We report on a measurement of splitting in the excitation spectrum of a condensate driven by an optical travelling wave. Experimental results are compared to a numerical solution of the Gross Pitaevskii equation, and analyzed by a simple two level model and by the more complete band theory, treating the driving beams as an optical lattice. In this picture, the splitting is a manifestation of the energy gap between neighboring bands that opens on the boundary of the Brillouin zone.

PACS numbers: 32.80.Qk

Perturbative bulk excitations over the ground state of a weakly-interacting Bose Einstein condensate (BEC) have been extensively studied using two-photon Bragg transitions \[.\] Their spectrum \[\hat{F}\], dynamics \[\hat{\mathcal{G}}\] and decay \[\hat{\mathcal{G}}\] are rather well understood. However, Bragg processes can also strongly excite the condensate, generating non-perturbative dynamics, such as Rabi oscillations between two (or more) macroscopically-populated momentum states \[\hat{c}_L \hat{c}^+_L\]. Rapid oscillations have been found to suppress various inhomogeneous broadening mechanisms, thus increasing the coherence time of the system \[\hat{\mathcal{G}}\].

Since the Bragg process may be viewed as the diffraction of an atomic wavepacket from a nearly perfect optical lattice, band theory may be employed for the study of such systems. A BEC in an optical lattice has proved to be an excellent system for the investigation of effects predicted long ago in solid state physics such as Bloch oscillations and Landau-Zener intra-band tunnelling \[\hat{c}_L \hat{c}^+_L\], and the Mott-insulator phase transition \[\hat{\mathcal{G}}\]. Much progress has been made in understanding the ground state of a BEC in an optical lattice, its weak excitations and the effects of interactions \[\hat{\mathcal{G}}\]. However strong excitations involve two beating macroscopically occupied modes, and lead to Rabi like oscillations. Thus they cannot be described as a Bogoliubov-like excitation over a single Bloch state.

In this paper we study the spectrum of a BEC driven by a strong resonant Bragg pulse, which leads to coherent Rabi oscillations between momentum states. We observe these oscillations in the time domain and a splitting between the energy bands in the frequency domain. The splitting is measured experimentally with Bragg spectroscopy, using an additional Bragg beam-pair as a weak probe, and found to agree with numerical solution of the time-dependent Gross-Pitaevskii equation (GPE). The splitting is also predicted by a simplified two-level dressed-state model. However some features are explained only by the more complete band theory. These theories do not include inhomogeneous and finite-size effects, nor interactions, but are in reasonable agreement with our experimental results.

The energy spectrum of a linear system is related to the time dynamics via Fourier transform. Therefore the oscillations in the time domain are translated to splitting in the spectrum, and the decay of the time-correlation function results in broadening of the spectral peaks \[\hat{\mathcal{G}}\]. In our experiment the chemical potential, which characterizes the non-linearity, is smaller than the Rabi frequency, but of the same order of magnitude. Hence this linear description is only approximately true for our system.

Our experimental apparatus is described in \[\hat{\mathcal{G}}\]. Briefly, a nearly pure (\(\sim 90\%\)) BEC of \(5(\pm 1) \times 10^4\) \(^{87}\)Rb atoms in the \(|F, m_f\rangle = |2, 2\rangle\) ground state, is formed in a magnetic trap with radial and axial trapping frequencies of \(\omega_r = 2\pi \times 226\) Hz and \(\omega_z = 2\pi \times 26.5\) Hz, respectively. The condensate is driven by a pair of strong counter-propagating Bragg beams with wave-vectors \(k_L\hat{z}\) and \(-k_L\hat{z}\) generating an optical lattice potential along the axial direction with a depth characterized by a Rabi frequency \(\Omega_d\). The laser frequency is red detuned 44 GHz from the \(^{87}\)Rb D2 transition in order to avoid spontaneous emission. As shown in \[\hat{\mathcal{G}}\], in the Rabi regime the mean field shift is largely suppressed, hence the frequency difference between the driving Bragg beams (in the laboratory frame) is set to \(\omega_d = 2\pi \times 15\) kHz, the free-particle resonance.

After driving pulses of varying duration, the magnetic trap is rapidly turned off. A typical absorption image after 38 msec time of flight expansion is shown in Fig. \[\hat{\mathcal{G}}\]. The wavepackets with wavenumber \(-2k_L\) and \(k = 0\) are clearly separated. In this image, \(\Omega_d \sim 3\pi\), hence most atoms are in the \(-2k_L\) wavepacket. The number of atoms in each wavepacket is measured by integration over the density in an area determined by a gaussian fit to the absorption image. We thus define \(N_{-2k_L}\) and \(N_0\) as the number of atoms in the wavepackets with wavenumbers \(-2k_L\) and 0 respectively.

