(Received 2 October 2011; accepted 18 November 2011; published online 12 December 2011)

We demonstrate that suspended single-crystal GaAs nanomembranes exhibit mechanical Q-factors exceeding $2 \times 10^6$ at room temperature, which makes them a very promising platform for optomechanics. Because of the completely removed substrate and their millimeter-scale lateral size, the membranes can be incorporated in macroscopic optical cavities for quantum optomechanics experiments. We have measured the mechanical mode spectrum and spatial profiles and find good agreements with theory. Our work paves the way for optomechanical experiments with direct band gap semiconductors in which not only radiation pressure but also other mechanisms involving embedded light emitters could be exploited for quantum optical control of massive mechanical systems. © 2011 American Institute of Physics. [doi:10.1063/1.3668092]

Quantum optomechanics has become an emerging field with the goal of engineering and detecting quantum states of massive mechanical systems such as the quantum ground state1,2 or entangled quantum states.3,4 In this rapidly expanding field, various materials and geometries are being pursued, in order to control the coupling between phonons and photons.5–7

Incorporating direct band gap semiconductor materials in optomechanics exhibits unexplored prospects due to a number of advantageous properties. In particular, GaAs enables the integration of optoelectronic functionality with nanomechanical elements.8 The noncentrosymmetric nature of the zinc-blende crystal structure of GaAs results in an appreciable piezoelectric coefficient, enabling efficient actuation or transduction.9 Furthermore, there is a proposal of cooling the lattice temperature of semiconductors down to 10 K, referred to as optical refrigeration, although experimental demonstrations have not yet been realized.10 Quantum dots embedded in GaAs also enable strong coupling between a photon and a confined exciton.11 Much effort has been invested in fabricating GaAs-based micro-resonators12,13 and improving their mechanical properties by strain engineering.14 Coupling the intrinsic physical properties of direct band gap semiconductors to mechanical modes would enable a multitude of effects within cavity quantum optomechanics engineering.15 Very recent results on both GaAs disk resonators and InP photonic crystal cavities show the feasibility of realizing optomechanical systems in direct band gap semiconductors,16–18 but it is widely observed that GaAs microresonators suffer from low $Q$-factors, which limit the optomechanical cooling performance. Here, we present the experimental realization of millimeter sized single-crystal GaAs nanomembranes with extremely high-$Q$ factors that have very promising applications.

The GaAs membrane is fabricated from a GaAs/AlGaAs heterostructure wafer comprised of a (100)-oriented GaAs substrate (thickness: 350 μm), Al0.85Ga0.15As etch stop layer (thickness: 1 μm), and a GaAs capping layer (thickness: 160 nm), which is shown in Fig. 1(a). The first step is to remove the substrate with selective citric acid wet-etching by using AlGaAs as an etch stop layer.19 Then a non-buffered hydrofluoric acid (HF (10%)) selective wet-etching follows in order to remove the AlGaAs sacrificial layer.20 The single-crystal nanomembranes made by our method are optically accessible from both sides, which enables implementing cavity optomechanical cooling schemes.

The detailed fabrication process is as follows: photore sist (AZ 5214E) with a thickness of 3 μm is coated on both sides of the wafer and the patterns of the holes with different diameters ranging from 500 μm to 1 mm are defined by photolithography. After 30 min hard baking at a temperature of 140°C on a hotplate, the wafer is immersed into citric acid/H2O2 solution (4 citric acid (50% by wt.)/1 H2O2 (30%))19 with magnetic stirring for 20 h to etch through the GaAs substrate. Thanks to the excellent etch rate selectivity for GaAs versus AlGaAs in the citric acid/H2O2 solution, the 160 nm GaAs layer is intact due to the protection of the AlGaAs layer and the photore sist during the citric acid wet-etching.

Once the substrate is etched away, another selective wet-etching follows to remove the AlGaAs sacrificial layer and finally a GaAs nanomembrane is formed after removing the photoresist.

We have observed that often a thin layer of photoresist and submicron-sized particles are left after the completion of photoresist removal, which is shown by the scanning electron micrograph (SEM) in Fig. 1(b). These residues can be significant sources of light scattering and deteriorations of mechanical Q-factors. The remnant resist can only be removed by oxygen plasma, while the submicron-sized particles speculated to be hydroxide of aluminium can be removed in potassium hydroxide (KOH) solutions. Figure 1(c) shows SEM of a nanomembrane after the oxygen plasma and KOH (25 g/100 ml deionized water) cleaning processes. We found that the shapes of the fabricated nanomembranes deviated significantly from the circular photolithography masks. This comes from the different etch rates for different crystallographic planes of GaAs in citric acid. A close inspection of the membranes reveals that they are not completely flat, but rather they are bowing with an amplitude at the center of the membranes on the order of a few microns. The size of the largest nanomembrane made by our method is roughly 1.36 mm in width and 1.91 mm in length.

We have characterized the mechanical properties of the nanomembranes via frequency noise spectrum by using cavity transmission measurements. A dielectric concave mirror and a 160-nm-thick GaAs membrane form a cavity with the measured finesse of about 10. By feeding the spectrum analyzer with the RF signal from the photodiode, we have observed 14 resonance frequencies ranging from 17.5 kHz to 60 kHz presenting a series of peaks corresponding to the different mechanical modes labeled by the mode numbers in the parentheses. Figure 2(a) shows the measured frequency noise spectrum in the 10 kHz-60 kHz range. The inset: ringdown measurement with a cavity input power of 5 μW.

fabrication and the relation between the stress and high Q-factors in this system.

In conclusion, we have realized high-Q GaAs nanomembranes with unprecedented sizes for cavity quantum optomechanics experiments. The resonance frequencies and mode profiles are both theoretically and experimentally investigated. Experimental data show good agreement with a simplified model based on a taut rectangular drumhead. The ringdown measurements reveal that the highest Q-factors of the mechanical modes can be up to $2.3 \times 10^6$ at room temperature, which underlines the potential of these nanomembranes for cavity cooling experiments. We will report on such studies in a future publication. Further steps can be envisioned by incorporating semiconductor quantum dots in nanomembranes to cool the nanomechanical modes to its ground state and patterning the nanomembranes for controlling of the coupling between phonons and photons.
