Abstract. We study large fluctuations in evolutionary games belonging to the coordination and anti-coordination classes. The dynamics of these games, modeling cooperation dilemmas, is characterized by a coexistence fixed point separating two absorbing states. We are particularly interested in the problem of fixation that refers to the possibility that a few mutants take over the entire population. Here, the fixation phenomenon is induced by large fluctuations and is investigated by a semiclassical WKB (Wentzel–Kramers–Brillouin) theory generalized to treat stochastic systems possessing multiple absorbing states. Importantly, this method allows us to analyze the combined influence of selection and random fluctuations on the evolutionary dynamics beyond the weak selection limit often considered in previous works. We accurately compute, including pre-exponential factors, the probability distribution function in the long-lived coexistence state and the mean fixation time necessary for a few mutants to take over the entire population in anti-coordination games, and also the fixation probability in the coordination class. Our analytical results compare excellently with extensive numerical simulations. Furthermore, we demonstrate that our treatment is superior to the Fokker–Planck approximation when the selection intensity is finite.

Keywords: population dynamics (theory), large deviations in non-equilibrium systems
1. Introduction and models

Systems in which successful strategies spread by imitation or reproduction can be described by evolutionary game theory (EGT), whose prototypical models are commonly studied in the context of evolutionary biology, ecology, sociology and economics [1]–[6]. Recently, it has been realized that techniques of statistical physics can help gain further insight into this interdisciplinary area [2,7]. Originally, EGT was formulated in terms of deterministic replicator equations valid to treat populations of infinite size [1,2,5] and related to the celebrated Lotka-Volterra equations [1]–[3], [8]–[10]. However, it has long been recognized that the picture emerging from replicator dynamics is often fundamentally altered by demographic fluctuations.

One of the most striking effects of fluctuations in EGT is fixation, which refers to the possibility for a few ‘mutants’ to take over (fixate) an entire population, causing the extinction of the ‘wild species’. To rationalize the effect of stochasticity in finite populations, Nowak et al [3,11] introduced a parameter $w$ controlling the interplay between random (demographic) fluctuations and selection (leading to nonlinear effects). This approach reflects the fact that evolutionary processes comprise two main competing mechanisms. On the one hand, there is selection by individuals’ different fitness (reproductive potential), which underlies adaptation [1,3,5,6], [12]–[15]. On the other hand, in all finite-size populations birth and death events cause random (demographic) fluctuations, which play a central role in neutral theories where selection is considered of marginal importance [16]–[19].

Most of the analytical results concerning EGT in finite populations have been obtained in the weak selection limit ($w \to 0$), which is often biologically relevant [20] and greatly simplifies the mathematical analysis. In particular, the fixation probability of a species

doi:10.1088/1742-5468/2010/09/P09009
under frequency-dependent selection in a finite population (of two species) has been computed in this limit [11]. However, very different behaviors have been obtained under strong and weak selection (see, e.g., [21]–[25]) and the respective influence of selection and demographic fluctuations on evolution still remains to be fully understood. Our purpose in this paper is to study fixation resulting from large fluctuations in two classes of evolutionary games (the anti-coordination and coordination classes, see below) under arbitrary (finite) selection strength, and to elucidate the nontrivial interplay between selection intensity and demographic fluctuations.

For the sake of concreteness, throughout this paper we will consider (symmetric) $2 \times 2$ evolutionary games. Here, one has a homogeneous (well-mixed) population comprising a total of $N$ individuals, where $n$ are of the ‘mutant’ species $A$ and $N-n$ are of the ‘wild’ type $B$. As usual, it is assumed that there are pairwise and symmetric interactions between individuals drawn at random. The reproductive potential of an individual is specified by the payoff of interaction with others [1]–[3], [5]. Specifically, when two individuals of species $A$ interact, both receive a payoff $a$. The interaction of a pair of individuals of different species yields payoffs $b$ and $c$ to the $A$ and $B$ individuals, respectively. Similarly, when two individuals of type $B$ interact, both get a payoff $d$. Therefore, the respective average (per individual) payoffs of species $A$ and $B$ are: $\Pi_A(n) = (n-1)/(N-1)a + (N-n)/Nn$, $\Pi_B(n) = n/(N-1)c + (N-n-1)/Nd$, with self-interactions being excluded. It is useful to introduce the difference between the average payoffs $\Delta \Pi(n) = \Pi_A(n) - \Pi_B(n) = (a-b-c+d)n/(N-1) - (d-b)N/(N-1) - (a-d)/(N-1)$. For populations of infinite size ($N \rightarrow \infty$), the dynamics is of mean-field type and commonly described by the replicator equations. The latter are obtained from the payoff matrix by comparing the success of a given type with the population average [1]–[3].