Figure \[\hat{\mathcal{G}}\] shows the time dynamics of the BEC exposed to the driving Bragg beams. The solid squares are data points, measuring the fraction of atoms in \(-2k_L\) cloud as a function of the duration of the driving pulse. The BEC undergoes oscillations at a frequency of \(2\pi \times 5.3 \pm 0.1\) kHz as found from a sinusoidal fit to data. The hollow points are numerical solutions of the GPE including finite time, and spatial inhomogeneity with \(\Omega_d\) as the only fit...
kHz. The oscillation frequency is slightly less than $\Omega_{d}$ due to interactions. This is because the higher density in the valleys of the optical potential creates a mean-field parameter $\Omega_d$. The Rabi frequency which yields the correct oscillation frequency is found to be $\Omega_d = 2\pi \times 5.5$ kHz. The oscillation frequency is slightly less than $\Omega_d$ due to interactions. This is because the higher density in the valleys of the optical potential creates a mean-field lattice potential opposing the optical one.

Next, we probe the spectrum of the oscillating BEC, with another pair of Bragg beams (turned on simultaneously with the driving Bragg beams), generating a weak lattice with a Rabi frequency $\Omega_p$. The probe beams, also counter-propagating along the axial direction, are linearly polarized perpendicular to the driving beams. The frequency difference between probe beams $\omega_p$ is always kept such that the 0 momentum wavepacket is diffracted by the probe lattice to a $2k_L$ momentum wavepacket whereas for the $-2k_L$ wavepacket, the Bragg-frequency of the probe beams is always doppler-shifted away from resonance. For the same reason, the driving beams are Doppler-shifted from the $2k_L$ state. A characteristic time of flight image is shown in Fig. 1. Here in addition to the clouds in states $-2k_L$ and 0, there are also atoms with wavenumber $2k_L$. The measured relative population of this momentum state $N_{2k_L}/(N_{-2k_L} + N_0 + N_{2k_L})$ as a function of the probe frequency difference $\omega_p$ forms the probe Bragg spectrum, which is plotted in Fig. 2 (black squares). The duration of the beams is set so the driving pulse would be close to an even multiple of $\pi$, in order to minimize collisions in the time of flight expansion.

The probe spectrum, without the driving beams ($\Omega_d = 0$) is similar to the well known Bogoliubov spectrum (Fig. 3a). The probe is weak in the sense that $\Omega_p \sim \Omega_d/8$, but since the probe pulse is greater than $\pi/2$ we observe a suppression in the mean field shift $\Omega_d$. The probe spectrum in the presence of the driving beams (Fig. 3b) shows a clear splitting in the spectrum of the oscillating condensate. The dotted line is a double Lorentzian fit to the experimental data, with a distance between the peaks of $\Delta E/h = 4.7 \pm 0.2$ kHz, comparable but larger than the chemical potential $\mu/h = 1.6$ kHz. The solid line is the full GPE simulation of the experiment, which gives a splitting of $\Delta E/h = 5.5$ kHz. We note this is not the frequency of oscillations in Fig. 2, but rather the Rabi frequency of the lattice itself. The mismatch between experimental and simulation results, may be due to a drift in the intensity of the laser beams between the oscillations measurement and the splitting measurement.

The width of the spectrum without driving (Fig. 5a) fits the GPE simulation, and is mostly due to finite time of the experiment. However the experimental peaks in Fig. 3b are substantially broader than predicted by the GPE. This broadening is robust and is observed for different values of $\Omega_d$, indicating broadening mechanisms which are beyond mean field. One such mechanism for a homogeneous condensate is due to uncertainty in a dressed state decomposition of the initial Fock state, that leads to a spectral broadening. For our experimental parameters this broadening is much less than the widths of the experimental peaks which are $3 \pm 0.4$ and $3.7 \pm 0.5$ kHz. We do not fully understand the broadening. The overall response of the system to the probe is smaller in Fig. 5b (with driving beams) than that in Fig. 5a.
with two momentum states: 0 and 2

The simplest model that explains the splitting in the spectrum is a noninteracting model of a closed system. The eigenstates of such a Hamiltonian are dressed states \[2\]. The energy difference between the two eigenstates is \(\Omega_0\), which is only half of that of the ground state of the BEC. In the weak lattice limit, \(\hbar k_L \ll \omega_r\) is the single photon recoil energy, we recover the two state result \(|k_L⟩ = 1/\sqrt{2}(|1⟩ + |2⟩)\), and a splitting of \(Ω_d\). For our parameters the band structure is obtained by numerical diagonalization and presented in Fig.\(4\). The predicted splitting between the two lowest bands is indeed within 1\% of \(Ω_d\), but contrary to the weak lattice approximation, \(|a_3(±k_L)| = |a_4(±k_L)| \approx 10\%\) of \(|a_3(±3k_L)| = |a_4(±3k_L)|\). This indeed leads to negligible occupations, but as we show shortly, to observable interference effects.

