I. INTRODUCTION

Nonlocality\textsuperscript{1,2} and quantum correlations\textsuperscript{3} are at the heart of many quantum technologies.\textsuperscript{4,45} In hybrid quantum-dot devices, Cooper pairs are a source of correlated electrons and their nonlocal splitting has experimentally\textsuperscript{18–33} and theoretically\textsuperscript{34–37} drawn much attention over the last few years. In particular, the nonlocal breaking of the particle-hole symmetry in such Cooper-pair splitters (CPSs) gives rise to peculiar thermoelectric effects.\textsuperscript{34–37} On the other hand, mesoscopic cavity quantum electrodynamics (cQED) devices\textsuperscript{38,39} are excellent tools for correlating few-level systems over a distance.\textsuperscript{40–45} Such cQED devices have applications in the readout of charge,\textsuperscript{46–52} spin,\textsuperscript{53–57} and valley-orbit states,\textsuperscript{58,59} as well as few-phonon manipulation when mechanical modes can be coaxed close to the ground state.\textsuperscript{60–65} A mechanism which induces nonlocal photon or phonon correlations through Cooper pair transport, implemented in a hybrid setup, bridges the gap between the study of heat flows in quantum-dot-based\textsuperscript{34–36,66,67} and circuit-QED devices.\textsuperscript{68–70}

In this work, we consider a CPS in a double-quantum-dot setup with each dot linearly coupled to a local resonator, constituted by either a microwave cavity\textsuperscript{49,51,54,71–74} or a mechanical oscillator.\textsuperscript{43,75–78} See Fig. 1(a). We demonstrate that this system is a platform to obtain full control on the heat and photon exchange of two originally uncoupled cavities. This induced coupling arises from the proximity between the dots and the superconducting lead, and has a purely nonlocal origin due to cross-Andreev reflection. Subsequent, we discuss the underlying physical mechanism following the lines of Ref. 79, where a single-quantum-dot system in the single-atom lasing regime has been investigated.

For large intradot Coulomb interactions, $U$, and superconducting gap, $\Delta \to \infty$, the proximity of the superconductor causes a nonlocal splitting (and recombination) of Cooper pairs into both dots with the pairing amplitude $\Gamma_S > 0$. The corresponding Andreev bound states $|\pm\rangle$ are a coherent superposition of the dots’ singlet, $|S\rangle$, and empty state, $|0\rangle$. The dots are further tunnel-coupled to normal contacts, which are largely negative-voltage-biased with respect to the chemical potential $\mu_S = 0$ of the superconductor. In this configuration, due to single-electron tunneling, the singlet state decays at rate $\Gamma_S$ into a singly-occupied state, $|\alpha\sigma\rangle (\alpha = L, R \text{ and } \sigma = \uparrow, \downarrow)$ and further into the empty state, see Fig. 1(b). For large dot onsite energies $\epsilon \gtrsim \Gamma_S$, the charge hybridization is weak ($|+\rangle \approx |S\rangle$, $|−\rangle \approx |0\rangle$), and the transitions $|+\rangle \rightarrow |\alpha\sigma\rangle$ and $|\alpha\sigma\rangle \rightarrow |−\rangle$ are faster than the opposite processes.\textsuperscript{79} See Fig. 1(c). This asymmetry in the relaxation ultimately explains how to pump or absorb energy within a single mode, and how to transfer photons between the cavities. In the latter case, when the energy splitting $\Delta$ between the Andreev bound states is close to the difference of the cavity frequencies, the relevant level structure of the uncoupled system is summarized in Fig. 1(d). We show below that the effective interaction couples the states...
[+, nL − 1, nR + 1] and [−, nL, nR], where na indicates the Fock number in the resonator α. An electron tunneling event favours transitions |+⟩ → |ασ⟩ → |−⟩ conserving the photon number. When the system reaches the state |−⟩ ≈ |0⟩, this coherent cycle restarts. When the system is in |+⟩, it can again decay. During each cycle, a boson is effectively transferred from the left to the right cavity. Since the two cavities are not isolated, but naturally coupled to external baths, a steady heat flow is eventually established between the cavities.

