ABSTRACT
Light is a critical environmental cue for plant growth and development. Plants actively monitor surrounding environments by sensing changes in light wavelength and intensity. Therefore, plants have evolved a series of photoreceptors to perceive a broad wavelength range of light. Phytochrome photoreceptors sense red and far-red light, which serves as a major photomorphogenic signal in shoot growth and morphogenesis. Notably, plants also express phytochromes in the roots, obscuring whether and how they perceive light in the soil. We have recently demonstrated that plants directly channel light to the roots through plant body to activate root phytochrome B (phyB). Stem light facilitates the nuclear import of phyB in the roots, and the photoactivated phyB triggers the accumulation of the photomorphogenic regulator ELONGATED HYPOCOTYL 5 in modulating root growth and gravitropism. Optical experiments revealed that red to far-red light is efficiently transduced through plant body. Our findings provide physical and molecular evidence, supporting that photoreceptors expressed in the underground roots directly sense light. We propose that the roots are not a passive organ but a central organ that actively monitors changes in the aboveground environment by perceiving light information from the shoots.

Light is not only an energy source for photosynthesis but also an important signal of monitoring environmental changes in plants. Light affects virtually all developmental and physiological events in plants, covering from germination, stem and leaf growth, flowering to senescence, and responses to environmental stresses. A series of photoreceptors that recognizes specific wavelengths of light have been discovered. Ultraviolet B light (UVB) is sensed by UVB-RESISTANCE 8, and blue light is perceived by cryptochromes and phototropins. The red/far-red light photoreceptor phytochromes have been most extensively studied in plants. Phytochrome photoreceptors sense red and far-red light, which serves as a major photomorphogenic signal in shoot growth and morphogenesis. Notably, plants also express phytochromes in the roots, obscuring whether and how they perceive light in the soil. We have recently demonstrated that plants directly channel light to the roots through plant body to activate root phytochrome B (phyB). Stem light facilitates the nuclear import of phyB in the roots, and the photoactivated phyB triggers the accumulation of the photomorphogenic regulator ELONGATED HYPOCOTYL 5 in modulating root growth and gravitropism. Optical experiments revealed that red to far-red light is efficiently transduced through plant body. Our findings provide physical and molecular evidence, supporting that photoreceptors expressed in the underground roots directly sense light. We propose that the roots are not a passive organ but a central organ that actively monitors changes in the aboveground environment by perceiving light information from the shoots.

Light cannot penetrate more than a few millimeters into soil layers, and thus most studies have been focused on the light responses of aboveground organs. Interestingly, plants express phytochromes not only in the shoots but also in the roots. Histochemical β-glucuronidase (GUS) staining using transgenic plants expressing GUS gene under the control of phytochrome A (phyA) or phyB gene promoter have shown that the phyA and phyB genes are expressed in both light- and dark-grown roots. In particular, the phytochrome genes are expressed specifically in the vascular bundles of the roots, raising a question as to the physiological role of root phytochromes.

To elucidate the function of root phytochromes, root phenotypes have been examined in Arabidopsis mutants that are defective in phytochrome or chromophore biosynthesis. It has been reported that the rate of primary root elongation is reduced in phyB mutant but not in phyA mutant. The phyB mutant is also defective in auxin transport from the shoots to the roots, resulting in reduced lateral root production. Gravitropic responses of the roots are also regulated by phytochromes. Light-mediated root gravitropism is significantly reduced in phyA phyB double mutant. In chromophore-defective mutant, root sensitivity to jasmonic acid is altered, suggesting that phytochromes are also involved in phytohormone signaling in the

roots. However, most of the previous studies have been performed using light-grown roots, and thus it is still unclear whether root phytochromes are functional in the dark soil.

More than 30 y ago, it has been suggested that light is conducted through the stem and root tissues. Recent studies also support the channeling of light through the vascular tissues. While the direct transduction of light through stems is widely perceived, it has not been explored how the stem-piped light influences root growth and morphology until our recent studies. With an aim of elucidating the physiological role of stem-piped light, we employed molecular, photochemical, and physical tools.

We established a controlled plant growth system, in which the shoots or the roots are selectively exposed to light. We performed RNA sequencing analysis using RNA samples extracted from the roots of plants that were treated with light in the controlled growth system. Bioinformatic analysis revealed that a group of light-responsive genes, including those encoding HY5 and its downstream targets CHALCONE SYNTHASE, and PHOTOLYASE 1, were induced in the roots under both stem light and root light conditions. Gene expression assays using the roots of photoreceptor mutants grown under shoot light conditions showed that phyB is responsible for the induction of HY5 gene and its downstream target genes in the roots under shoot light conditions.

We also employed micrografting tools to generate chimeric plants harboring phyB mutation in either the shoots or the roots. Grafting of wild type plants with phyB mutant or transgenic plants expressing a constitutively active phyB revealed that root phyB is necessary for the induction of HY5 gene and its downstream target genes in the roots under shoot light conditions.

Collectively, our observations demonstrate that aboveground light is directly transduced through plant body to the roots and activates root phyB in mediating root growth and gravitropism. Meanwhile, it has been suggested that light triggers the synthesis of chemicals

Figure 1. Schematic modes of stem-to-root light signal transduction. Aboveground light is either directly transduced via vascular tissues to the roots (mode 1) or triggers the production of signaling molecules, such as mobile chemicals and HY5 transcription factor, which migrate to the roots (mode 2). In mode 1, stem-piped light activates root phyB, which stabilizes HY5. The root phyB-HY5 module mediates root growth and gravitropism. In mode 2, the mobile signaling molecules, including auxin and HY5, move from the shoots to the roots, where they regulate root growth and nitrate uptake.
and proteins in the shoots, which migrate to the roots.\textsuperscript{2,24,25} The root-targeted signaling molecules affect root growth and nitrate transport in the roots. It is thus likely that both light and mobile molecules transmit aboveground information to the roots to achieve optimal root growth and development under fluctuating environmental conditions (Fig. 1). It is notable that responses of the roots to the stem-piped light occur earlier than those of mobile molecules,\textsuperscript{13,24,25} suggesting that light and signaling molecules have different roles in root biology.

The roots are thought to be a passive organ compare with the shoots. Previous studies have shown that the shoots are major site of photosynthesis, circadian clock function, and perception of environmental cues.\textsuperscript{2,3,26} Our findings indicate that the roots actively monitor aboveground environment by directly sensing stem-piped light and provide strong evidence, supporting that the roots are not just a passive organ but a central organ in shaping physiological events in response to environmental changes.

While our data support the role of stem-piped light in modulating root growth and gravitropism, it is still unclear how light is conducted through plant body. It has been shown that vascular tissues are effective light conductors in woody and herbaceous plants.\textsuperscript{20,21} Together with optical properties of water, which efficiently guides light transduction,\textsuperscript{27} it seems that xylem is a primary route for light transduction. Further works using plants with altered xylem development and architecture would be useful to examine this hypothesis.