For $N \rightarrow \infty$, $x \equiv n/N$, the mutant concentration, can be regarded as a continuous variable and the dynamics is specified by the following replicator equation:

$$
\dot{x} = x(1-x)\Delta \Pi(x), \quad \Delta \Pi(x) = (a-c)x - (d-b)(1-x). \quad (1)
$$

This equation is characterized by two absorbing fixed points $x = x_A^* = 1$ and $x = x_B^* = 0$ corresponding to a system with all As and Bs, respectively. Moreover, there can be an interior fixed point obtained by solving $\Delta \Pi(x^*) = 0$:

$$
x^* = \frac{d-b}{a-b-c+d}. \quad (2)
$$

Depending on the entries of the payoff matrix, one has various classes of games representing models of cooperation dilemmas [2, 13, 25]. When one species always dominates the other, one has the dominance class, where $A$ is the dominant type when $a > c$ and $b > d$, while $B$ is dominant when $a < c$ and $b < d$. In this work we are interested in the other two classes, anti-coordination games (ACG) and coordination games (CG), where there exists an interior fixed point corresponding to a coexistence state. In the class of ACG (e.g., ‘snowdrift’ and ‘hawk-dove’ games [1, 2, 5]), $c > a, b > d$ and $x^*$ is an attractor corresponding to the stable coexistence of $A$ and $B$ types. Here, the absorbing states $x_A^*$ and $x_B^*$ are (evolutionary) unstable. On the other hand, in the class of CG (e.g., ‘stag-hunt’ game [1]–[3]) $a > c, d > b$ and $x^*$ is repelling, while the absorbing states are (evolutionary) stable.

Fluctuations arising from the discreteness of individuals and from the stochastic nature of the interactions may drastically alter the predictions of the deterministic
replicator equations [26]. In particular, a few mutants can always attain fixation by
taking over the entire population (see below). The resulting stochastic evolutionary
dynamics is aptly described in terms of single-step birth–death processes [27]–[29], for
which a key quantity is the time-dependent probability distribution function (PDF) $P_n(t)$
of population sizes. The latter gives the probability of finding the system in a state with
$n$ individuals of species $A$ at time $t$, and obeys the following master equation:

$$\frac{dP_n(t)}{dt} = T^+(n - 1)P_{n-1} + T^-(n + 1)P_{n+1} - [T^+(n) + T^-(n)]P_n. \quad (3)$$

Here $T^+(n)$ and $T^-(n)$ respectively denote the transition rates from a state with $n$ $A$s to a
state with $n + 1$ and $n - 1$ $A$s. As the state space is bounded, $n \in [0, N]$, and $n = 0$ and $N$
are absorbing states, the transition rates at the boundaries satisfy $T^+(0) = T^+(N) = 0$.

According to general prescriptions of EGT, the transition rates are functions of each
species’ fitness (effective potential to reproduce), $f_\sigma$, with $\sigma \in \{A, B\}$, i.e. $T^\sigma(n) = T^\sigma[f_\sigma(n)]$. The fitness of an individual of species $\sigma$ is $[3, 11]$ $f_\sigma(n) \equiv 1 - w + w\Pi_\sigma(n)$. Here,
the interplay between random fluctuations and selection is controlled by the parameter
$w$ (with $0 \leq w \leq 1$), where in the neutral case, $w = 0$, there is no selection (but only
random fluctuations), while in the strong selection regime, $w = 1$, the influence of random
fluctuations is negligible.