The effect discussed above refers to a single operation point of the system. More generally, using a master equation approach, we show that the interaction between the CPS and the two resonators opens a rich set of inelastic resonant channels for the electron current through the dots, involving either absorption/emission of photons from a local cavity or nonlocal transfer processes. By tuning ε to match these resonances, the CPS acts as a switch allowing the manipulation of heat between the resonators. Each resonant process can be captured with good approximation by an effective Hamiltonian which is valid close to the resonance and generalizes the mechanism described above.

This work is structured as follows. After introducing our model and the employed master equation in Sec. II, we provide therein an effective Hamiltonian describing local and nonlocal transport processes. In Section III, we discuss the possibility of simultaneous cooling (and heating) of the resonators. Section IV is dedicated to the nonlocal photon transfer between them, and in Sec. V we analyze the efficiency of this transfer. Finally, we draw our conclusions in Sec. VI.

II. COOPER-PAIR SPLITTER COUPLED TO RESONATORS

We consider the effective model for two single-level quantum dots proximized by a s-wave superconductor, and each linearly coupled to a local harmonic oscillator. For large intradot Coulomb interaction, U ≫ |e|, the subgap physics of the system is described by the effective Hamiltonian 28,32,80–86

$$H = \sum_{\alpha\sigma} \epsilon N_{\alpha\sigma} - \frac{\Gamma_S}{2}(d_{\alpha L}^+ d_{\alpha L} - d_{\alpha R}^+ d_{\alpha R}^+) + \text{H.c.} + \sum_{\alpha, \sigma} \omega_\alpha b_{\alpha \sigma}^\dagger b_{\alpha \sigma} + \sum_{\alpha, \sigma} \lambda_\alpha (b_{\sigma}^\dagger b_{\alpha} + b_{\sigma} b_{\alpha}) N_{\alpha\sigma},$$

where h = 1. Here, dασ is the fermionic annihilation operator for a spin-σ electron in dot α, with the corresponding number operator Nασ and onsite energy $\epsilon$. The interaction of the dot with the σ-oscillator of frequency $\omega_\alpha$ and corresponding bosonic field $b_\alpha$ is realized through the charge term, with coupling constant $\lambda_\alpha$. The relevant subspace of the electronic subsystem is spanned by six states: The empty state |0⟩, the four singly-occupied states |ασ⟩ = dασ|0⟩ and the singlet state |S⟩ = $\frac{1}{\sqrt{2}}(d_{\alpha L}^+ d_{\alpha L} - d_{\alpha R}^+ d_{\alpha R}^+)$. Triplet states and doubly-occupied states are inaccessible due to large negative voltages, see Fig. 1(a), and large intradot Coulomb repulsion. Finally, in the subgap regime, the superconductor can only pump Cooper pairs, which are in the singlet state. The states |0⟩ and |S⟩ are hybridized due to the $\Gamma_S$-term, yielding the Andreev states |+⟩ = $\cos(\theta/2)|0⟩ + \sin(\theta/2)|S⟩$ and |−⟩ = $-\sin(\theta/2)|0⟩ + \cos(\theta/2)|S⟩$, with the mixing angle $\theta = \arctan[\Gamma_S/(\sqrt{2}\epsilon)]$. We denote their energy splitting by $\delta = \sqrt{4\epsilon^2 + 2\Gamma_S^2}$.

Electron tunneling into the normal leads and dissipation for the resonators can be treated in the sequential-tunneling regime to lowest order in perturbation theory, assuming small dot-lead tunneling rates, $\Gamma_S \ll \Gamma_S, k_B T$ and large quality factors Q α = $\omega_\alpha / \kappa_\alpha$ for the resonators, i.e., $\kappa_\alpha \ll \omega_\alpha, k_B T$. Here, $\kappa_\alpha$ is the decay rate for the α-resonator and $T$ is the temperature of the fermionic and bosonic reservoirs. The fermionic and bosonic transition rates between two eigenstates |i⟩ and |j⟩ of Hamiltonian (1) are given by Fermi’s golden rule, 87

$$w_{\text{el},ij-i}^{\alpha,s} = \Gamma f_\alpha(s E_{ji}) \sum_\sigma |\langle j| d_{\alpha\sigma}^{\dagger}|i⟩|^2,$$

$$w_{\text{ph},ij-i}^{\alpha,s} = s\kappa_\alpha n_B(E_{ji}) |\langle j| b_{\alpha\sigma}^{\dagger}|i⟩|^2,$$

