAOPHOT, and PHOTCAL using the point spread function (PSF) method (Stetson 1987) for the frame obtained on 8/11/02 (Asiago) and using only aperture photometry for the others. The calibration coefficients were used to complement Asiago ones since two peripheral and less deep field were taken during a non photometric night. Figs. 1 and 3 show the finding charts of the covered area.

\(^\dagger\) IRAF is distributed by NOAO, which are operated by AURA under cooperative agreement with the NSF.
Fig. 2. DAOPHOT errors in the colour indexes and $V$ magnitude as a function of $V$

equations obtained by observing Landolt (1992) PG 0231+051 and PG 2213-006 fields at the Asiago Observatory, are:

\begin{align*}
  u &= U + u_1 + u_2(U - B) + u_3X \quad (1) \\
  b &= B + b_1 + b_2(B - V) + b_3X \quad (2) \\
  v &= V + v_1b + v_2b(B - V) + v_3X \quad (3) \\
  v &= V + v_1v + v_2v(V - I) + v_3X \quad (4) \\
  i &= I + i_1 + i_2(V - I) + i_3X \quad (5)
\end{align*}

where $UBVI$ are standard magnitudes, $ubvi$ are the instrumental ones, $X$ is the air-mass and the derived coefficients are presented in the bottom of Table 1. Since observations from Teramo Observatory were taken during a non photometric night, they were zero-point and color-term related to the Asiago data. As for $V$ magnitudes, when $B$ magnitude was available, we used expression (3) to compute them, elsewhere expression (4) was used. The standard stars in these fields provide a very good color coverage which allows us to obtain reliablys transformations. For the extinction coefficients, we assumed the typical values for the Asiago Observatory (Desidera et al. 2002 †). The photometric error trends against the $V$ magnitude data are shown in Fig. 2, where one can clearly distinguish the error trends for TNT and Asiago observations.

The photometric data for some of the brightest stars in the region of NGC 6996 are shown in Table 2. The full table is only available electronically at CDS.

Fig. 3. Finding chart of the NGC 6996 region (V filter). The black solid circle indicates the adopted angular size (radius = 7\arcmin) for the cluster (see Sect 3.1 and Fig. 5). Adopted likely and probable cluster members are enclosed in small circles and triangles, respectively. For a coordinate reference, the center (X = 0; Y = 0) corresponds to the cluster coordinates (see Sect 3.1) and each X-Y are expressed in arcsecs. North is up, East on the left.

2.2. Spectroscopy

Spectroscopic observations were carried out with the AFOSC camera at the 1.82m Copernico telescope of Cima Ekar (Asiago, Italy), in the following nights: July 21, September 18 and October 1, 2003. The instrument was used in low dispersion mode (R=600), the grism #4 was chosen to have a large spectral coverage (3500-7000 Å) and the exposure time ranged from 10 to 30 minutes, according to the brightness of the stars. The data has been reduced with the IRAF package for one-dimensional spectroscopy CTIOSLIT and by using the Hg-Cd lamp spectra for wavelength calibration purposes. In order to have flux-calibration, a few standard spectrophotometric stars were also observed. Spectra (see Fig. 4) were classified in two different ways:

- by comparing them with a library of spectroscopic standards (e.g. Jacoby et al. 1984; Torres-Dodgen & Weaver 1993);
Fig. 4. Spectra of some bright stars in the field of NGC 6996. A few interesting lines are indicated. See Table 2 for details. Numbers correspond to Zdanavicius & Straizys (1990) identification.

– by measuring the equivalent width of some absorption lines (mainly $H_\alpha$, $H_\beta$ and $H_\gamma$) (see Jaschek & Jaschek 1987).

At this resolution we estimate an error in the spectral type derivation of ±1 tenth. The derived spectral types and luminosity classes are reported in Table 2 and Fig. 4.

3. Data Analysis

3.1. Cluster angular size

To derive an estimate of the cluster angular size, we computed surface stellar densities at increasing concentric 1′ wide annuli around the adopted cluster center
(α2000 = 20°56′30″; δ2000 = +44°38′00″) over: a) the corresponding DSS-2\(^2\) red image, and b) the 2MASS infrared data. The results are shown in Fig. 5, where the dotted line is the field star density level as derived from mean star counts in two 2MASS fields, 20′ southward and northward NGC 6996, respectively. The patchy distribution of dust and gas clearly renders it difficult to fix a cluster radius. However, by inspecting both DSS maps and this plot we argue that the cluster radius is \(\sim 7′\), the point (dashed vertical line in Fig. 5) at which the stellar density more clearly reaches the field level. Therefore, we adopt this value as angular radius, which turns out to be almost twice the estimates reported by Lyngå(1987) and Dias et al. (2002) (6′ and 8′ in diameter, respectively).