With the probe beams, the Hamiltonian governing the model homogeneous system in the driving lattice frame is \(H = H_0 + H_p\) with

\[
H_p = \hbar \Omega_p \cos(2k_L z - \omega_p t) = V_p e^{-i\omega_p t} + \text{c.c.}
\]  

\[
H_p = \hbar \Omega_p \cos(2k_L z - \omega_p t) = V_p e^{-i\omega_p t} + \text{c.c.}
\]

with \(V_p = \Omega_p^2 e^{2ik_L z} / 2\). In the rotating wave approximation \(H_p\) is a momentum shift operator coupling state \(|k⟩\) to \(|k + 2k_L⟩\). Since \(\omega_p < \omega_r\), it can be treated by the use of first-order time-dependant perturbation theory, giving probability amplitudes for transitions between bands. The momentum transferred to the condensate by the redistribution of photons in the probe beams is a multiple of the reciprocal lattice vector \(2k_L\), hence also with the probe beams the initial quasi-momentum \(q = k_L\) is conserved.

The dashed line in Fig.\(3\) is the full first order perturbation theory expectation of the population of state \(3k_L⟩\) in the moving frame of reference, which is equal to \(2k_L\) in the laboratory frame of reference. Aside from a mean-field shift, this simple model seems to fit the GPE simulation quite well.

Since the splitting between band 3 and 4 is negligible, the splitting in the spectrum of the probe in this non-interacting model is essentially the splitting between the two lowest bands (see Fig.\(3b\)).

There is a clear asymmetry in the peak heights which is in good agreement with the GPE simulation. This asymmetry is due to quantum interferences between pathways.

\[
|n, q⟩ = \sum_m a_{n,q}(k)(|q + 2mkL⟩
\]
of the probe excitation. The probe couples each of the lower bands (1 and 2) to each of the higher bands (3 and 4) by two paths. In the weak lattice approximation there is only the path $|k_L \rangle \rightarrow |3k_L \rangle$, however due to the nonvanishing $a_3(k_L)$ and $a_4(k_L)$, there is also a path $|−k_L \rangle \rightarrow |k_L \rangle$. These paths are marked by arrows connecting the relevant amplitudes in Fig 4(b). The interference between both paths is constructive for transitions from band 2 and destructive for transitions from band 1. Therefore the lower energy peak in the splitting, corresponding to transitions from band 2 should be larger than the higher energy peak which corresponds to transitions from band 1.

In the experiment, the frequency difference between the driving Bragg beams is equal to the free particle resonance $\hbar \omega_d = 4E_R$. For other values of $\hbar \omega_d$, the Rabi oscillations are not full. As the detuning from resonance grows, the amplitude of oscillations is reduced and the frequency of oscillations grows. In the spectral domain the frequency difference between the two peaks of Fig. 4(b) grow with the detuning from resonance. The amplitude of one peak grows while it’s position in frequency shifts towards the excitation energy of a free Bogoliubov quasiparticle. The other peak shrinks in size as the detuning of $\omega_d$ from resonance grows. In Fig. 5 we plot the values of $\omega_p$ at the peak of the spectrum versus $\omega_d$, as obtained by numerically solving the GPE for $\Omega_d = 5.5$ kHz. We compare this to the energy splitting of a non-interacting two-level system, calculated for the same parameters, and shifted up by 1.3 kHz. As in the resonant case, the splitting is in good agreement with the GPE, except for a constant shift due to interactions.

In conclusion, we measure a splitting in the Bragg excitation spectrum of a BEC undergoing Rabi oscillations between two momentum states. Experimental data fits well with numerical GPE simulations. The main features are captured by a simple noninteracting model, whereas the main contribution of interactions is found to be the mean field shift of the probe spectrum, captured by the GPE, and an increase in the width which is not captured by the GPE. The splitting in the spectrum results in a splitting in the energy of the atoms undergoing incoherent collisions. Experimentally, a divergence from the known s-wave scattering halo was measured for a rapidly oscillating BEC. There too, a pronounced asymmetry was found between the inner collisional shell and the outer one.

We numerically solve the GPE for the order parameter of the condensate as described in [22]:

$$i\hbar \partial_t \psi = \{-\hbar^2 \nabla^2/2M + V + g|\psi|^2\} \psi,$$

with the time dependent external potential typically of the form $V(r,t) = M/2(\omega^2 r^2 + \omega^2 z^2) + \hbar \Omega_L \cos(2k_L z - \omega_d t) + \hbar \Omega_p \cos(2k_L z - \omega_p t)$. All other parameters for the simulation are as in the experimental system, described above. The ground-state is found for $t<0$ by imaginary time evolution. We exploit the cylindrical symmetry to evolve the wavefunction on a two dimensional grid $N_z \times N_r (4096 \times 32)$, using the Crank-Nicholson differencing method with alternating direction implicit algorithm.