In this paper we consider the following update rules commonly used in the EGT
literature, specifying the functional dependence of $T^\pm$ on the species fitnesses. For the
frequency-dependent Moran process (fMP) [2, 3, 30], one has

$$T^+(n) = \frac{f_A(n)}{\bar{f}(n)} \Phi(n), \quad T^-(n) = \frac{f_B(n)}{\bar{f}(n)} \Phi(n), \quad (4)$$

where $\bar{f}(n) = [nf_A(n) + (N - n)f_B(n)]/N$ is the population average fitness and $\Phi(n) \equiv
n(N - n)/N^2$. For the linear Moran process (LMP) [30, 32], the transition rates are

$$T^+(n) = \frac{1}{2} \{1 + [f_A(n) - \bar{f}(n)]\} \Phi(n), \quad T^-(n) = \frac{1}{2} \{1 + [f_B(n) - \bar{f}(n)]\} \Phi(n). \quad (5)$$

As the LMP is obtained from a small $w$ expansion of the fMP, (5) can be regarded as the
‘weak selection’ counterpart of the rates (4). A process closely related to the LMP is the
‘local update’ process (LUP) [30, 32] with rates

$$T^+(n) = \frac{1}{2} \{1 + [f_A(n) - f_B(n)]\} \Phi(n), \quad T^-(n) = \frac{1}{2} \{1 + [f_B(n) - f_A(n)]\} \Phi(n). \quad (6)$$

Here, for simplicity and without restriction, we have assumed that the maximum payoff
difference is 1 [30]. Finally, for the Fermi process (FP) [7, 23, 25, 30], one has

$$T^+(n) = \{1 + \exp[f_B(n) - f_A(n)]\}^{-1} \Phi(n),$$
$$T^-(n) = \{1 + \exp[f_A(n) - f_B(n)]\}^{-1} \Phi(n). \quad (7)$$

In the following, we omit in all these cases the self-interaction terms in the expressions
of $\Pi_A(n)$ and $\Pi_B(n)$.\footnote{One can also account for self-interaction terms of order $O(N^{-1})$ in $T^\pm(n)$ [37]. However, while this unnecessarily complicates the mathematical treatment, it does not bring about any qualitative differences in the results.} Note that multiplying both sides of (3) by $n$ and summing over all $n$s, one obtains an equation for the mean number of $A$ individuals. In the leading order
of $N \gg 1$ (mean-field limit) and upon rescaling time, one arrives at the following rate

$$\frac{d\langle n \rangle}{dt} = \frac{\langle n \rangle}{N} \sum [T^+(n) - T^-(n)] - [\bar{f}(n) - \bar{f}(n + 1)]\langle n \rangle.$$
equation for the concentration of mutants: \( \dot{x} = T^+(Nx) - T^-(Nx) \). Such a replicator-like equation shares the same properties (fixed points and stability) of equation (1), but generally differs from it when \( f \) is non-constant (see, e.g., \([5,32]\)).

Let us denote by \( \phi_i^A \) the probability that \( i \) mutants of species \( A \) (usually \( i \ll N \)) replace all the individuals of the wild type \( B \). That is, \( \phi_i^A \) is the probability of fixation of the \( A \) species starting with \( i \) mutants. The conditional and unconditional mean fixation times (MFTs) \( \tau_i^A \) and \( \tau_i \), respectively, are the times associated with the fixation event. The former, \( \tau_i^A \), is the average time it takes for \( i \) mutants of species \( A \) to take over the population, while the latter, \( \tau_i \), is the mean time it takes the population, initially comprising \( i \) individuals of species \( A \), to become homogeneous again (i.e. populated either by all \( A \) s or all \( B \) s). For all one-dimensional single-step birth–death processes, such as those defined by (4)–(7), there are exact formulae for the above quantities \([23,24,27,28]\).