3.2. Proper motions

Important information on the kinematics and membership of the brightest stars in and around a star cluster might in principle be derived from the proper motions as available in the Tycho-2 catalogue (Høg et al. 2000). With this aim in mind, we collected proper motion components for 22 stars in a field of 10′ radius centered in NGC 6996. They are shown as a vector point diagram in Fig. 6. The points distribution is characterized by a clump of several stars and few others placed around it. This fact can be readily interpreted as indicative of the presence of a star cluster. However, on the basis of the analysis here below, we found only 3 member stars with available proper motion from Tycho-2, and therefore we restrain from any kinematic analysis of NGC 6996 stars.

3.3. Photometric diagrams

The color-color diagrams (CCDs) and the color-magnitude diagrams (CMDs) from our data are shown in Figs. 7 and 8, respectively. In Fig. 9 we present the corresponding CMDs from 2MASS data for the cluster region stars (\(R < 7′\)) and for a region around it (see caption) that is used as comparison field. Some remarkable features in all these diagrams are the following ones:

- The Main Sequence (MS) in Fig. 7, 8 and 9 is significantly wide, a fact that we mainly ascribe to differential reddening due to the patchy distribution of gas and dust inside the cluster itself;
- the reddening (see Fig. 7b) law inside NGC 6996 does not seem normal, and turns out to be significantly different from that commonly accepted to hold for the Cygnus region (Johnson 1965). Indeed most of the stars follow a parallel path to a higher

Notes:
- # and #ZS columns indicate our numbering and that from Zdanavicius & Straizys (1990), respectively.
- #ZS numbers with an asterisk indicate stars separated in two components (values correspond to the brightest one).
- The full Table 2 is available, with all the photometric measurements, in electronic version at the CDS.
excess ratio. This is quite an usual situation in very young open clusters and star forming regions (e.g. Vázquez et al. 1996, Carraro et al. 2003) but not so common in older clusters;

– a noticeable gap appears at $B - V \approx 0.6$ and $V \approx 13$. This is not an unexpected feature, since several other young or intermediate age clusters have been found to exhibit gaps (e.g. Giorgi et al. 2002; Yadav & Sagar 2002; Baume et al. 2003b).
Table 3. Computed $R_V$ values by using different methods.

| Method            | Obtained $R_V$ value |
|-------------------|----------------------|
| Variable Extinction | 3.4 ± 0.2            |
| Excesses Relation  | 4.2 ± 0.1            |
| Color Difference   | 4.0 ± 0.4 (s.d.)     |

3.4. Cluster membership

As a first step, we base our membership assignment procedure on a synoptic analysis of the star positions in the various photometric diagrams (e.g. Baume 1999, 2003ab; Carraro 2002). By inspecting Fig. 7a, we notice that up to $(B - V) \approx 0.6$ stars are placed onto an apparent well recognizable MS composed by B and later type stars according to a Schmidt-Kaler’s (1982) ZAMS. They have also a compatible position on the CMDs of Fig. 8 and 9 down to $V \approx 13.5$. However, the considered B-type stars are more dispersed in these diagrams.

As a second step, we combine the magnitudes and colors with our spectral classification and that given by Zdanavicius & Straizys (1990), when available, and the result is that most of the brighter stars have very low excess values or/and low distance modulus, and only A-type stars have acceptable solutions. Therefore, the stars from the first group were considered as cluster non members (nm, probably interlopers), whereas the later ones as likely cluster members (lm). Additionally, following the ZAMS path along the CCDs and CMDs toward later than A spectral types we identify other stars with compatible positions on the photometric diagrams. Here however the stellar contamination by field stars starts to become important, and therefore we adopt them as probable cluster members (pm). This membership assignment produces an amount of stars in different bins of $V$ magnitude that is in agreement with the over-excess of stars present in Fig. 9a when compared to Fig. 9b.