with $f_\alpha^{(s)}(x) = \{\exp[x - \mu_\alpha/k_B T] + 1\}^{-1}$ the generalized Fermi function ($s = \pm$ at chemical potential $\mu_\alpha$, and $n_B(x) = \exp[x/k_B T] - 1$) the Bose function. $E_{ji} \equiv E_j - E_i$ denotes the energy difference between two eigenstates. We use the notation $d_{\alpha\sigma}^{(\pm)}$ ($d_{\alpha\sigma}^{(s)}$) for fermionic annihilation (creation) operators, and correspondingly $b_{\alpha\sigma}^{(\pm)}$ for the bosonic ones. The populations $P_i$ of the system eigenstates obey a Pauli-type master equation of the form 28,88,89

$$\dot{P}_i = \sum_j w_{ji-i} P_j - \sum_j w_{ij-i} P_i,$$

which admits a stationary solution given by $P_i^{\text{st}}$. The total rates entering Eq. (4) are given by $w_{ji-i} = \sum_\alpha (w_{\text{el},ij-i}^{\alpha,s} + w_{\text{ph},ij-i}^{\alpha,s})$. As mentioned before, we assume the chemical potentials of the normal leads $\mu_\alpha = -eV$ to be largely negative-biased, i.e., $U, |\Delta| \gg eV \gg k_B T$, $\Gamma_S$, with $V > 0$ and $e > 0$ denoting the applied voltage and the electron charge, respectively. In this regime, the electrons flow unidirectionally from the superconductor via the quantum dots into the leads; the temperature of the normal leads becomes irrelevant, and the rates $w_{\text{el},ij-i}^{\alpha,s}$ vanish. Under these assumptions, the stationary electron current through lead α is simply given by $I_\alpha = e\Gamma\sum_\sigma N_{\alpha\sigma}$. For a symmetric configuration, as assumed here, both stationary currents coincide, $I_L = I_R$. To evaluate the stationary current and the other relevant quantities, we diagonalize numerically Hamiltonian (1), and build the transition-rate matrices appearing in Eq. (4). The stationary populations, $P_i^{\text{st}}$, are then found by solving the system of Eqs. (4) for $\dot{P}_i = 0$.

In order to explain our numerical results, we perform the Lang-Firsov polaron transformation to Hamiltonian (1). 90–92 For an operator $O$, we define the unitary transformation $\tilde{O} = e^{\xi O} e^{-\xi}$, with $\xi = \sum_{\alpha,\sigma} \Pi_\alpha N_{\alpha\sigma}$ and $\Pi_\alpha = (\lambda_\alpha / \omega_\alpha) (b_{\alpha\sigma}^\dagger - b_{\alpha\sigma})$. The polaron-transformed Hamiltonian reads then

$$\tilde{H} = \sum_{\alpha,\sigma} \bar{\epsilon}_\alpha N_{\alpha\sigma} - \frac{\Gamma_S}{\sqrt{2}} (|S⟩\langle 0|X + |0⟩\langle S|X^\dagger) + \sum_\alpha \omega_\alpha b_{\alpha\sigma}^\dagger b_{\alpha\sigma},$$

with $\bar{\epsilon}_\alpha = -\lambda_\alpha^2 / \omega_\alpha$ and $X = \exp(\sum_\alpha \Pi_\alpha)$. 93 Equation (5) contains a transverse charge-resonator interaction term to all
orders in the couplings \( \lambda_\alpha \). Intriguingly, this coupling has a purely nonlocal origin stemming from the cross-Andreev reflection. By expanding \( X \) in powers of \( \Pi \equiv \sum_\alpha \Pi_\alpha \) assuming small couplings \( \lambda_\alpha \ll \omega_\alpha \), and moving to the interaction picture with respect to the noninteracting Hamiltonian, we can identify a family of resonant conditions given by

\[
\delta \approx |p\omega_\alpha \pm q\omega_R|,
\]

with \( p, q \) nonnegative integers, as discussed in Appendix A.