For instance, the fixation probability is

\[
\phi_i^A = \frac{1 + \sum_{k=1}^{i-1} \prod_{l=1}^{k} \gamma_l}{1 + \sum_{k=1}^{N-1} \prod_{l=1}^{k} \gamma_l}, \tag{8}
\]

where \( \gamma_l = T^-(i)/T^+(i) \), while for the unconditional MFT, one has

\[
\tau_i = -\tau_1 \sum_{k=1}^{N-1} \prod_{m=1}^{k} \gamma_m + \sum_{k=1}^{N-1} \sum_{l=1}^{k} \frac{1}{T^+(l)} \prod_{m=l+1}^{k} \gamma_m, \quad \tau_1 = \phi_1^A \sum_{k=1}^{N-1} \sum_{l=1}^{k} \frac{1}{T^+(l)} \prod_{m=l+1}^{k} \gamma_m. \tag{9}
\]

Even though the expressions (8)–(9) are exact, they are unwieldy and cannot be generalized to multi-step processes and to \( s \times s \) games, with \( s > 2 \). Furthermore, it is highly nontrivial to extract their asymptotic behavior. In fact, with the exception of \([24]\) where the fixation probability and MFTs were calculated in the leading order for the fMP (focusing on \( w = 1 \)), most of the analytical results in the literature have been obtained in the weak selection limit, \( Nw \ll 1 \), often using the Fokker–Planck equation (FPE) \([23,25,30,31]\).

In this paper we go beyond the weak selection limit and investigate the fixation phenomenon induced by large fluctuations in the classes of ACG and CG. Our approach relies on the WKB approximation \([33]\) applied directly to the master equation (3) \([34]–[37]\), which we generalize to account for the existence of multiple absorbing states. Here, the WKB approximation is an asymptotic series expansion in powers of \( 1/N \ll 1 \) based on an exponential ansatz\(^4\) (see equation (13)) and differs from the van Kampen system size expansion that yields the FPE \([27,28]\) (see section 3.2). With the WKB approach and for any finite selection intensity, we accurately compute the MFTs and fixation probability (including pre-exponential factors) for generic transition rates. Our general results are then applied to the processes defined by the transition rates (4)–(7) and successfully compared with extensive numerical simulations. The predictions of our WKB approach are also shown to be superior to those of the FPE when \( w \) is finite (see also \([38]\)).

The remainder of this paper, of which a brief account has recently been given in \([39]\), is organized as follows. The next section is dedicated to the ACG, for which a general treatment is presented in section 2.1, while applications are discussed in section 2.2. Section 3 concerns the CG class, with general results and applications discussed in

---

\(^4\) The WKB treatment of the master equation via ansatz (13) is analogous to the semiclassical treatment of quantum mechanics in terms of \( \hbar \) \([33]\).
sections 3.1 and 3.2, respectively. Finally, we give a summary of our findings and present our conclusions in section 4. Some technical details are relegated to an appendix.

2. Anti-coordination games: metastability, fixation times and probability

In this section we use the WKB approach to investigate large fluctuations in systems of evolutionary games characterized by metastability. For \( N \gg 1 \), in general this case arises in the ACG, to which the snowdrift and hawk–dove games belong [1]–[3]. In ACG, the elements of the payoff matrix satisfy \( b > d \) and \( c > a \). Here, the attracting (interior) fixed point \( x^* \) (see equation (2)) in the language of the replicator equation (1) separates the repelling fixed points \( x^A_\lambda \) (all As) and \( x^B_\pi \) (all Bs). In the presence of internal noise, \( x^* \) corresponds to a long-lived metastable state, where after a sufficiently long time the system is eventually driven into one of the two absorbing states via a large fluctuation. In this section we first derive general results concerning the metastable dynamics of stochastic systems possessing two absorbing states. Then, using the transition rates (4)–(7), we apply these findings to the case of ACG.

2.1. General treatment and results

Our starting point is the master equation (3). In the case of a finite space \( n \in [0, N] \), one can always expand \( P_n(t) \) in a finite series of eigenvectors and eigenvalues of the stochastic generator associated with the Markov chain (3). We assume here and henceforth that \( N \gg 1 \). In this case, for any (sufficiently large) given initial population of As, after a relaxation timescale \( t_r \), the system converges to a long-lived metastable (coexistence) state prior to fixation of either species. This metastable state corresponds to a PDF of population sizes peaked in the vicinity of \( n_* = N x^* \), where \( x^* \) is the attracting interior fixed point of (1). Here, the MFT \( \tau \) is associated with the slow decay of the metastable state, see below, and satisfies \( t_r \ll \tau \). That is, fixation occurs in the aftermath of a long-lasting coexistence state.