Stars #ZS 6 and 14 (numbering from Zdanavicius & Straizys 1990) deserve special attention. The former lies below the ZAMS in the CCD of Fig. 7a, and by inspecting also its position in the CMDs we interpret its color as due to binarity, the secondary being a cool red star. The latter is a red star classified as a K2 III. Looking at its location in the CMDs, also in relation with the superposed isochrones (see below), we are inclined to consider it a cluster member. Unfortunately, it has no proper motion measurements (from Tycho-2) and therefore we adopt it as a probable member (pm).
Fig. 7. Color-color diagrams (CCDs) of stars in the region of NGC 6996. a) $U - B$ vs. $B - V$ diagram. Symbols have the following meaning: circles are likely member stars ($lm$), triangles are probable member stars ($pm$), white squares are non members ($nm$) and small hollow circles are stars without any membership assignment. The solid line is the Schmidt-Kaler’s (1982) ZAMS, whereas the dashed lines are the same ZAMS, but shifted by $E_{B-V} = 0.43$ and 0.65, respectively (see also Fig 10a). The dashed arrow indicates the reddening path. b) $B - V$ vs. $V - I$ diagram. Symbols as in Fig. 7a. Solid lines are the intrinsic positions for stars of luminosity classes V and III (Cousins 1978ab). The two dashed lines give the typical excess ratio for the Cygnus region ($E_{V-I}/E_{B-V} = 1.25$) and that adopted for the cluster ($E_{V-I}/E_{B-V} = 1.69$).

4. Cluster basic parameters

4.1. Corrected colors and magnitudes

In order to infer the intrinsic colors, when spectral classification is available we derive individual excesses by using Schmidt-Kaler (1982) relations. Figs. 7a and 10b show that the typical relation $E_{U-B}/E_{B-V} = 0.81 + 0.05 E_{B-V}$ for the Cygnus region (Johnson 1965) fit the point distribution much better than the normal one ($E_{U-B}/E_{B-V} = 0.72$). We use then the former relation to obtain some additional individual excesses from the CCD of Fig. 7a for stars without spectral classification. Then by considering all the adopted likely members and probable members with $V < 14$, we found a mean excesses of $E_{B-V} = 0.52 \pm 0.08$ (s.d.) and $E_{U-B} = 0.44 \pm 0.08$ (s.d.). The mean values are
Fig. 8. Color-magnitude diagrams (CMDs) for all the stars covered in the field of NGC 6996. Symbols as in Fig. 7a. The solid line is the Schmidt-Kaler (1982) empirical ZAMS shifted by the apparent distance modulus $V - M_V = 11.2$ ($V - M_V = V_0 - M_V + 4.1 \times (E_{B-V})$, see section 4). The dashed curves are the isochrones from Girardi et al. (2000). The reported numbers give the log(age). Then adopted as representative of the cluster color excess, whilst the lowest value is interpreted as the foreground color excess.

As for the reddening law in the direction of NGC 6996, it readily appears to be anomalous, and therefore we proceeded to compute the ratio $R_V = A_V/E_{B-V}$ by using the Excesses Relation Method (Fig. 10c), the Variable Extinction Method (Fig. 10d) and the Color Difference Method (Fig. 11). To build Figs. 10c and 10d up, we compute individual $E_{B-V}$, $E_{V-I}$ and $V - M_V$ values by means of the Schmidt-Kaler (1982) and Cousins (1978ab) calibration relations, a method also applied in Tr 14 (Vázquez et al. 1996) and in NGC 3293 (Baume et al. 2003). In the case of the Color Difference Method we combined the information from spectral classification, optical photometry and near infrared one from the 2MASS. For other applications of this method, see Thé & Graafland (1995) and Carraro et al. (2003).

It is clear from Fig. 10c that star positions follow a path different from the typical one for Cygnus region ($E_{V-I}/E_{B-V} = 1.25$) resulting in a higher $R_V$ value. This is not
Fig. 9. CMDs from 2MASS catalog. Symbols as in Fig. 7a. a) Stars placed inside the cluster area ($R < 7'$, see Fig. 5). b) Stars located in the comparison field around the cluster ($R > 8.85'$ and inside a box $20' \times 20'$). The solid line in panel a) and the dotted one in panel b) are the intrinsic position for MS stars from the Schmidt-Kaler (1982) and Koornneef (1983) calibrations fitted to the apparent distance modulus $K - M_K = 9.6$ 

$$K - M_K = V_0 - M_V + (3.1 - 2.78) (4.1/3.1) E_{B-V}$$

(see section 4). The dashed curves are the isochrones from Girardi et al. (2000). The reported numbers give the log(age).

very evident in Fig. 10d where there is a larger spread due probably to the presence of binaries. However, by performing least squares fittings over Figs. 10c and 10d and an extrapolation in Fig. 11, we obtain almost similar values (see Table 3). Therefore we adopt $R_V = 4.1$ to compute corrected magnitudes $V_0 = V - R_V \times E_{B-V}$ for cluster likely and probable members. This $R_V$ value yields a mean cluster absorption $\langle A_V \rangle = 2.13$.