Here, \( \delta = \sqrt{4\epsilon^2 + 2\Gamma_\alpha^2} \) is the renormalized energy splitting of the Andreev states due to the polaron shift, with \( \bar{\epsilon} = \epsilon - \sum_\alpha \frac{\delta^2}{\omega_\alpha} \). The renormalized mixing angle reads \( \bar{\theta} = \text{arctan} [\Gamma_\alpha/(\sqrt{2}\bar{\epsilon})] \). Around the conditions stated in Eq. (6), a rotating-wave approximation yields an effective interaction of order \( p + q \) in the couplings \( \lambda_\alpha \). Hereafter, we discuss in detail the resonances at \( \delta = \omega_L = \omega_R \) and \( \delta = \omega_L - \omega_R \) corresponding to one- and two-photon processes, respectively. They can be fully addressed by expanding \( X \) up to second order in \( \lambda_\alpha/\omega_\alpha \) and subsequently performing a rotating-wave approximation, see Appendix A.

III. SIMULTANEOUS COOLING AND HEATING

For \( \delta = \omega_L = \omega_R \), one can achieve simultaneous cooling as well as heating of both resonators, which is already described by the first order terms in \( \lambda_\alpha \) of Eq. (5). Here, we consider two identical resonators and tune the dot levels \( \epsilon \) around the resonance condition \( \delta = \omega_\alpha \), i.e., \( \bar{\epsilon} = \pm \sqrt{\omega_\alpha^2 - 2\Gamma_\alpha^2}/2 \). The effective first-order interaction Hamiltonian reads after a rotating-wave approximation

\[
H_{\text{loc}} = \sum_\alpha \frac{1}{2} \lambda_\alpha \sin \bar{\theta} (b_{\alpha} \tau_+ + b_{\alpha}^\dagger \tau_-).
\]

as we show in Appendix A. The operators \( \tau_\pm = |+\rangle\langle-| \) and \( \tau_\pm = |\alpha\rangle\langle\alpha'| \) describing the hopping between the two-level system formed by the states \( |+\rangle \) and \( |-\rangle \), coupled to the modes through a transverse Jaynes-Cummings-like interaction. The effective coupling is proportional to \( \sin \bar{\theta} = \sqrt{2}\Gamma_\alpha/\delta \), and, thus, a direct consequence of the nonlocal Andreev reflection. The effective interaction in Eq. (7) coherently mixes the three states \( |+, n_L, n_R\rangle, |-, n_L + 1, n_R\rangle \), and \( |-, n_L, n_R + 1\rangle \) which are degenerate for \( H_{\text{loc}} = 0 \). When \( |\epsilon| \gtrsim \Gamma_\alpha \), the hybridization between the charge states is weak. The sign of \( \epsilon \) changes the bare dots’ level structure: For \( \epsilon < 0 \), \( |+\rangle \approx |0\rangle \) and \( |-\rangle \approx |S\rangle \), whereas for \( \epsilon > 0 \), \( |+\rangle \approx |S\rangle \) and \( |-\rangle \approx |0\rangle \). In the latter case, the chain of transitions \( |+\rangle \rightarrow |+\alpha\rangle \rightarrow |\alpha\sigma\rangle \rightarrow |-\rangle \) is faster than the opposite process, see Fig. 1(c). For \( \epsilon < 0 \), energy is pumped into the modes. Conversely, for \( \epsilon > 0 \), we can achieve simultaneous cooling of the resonators. In Fig. 2, we show the stationary electron current \( I_\alpha \) (calculated using the full Hamiltonian (1)), together with the average photon number \( \bar{n}_\alpha = \langle b_{\alpha}^\dagger b_{\alpha} \rangle \) of the corresponding resonator, as a function of \( \epsilon \). The broad central resonance of width \( \Gamma_\alpha \) corresponds to the elastic current contribution mediated by the cross-Andreev reflection. The additional inelastic peak at negative \( \epsilon \) is related to the emission of photons in both resonators at \( \delta \approx \omega_\alpha \). At finite temperature, a second sideband peak emerges at positive \( \epsilon \), where the resonators are simultaneously cooled down. The cavities are efficiently cooled into their ground state for a wide range of values of \( \Gamma_\alpha \), as can be appreciated in the inset of Fig. 2(b). The optimal cooling region is due to the interplay between the effective interaction with the resonator—which vanishes for small \( \Gamma_\alpha \)—and the hybridization of the empty and singlet state, which increases as \( \epsilon \) approaches the Fermi level of the superconductor and reduces the asymmetry of the transitions \( |\pm\rangle \leftrightarrow |\alpha\sigma\rangle \).