It turns out that, for times \( t \gg t_r \), when the system has already converged into the metastable state, the higher-excited eigenvectors have already decayed (see, e.g., [40]). At such times, only the first-excited eigenvector of (3), \( \pi_n \), called the quasi-stationary distribution (QSD), survives and determines the shape of the metastable PDF. Correspondingly, the decay rate of the metastable PDF is determined by the first-excited eigenvalue of (3) [40]. While the metastable PDF decays, the probabilities \( P_0(t) \) and \( P_N(t) \) slowly grow in time and, at \( t \to \infty \), reach some final values such that \( P_0(\infty) + P_N(\infty) = 1 \). Therefore, at \( t \gg t_r \), one can write

\[
P_{n=1,\ldots,N-1}(t) \simeq \pi_n e^{-t/\tau}, \quad P_0(t) \simeq \phi(1 - e^{-t/\tau}), \quad P_N(t) \simeq \phi(1 - e^{-t/\tau}). \tag{10}
\]

From this metastable dynamics one can immediately see that \( \tau \) is the (unconditional) MFT, while \( \phi = \phi^B \) is the fixation probability of species B, and \( 1 - \phi \) is the fixation probability of species A.

It follows from (10) that \( \dot{P}_0 + \dot{P}_N = (1/\tau)e^{-t/\tau} \), while from the master equation (3) one has \( \dot{P}_N = T^+(N-1)\pi_{N-1}e^{-t/\tau} \) and \( \dot{P}_0 = -T^-(1)\pi_1 e^{-t/\tau} \). We thus obtain

\[
\dot{P}_0(t) = \left[ \tau^{-1} - T^+(N-1)\pi_{N-1} \right] e^{-t/\tau} = T^-(1)\pi_1 e^{-t/\tau},
\]

whose solution (with \( P_0(0) = 0 \)) is

\[
P_0(t) = \left[ 1 - \tau T^+(N-1)\pi_{N-1} \right] (1 - e^{-t/\tau}).
\]

Using this solution and equation (10), we
obtain the fixation probability $\phi$ which turns out to be the relative flux into the absorbing state $n = 0$. Moreover, as the unconditional MFT is the (inverse of the) decay rate of the metastable state, it is given by the (inverse of the) sum of probability fluxes into the two absorbing states. Thus, we have

$$\phi = T^-(1)\pi_1\tau, \quad \tau = [T^-(1)\pi_1 + T^+(N - 1)\pi_{N-1}]^{-1}, \quad (11)$$

where the unknowns $\pi_1$ and $\pi_{N-1}$ will be determined shortly. Correspondingly, $\tau^A$ and $\tau^B$—the conditional MFTs of species $A$ and $B$, respectively—can also be found. The former is the mean time it takes the $A$ species to fixate conditioned on the non-fixation of the $B$ species; it is determined by the inverse of the flux to the state $n = N$. Using the same reasoning for $\tau^B$, we thus have $\tau^A = [T^+(N - 1)\pi_{N-1}]^{-1}$ and $\tau^B = [T^-(1)\pi_1]^{-1}$.

Note that, since we have assumed that the system reaches the metastable state prior to fixation, our results (11) are independent of the initial condition. As we shall see below, this assumption holds for ACG when the selection strength is finite.

Substituting the metastable ansatz (10) into equation (3), we arrive at the quasi-stationary master equation (QSME). Neglecting the exponentially small term $\pi_n/\tau$ (to be verified a posteriori) on the left-hand side, the QSME becomes

$$0 = T^+(n - 1)\pi_{n-1} + T^-(n + 1)\pi_{n+1} - [T^+(n) + T^-(n)]\pi_n. \quad (12)$$

In the following, this equation is analyzed by using the WKB approximation. Our aim, in addition to finding the fixation probability and MFTs, is to find the complete QSD, $\pi_n$, and demonstrate the non-Gaussian nature of its tails. To do so, and since there are two absorbing states in this problem, we solve the QSME (12) separately in three overlapping regions: in the bulk and not too close to the absorbing boundaries, and in the close vicinities of $n = 0$ and $N$. These solutions are then matched in their regions of joint validity.