It is worth noticing that this estimate is comparable with the absorption map in this region obtained by Goudis & White (1979).

4.2. Cluster distance and age

The distance of NGC 6996 is derived by superposing the Schmidt-Kaler (1982) ZAMS onto the reddening-free CMD (Fig. 12). The best ZAMS fitting was achieved for a distance modulus $V_0 - M_V = 9.4 \pm 0.2$ (error from inspection). We also apply the spectroscopic parallax method to 10 likely and probable member stars of luminosity
Fig. 10. a) $E_{B-V}$ distribution for stars inside the 7' cluster radius (white histogram) and for adopted likely and probable cluster members (dashed histogram). b) $E_{U-B}$ vs. $E_{B-V}$ diagram for stars with available spectral classification. c) $E_{V-I}$ vs. $E_{B-V}$ diagram. d) Variable extinction method. class V (see Table 3) by using the relation of spectral types and $M_V$ from Schmidt-Kaler (1982). This method yields a value $V_0 - M_V = 9.0 \pm 0.4$ (s.d.). The large dispersion of the last value and its difference from the ZAMS fit can be ascribed to the presence of binary and somewhat evolved stars included in the computation. The adopted distance modulus is therefore $V_0 - M_V = 9.4 \pm 0.2$ which in turn implies that NGC 6996 is located $760 \pm 70$ pc away from the Sun.
As for the age of NGC 6996, we over-imposed on the CMD (see Fig. 12) a set of isochrones derived from Girardi et al. (2000) evolutionary models (computed with solar metallicity, mass loss and overshooting). The fit has been performed taking into account only MS stars and is compatible with an age for the cluster of about 310 Myr (log(8.5)). By assuming that stars having A0 spectral type are still along the MS, we derive again an age near to 390 Myr (log(8.6)) for this cluster. Both procedures yield then similar results and we adopt 350 ± 50 Myr as the cluster age.

5. Discussion and conclusion

We have presented the first multicolor CCD photometric study in the region of the open cluster NGC 6996 together with spectral classification of some bright stars. NGC 6996 turns out to be a moderate age open cluster (≈ 350 Myr) located close to the west edge of NGC 7000, the North America Nebula. Our analysis places the cluster at a distance of 760 ± 70 pc. The evidence emerges of a significant differential reddening affecting the stars’ positions in all the photometric diagrams. We also point out that the reddening law has an anomalous value in the direction of this cluster.

To address the issue of its possible connection with the Nebula, we firstly summarize what it is known about the distance of the Nebula itself (see for reference Fig. 1). According to Straizys et al. (1999) the dust cloud that separates the North America and Pelican nebulae is placed at about 580 pc from the Sun. As for H II region (NGC 7000 itself), the distance is far from being reasonably contrained. In fact different works claim for very different distance estimates, ranging from 420 pc (Beer 1964) to 1980 pc (Dieter 1967). HD 199579, an O6 star considered responsible for at least part of the excitation of the region, is placed at a distance of 1200 pc by Miller (1968) and 830 pc by Garmany & Stencel (1992), which consider the star a member of the Cyg OB7 association. According to many other authors however, the most accepted value seems to be ∼ 1 kpc (Downes & Rinehart 1966; Wendeker 1968; Goudis 1976; Bally & Scoville 1980).

If we accept this value as the distance of NGC 7000, NGC 6996 turns out to have no apparent relationship with the HII region, the cluster being placed about 300 pc closer to the Sun. The cluster age, and the absence of early spectral type stars further corroborate this hypotesis.

The computed $R_V$ value for the cluster region is higher than the common one holding for the Galaxy (3.1, Mathis 1990), and at odd with previous studies (e.g. Cambrésy et al. 2002) which assign to NGC 7000 a normal $R_V$ ratio. High $R_V$ values are indicative of the
presence of dust grain of large size, typically larger than 0.05 micron. Since NGC 6996 is dominated by A type stars, UV radiation is not very effective, and one expects that dust grains grow in size (Kim & Martin 1996). Alternatively, another possibility would be that small size dust grains have been kicked off the cluster by a presumed population of massive stars already died as type II SNe (McKee 1989), a scenario which is quit compatible with the age of the cluster.