IV. NONLOCAL PHOTON TRANSFER

By keeping terms up to second order in \( \lambda_\alpha \) in Eq. (5), we can describe the resonances around \( \delta = \omega_L - \omega_R \) and \( \delta = \omega_L + \omega_R \). Assuming without loss of generality \( \omega_L > \omega_R \), a rotating-wave approximation yields the effective interaction terms \( H_{\text{NL}}^{(+)} = \lambda_{\text{NL}}(b_{\alpha}^\dagger b_{\alpha} b_{\alpha}^\dagger b_{\alpha} \tau_+ + \text{h.c.}) \) for \( \delta \approx \omega_L - \omega_R \), and \( H_{\text{NL}}^{(-)} = \lambda_{\text{NL}}(b_{\alpha}^\dagger b_{\alpha} b_{\alpha}^\dagger b_{\alpha} \tau_- + \text{h.c.}) \) for \( \delta \approx \omega_L + \omega_R \), see Appendix A. These terms show that the two resonators become indirectly coupled through the charge states, with the strength

\[
\lambda_{\text{NL}} = \frac{\Gamma_\alpha \lambda_\alpha}{\sqrt{2}\omega_L \omega_R} \cos \bar{\theta}.
\]

We remark that this interaction is, as well, purely nonlocal. \( H_{\text{NL}}^{(+)} \) describes the hybridization of the states in the subspace...
flowing from the bosonic reservoir $\alpha$ to the corresponding resonator. It is negative (positive) when the resonator is cooled (heated), and vanishes for an oscillator in thermal equilibrium. As a figure of merit for local cooling, we can estimate the number of bosonic quanta subtracted from the resonator on average per unit time, and compare it to the rate at which Cooper pairs are injected into the system. The latter rate is given by $|I_\ell|/2e$ with $I_\ell = -(I_\ell + I_R)$ being the Andreev current through the superconductor found from current conservation. Consequently, the local cooling efficiency around $\tilde{\delta} = \omega_\alpha$ can be defined as $\eta_{\text{loc}}(\alpha) = 2e|\dot{E}_\alpha|/|I_\ell| |\omega_\alpha|$. Similarly, around $\tilde{\delta} = \omega_L - \omega_R$, we define the heat transfer efficiency

$$\eta_{\text{NL}} = 2e|\dot{E}_L - \dot{E}_R| / |I_\ell| (\omega_L - \omega_R).$$

V. HEAT TRANSFER AND EFFICIENCY

To quantify the performance of both cooling and nonlocal photon transfer, we calculate the stationary heat current

$$E^{\text{ph}}_{\alpha} = \sum_{i,j,s} E_{ij} \gamma^{\alpha,s} \beta_{ph,j,i} P^s_i$$

for the dots’ gate voltages to tune dynamically the strength of the nonlocal features. Further practical applications include
high-efficiency nanoscale heat pumps and cooling devices for nanoresonators.

A discussion on the experimental feasibility of our setup is in order. For single quantum dots coupled to microwave resonators, \( \lambda_\alpha/(2\pi) \) can reach 100 MHz, with resonators of quality factors \( Q \sim 10^4 \) and frequencies \( \omega_\alpha/(2\pi) \sim 7 \) GHz.\(^{59,51} \)

For mechanical resonators, coupling strengths of \( \lambda_\alpha/(2\pi) \sim 100 \) kHz for frequencies of order \( \omega_\alpha/(2\pi) \sim 1 \) MHz and larger quality factors up to \( 10^5 \sim 10^6 \) have been reported.\(^{56} \)

In a double-quantum-dot Cooper-pair splitter setup, the cross-Andreev reflection rate is approximately \( \Gamma_\alpha \sim 10^2 \) GHz for distances of order \( \lambda \sim 1 \) nm, with larger distance factors up to \( \lambda \sim 10 \) nm that can reach 100 MHz, with resonators of \( \lambda \sim 1 \) GHz.\(^{49,51} \)