In the bulk region (whose accurate boundaries are specified below) we employ the WKB ansatz:

$$\pi_n \equiv \pi_{xN} = \pi(x) = Axe^{-NS(x)-S_1(x)}, \quad (13)$$

where $N \gg 1$, and we have introduced the rescaled coordinate $x = n/N$. Here, $S(x)$ is the action while $S_1(x)$ is the amplitude. To have a consistent perturbation theory, we assume that these quantities are smooth functions of order unity. The constant pre-factor $A$ is introduced for technical convenience. It is convenient to rewrite the transition rates as continuous functions $T_{\pm}(x) \equiv T^\pm(n)$ of the rescaled continuous coordinate $0 \leq x \leq 1$.

We will assume that, in the bulk, $T_{\pm}(x) = O(1)$, which is satisfied by all the transition rates (4)–(7).

Plugging ansatz (13) into equation (12), and expanding the functions of $x \pm N^{-1}$ up to $O(N^{-1})$, we arrive at

$$\pi(x)\left\{T_{+}(x)\left[e^{S'}\left(1 - \frac{S''}{2N} + \frac{S_1}{N}\right) - 1\right] + T_{-}(x)\left[e^{-S'}\left(1 - \frac{S''}{2N} - \frac{S_1}{N}\right) - 1\right] + \frac{1}{N}\left[e^{-S'}T_{-}(x) - e^{S'}T_{+}(x)\right]\right\} = 0. \quad (14)$$

This equation can be solved order by order in $N \gg 1$. In the leading $O(1)$ order, one obtains a stationary Hamilton–Jacobi equation for the action $S(x)$, $H[x, S'(x)] = 0$ with

doi:10.1088/1742-5468/2010/09/P09009
where we have defined the auxiliary momentum coordinate $p$ trajectory \[37\], of the auxiliary Hamiltonian (15) \[35\]. It turns out that there is exactly one (real) such trajectory [37], $p_a(x)$, called the activation trajectory. It represents the ‘optimal path’ along which the stochastic system evolves, almost with certainty, from the metastable state towards fixation. Here, the solution of $H[x, p_a(x)] = 0$ is $p_a(x) = -\ln[T_+(x)/T_-(x)]$ [37].

The corresponding action along this trajectory is

$$S(x) = -\int_x^z \ln[T_+(\xi)/T_-(\xi)] \, d\xi. \quad (16)$$

In the subleading $\mathcal{O}(1/N)$ order, one arrives at a first-order transport-like differential equation for $S_1(x)$, whose solution is [36,37]

$$S_1(x) = \frac{1}{2} \ln[T_+(x)T_-(x)]. \quad (17)$$

Therefore, the solution in the bulk region can be written as

$$\pi(x) = \frac{\mathcal{A}}{\sqrt{T_+(x)T_-(x)}} e^{N \int_x^z \ln[T_+(\xi)/T_-(\xi)] \, d\xi}. \quad (18)$$

It is worth emphasizing that this solution is valid in the regime where $T_-(x) = \mathcal{O}(1)$, i.e. not too close to the absorbing boundaries $x = 0$ and $1$, where the transition rates vanish. As for $N \gg 1$ the QSD is strongly peaked in the vicinity of the attracting fixed point $x^*$, the constant $\mathcal{A}$ can be determined by normalizing to unity the Gaussian asymptote of the QSD around $x^*$. The latter is obtained by expanding equation (13) to second order about $x^*$ and using $p_a(x^*) = 0$ (since $T_+(x^*) = T_-(x^*)$). Normalizing the resulting Gaussian asymptote, $\pi(x) \simeq \mathcal{A} e^{-NS(x^*) - S_1(x^*) - (N/2)S''(x^*)(x-x^*)^2}$, yields the constant $\mathcal{A}$ and therefore the QSD is given by

$$\pi(x) = T_+(x^*) \sqrt{\frac{S''(x^*)}{2\pi N T_+(x)T_-(x)}} e^{-N[S(x^*) - S_1(x^*)]} \quad (19)$$

Here, $S''(x^*) = T'_+(x^*)/T_-(x^*) - T'_-(x^*)/T_+(x^*) > 0$, as $x^*$ is an attracting fixed point and so $T'_+(x^*) - T'_-(x^*) < 0$.