In the following, we restrict Eq. (5) of main text to first order in \( \lambda \), we can express the Hamiltonian (5) of main text to second order by

\[
\hat{H} = \sum_{\alpha} \epsilon_\alpha N_{\alpha} + \frac{\hat{\delta}}{2} \tau_\alpha + \sum_{\alpha} \omega_\alpha b_\alpha^\dagger b_\alpha \\
- \frac{\Gamma_\alpha}{2 \sqrt{2}} \left[ 2 i \tau_\alpha + (\sin \theta \tau_\alpha + \cos \theta \tau_\alpha) \Pi^2 \right] + O(\Pi^3). \tag{A4} \]

We now move to the interaction picture with respect to the noninteracting Hamiltonian \( \hat{H}_0 = \sum_{\alpha} \epsilon_\alpha N_{\alpha} + \frac{\hat{\delta}}{2} \tau_\alpha + \sum_{\alpha} \omega_\alpha b_\alpha^\dagger b_\alpha \). By reducing the definition of \( \Pi \), we obtain in the interaction picture the Hamiltonian

\[
H_{\text{int}}(t) = - \sum_{\alpha} \frac{\lambda_\alpha \Gamma_\alpha}{\omega_\alpha \sqrt{2}} \left( e^{i\omega_\alpha t} b_\alpha^\dagger - e^{-i\omega_\alpha t} b_\alpha \right) \left( e^{i\delta t} \tau_\alpha - e^{-i\delta t} \tau_\alpha \right) \\
- \frac{\Gamma_\alpha \lambda L \lambda R}{\sqrt{2} \omega L \omega R} \left[ e^{i\Omega t} b_\alpha^\dagger b_\alpha^\dagger + e^{-i\Omega t} b_L b_R - e^{i(\Delta \omega)t} b_\alpha^\dagger b_R - e^{-i(\Delta \omega)t} b_L b_\alpha^\dagger \right] \left[ \sin(\bar{\theta}) \tau_\alpha + \cos(\bar{\theta})(e^{i\delta t} \tau_\alpha + e^{-i\delta t} \tau_\alpha) \right] \\
- \sum_{\alpha} \frac{\Gamma_\alpha \lambda_\alpha^2}{2 \sqrt{2} \omega_\alpha^2} \left[ e^{2i\omega_\alpha t} (b_\alpha^\dagger b_\alpha)^2 + e^{-2i\omega_\alpha t} b_\alpha^2 - 1 \right] \left[ \sin(\bar{\theta}) \tau_\alpha + \cos(\bar{\theta})(e^{i\delta t} \tau_\alpha + e^{-i\delta t} \tau_\alpha) \right] + O(\lambda_\alpha^3/\omega_\alpha^3). \tag{A5} \]

Here, we have introduced \( \Omega = \omega_L + \omega_R \) and \( \Delta \omega = \omega_L - \omega_R \). Hamiltonian (A5) contains all the terms that lead to cooling, heating, and nonlocal photon transfer. To isolate these features, we will focus on the relevant resonances \( \delta \approx \omega_\alpha \), \( \alpha \approx \Omega \), and \( \delta \approx \Delta \omega \). First, let us consider two identical resonators of frequency \( \omega_\alpha = \omega \) and tune \( \epsilon \) such that \( \delta = \omega \). Notice that this can be fulfilled by two values of \( \epsilon \), of opposite sign. In the following, we restrict Eq. (A5) to first order in \( \lambda_\alpha \), and then discard the fast-oscillating terms by performing a standard rotating-wave approximation (RWA). Thus, we obtain the time-independent interaction Hamiltonian given by Eq. (7)
in the main text,
\[ H_{\text{RWA}}^{\alpha} = \sum_{\alpha} \frac{1}{2} \lambda_{\alpha} \sin(\tilde{\theta}) (b_{\alpha} \tau_+ + b_{\alpha}^\dagger \tau_-). \]  

(A6)

We have used here the resonance condition \( \omega = \tilde{\delta} \) and the relation \( \sin \tilde{\theta} = \sqrt{2} \Gamma_S / \tilde{\delta} \).

Let us now consider the nonlocal resonance, \( \tilde{\delta} = \Delta \omega \). A peculiarity is here, that we have to go to second order in \( \lambda_{\alpha} \), since the first-order terms become in the RWA fast rotating and, thus, average to zero. The corresponding effective Hamiltonian reads
\[ H_{\text{RWA}}^{\delta=\Delta \omega} = \sum_{\alpha} \frac{\Gamma_{\alpha} \lambda_{\alpha}^2}{2 \sqrt{2} \omega_{\alpha}^2} (2n_\alpha + 1) \sin \tilde{\theta} \tau_+ + \lambda_{\alpha \text{NL}} (b_{\alpha}^\dagger b_{R} \tau_- + \text{H.c.}), \]

(A7)

with \( n_{\alpha} = b_{\alpha}^\dagger b_{\alpha} \) the photon number operator, and \( \lambda_{\alpha \text{NL}} \) stated in Eq. (8) of the main text. The second term corresponds to the interaction \( H_{\alpha \text{NL}} \) (main text), and is responsible for the coherent transfer of photons between the cavities, leading to a stationary energy flow. The first term in Eq. (A7) proportional to \( n_{\alpha \tau_\alpha} \) can be seen as a dispersive shift of the cavity frequencies, which depends on the Andreev bound state. As the quantities reported in Fig. 3 of the main text are averages calculated from the density matrix, this translates into a fine double-peak structure of the nonlocal resonance, see Fig. 3(c) of the main text. Further, the additional term proportional to \( \tau_\alpha \) renormalizes the level splitting \( \tilde{\delta} \) and, therewith, the resonance condition, \( \tilde{\delta} = \Delta \omega \).

Considering the condition \( \tilde{\delta} = \omega \), we obtain the effective RWA Hamiltonian
\[ H_{\text{RWA}}^{\delta=\omega} = \sum_{\alpha} \frac{\Gamma_{\alpha} \lambda_{\alpha}^2}{2 \sqrt{2} \omega_{\alpha}^2} (2n_\alpha + 1) \sin \theta \tau_+ + \lambda_{\alpha \text{NL}} (b_{\alpha}^\dagger b_{R} \tau_- + \text{H.c.}). \]

(A8)

Here, the relevant interaction (\( H_{\alpha \text{NL}}^{++} \) of the main text) describes absorption (and emission) from both cavities simultaneously while flipping the Andreev state. So, this second-order effect may entail simultaneous cooling, \( \epsilon > 0 \), and heating, \( \epsilon < 0 \), of both cavities.

From the last line of Eq. (A5), one can infer an effective RWA Hamiltonian governing the resonance condition \( \delta \approx 2\omega_{\alpha} \). It is similar to Eq. (A6), but involves absorption and emission of two photons from the same cavity. Indeed, this two-photon resonance is also observable in Fig. 3(a) of the main text and yields cavity cooling for \( \epsilon > 0 \) and heating for \( \epsilon < 0 \), respectively.

By including terms up to \( n \)-th order in \( \Pi \) in Eq. (A4), one obtains terms \( (b_{\alpha}^\dagger)^n b_{\beta}^\dagger \) and \( (b_{\alpha}^\dagger b_{\beta})^n \), which, after moving to the interaction picture and performing a suitable RWA, will yield \( n \)-photon local absorption/emission processes. The expansion contains also terms of the form \( (b_{\alpha}^\dagger)^n (b_{\beta})^n \) and \( (b_{\alpha}^\dagger b_{\beta})^n \) together with their Hermitian conjugates, with \( p + q = n \) (\( \tilde{\alpha} = R \) if \( \alpha = L \) and vice versa). The former terms describe the coherent transfer of \( |p - q| \) photons between the cavities, while the latter describes coherent emission and re-absorption of \( p \) and \( q \) photons from the cavities, respectively. The general (approximate) resonance condition thus reads \( \delta \approx |\Delta \omega_s + \epsilon \omega_R| \), stated in Eq. (6) in main text. If either \( p \) or \( q \) is zero, the resonance corresponds to local cooling/heating of the cavities.

Notice that the polaron transformation also gives rise to a modification of the tunneling Hamiltonian, which describes inelastic dot-lead tunneling events scaling with $\Gamma(\omega_q/\omega_\alpha)^2$. However, in our operative regime, such processes can be neglected since $\Gamma \ll \Gamma_\Sigma$ and $\omega_q \ll \omega_\alpha$ ensure $\Gamma(\omega_q/\omega_\alpha)^2 \ll \Gamma \ll \Gamma_\Sigma$.