We now turn to dealing with the QSME (12) in the close vicinities of the absorbing boundaries where the WKB approximation breaks down. First, expanding the transition rates $T_\pm(x) \simeq x T'_\pm(0)$ about $x = 0$ (where $T_\pm(0) = 0$), and multiplying equation (12) by $N$, one has

$$0 = T'_+(0)(n-1)\pi_{n-1} + T'_-(0)(n+1)\pi_{n+1} - n[T'_+(0) + T'_-(0)]\pi_n,$$

whose recursive solution is [37]

$$\pi_n = \frac{(R_0^n - 1)\pi_1}{(R_0^n - 1)n}. \quad (20)$$

Here we have introduced the parameter $R_0 \equiv T'_+(0)/T'_-(0)$. This procedure turns out to be valid in the range $1 \leq n \ll \sqrt{N}$ [37]. Similarly, close to the boundary $n = N$, the rates in the QSME (12) can be expanded in the vicinity of $x = 1$ yielding

\[do:10.1088/1742-5468/2010/09/P09009\]
Large fluctuations and fixation in evolutionary games

0 = \mathcal{T}'(N - n + 1)\pi_{n-1} + \mathcal{T}'(N - n - 1)\pi_{n+1} - (N - n)[\mathcal{T}'(1) + \mathcal{T}'(1)]\pi_n. \quad \text{The solution of this equation, valid for } 1 \leq N - n \ll \sqrt{N} \text{ and with } R_1 \equiv \mathcal{T}'(1)/\mathcal{T}'(1), \text{ satisfies}

\pi_n = \frac{(R_1^{N-n} - 1)\pi_{N-1}}{(R_1 - 1)(N - n)}. \quad (21)

We are in the position to find the complete QSD by matching equations (20) and (21) with the asymptotes of (19) in the regions \( 1 \ll n \ll \sqrt{N} \) and \( 1 \ll N - n \ll \sqrt{N} \), respectively. In the vicinity of \( n = 0 \), the asymptote of (19) can be found by writing

\[ S(x) \approx S(0) + xp_a(0), \quad \text{with } p_a(0) = \ln[\mathcal{T}'(0)/\mathcal{T}'(0)], \]

which yields

\[ \pi(x) = \frac{\mathcal{T}(x^*)\sqrt{S''(x^*)}}{x\sqrt{2\pi N \mathcal{T}'(0)\mathcal{T}'(0)}} R_0^{Nx} e^{-N[S(0)-S(x^*)]}. \] \quad (22)

This asymptote is valid for \( 1 \ll n \ll \sqrt{N} \) [37]. Similarly, the asymptote of equation (19) in the vicinity of \( x = 1 \) is

\[ \pi(x) = \frac{\mathcal{T}(x^*)\sqrt{S''(x^*)}R_1^{N(1-x)}}{(1 - x)\sqrt{2\pi N \mathcal{T}'(1)\mathcal{T}'(1)}} e^{-N[S(1)-S(x^*)]}, \] \quad (23)

and is valid for \( 1 \ll N - n \ll \sqrt{N} \). Matching equations (22) and (23), respectively, with equations (20) and (21) yields

\[ \pi_1 = \sqrt{NS''(x^*)} \mathcal{T}(x^*)(R_0 - 1) \sqrt{\mathcal{T}'(0)\mathcal{T}'(0)} e^{-N[S(0)-S(x^*)]}, \]

\[ \pi_{N-1} = \sqrt{NS''(x^*)} \mathcal{T}(x^*)(R_1 - 1) \sqrt{\mathcal{T}'(1)\mathcal{T}'(1)} e^{-N[S(1)-S(x^*)]} \] \quad (24)

With the expressions (19)–(21) and (24), the QSD has been completely determined. The fixation probability and the MFTs can then be computed according to (11). In fact, as \( \mathcal{T}^-(1) \simeq (1/N)\mathcal{T}'(0) \) and \( \mathcal{T}^+(N - 1) \simeq (1/N)|\mathcal{T}'(1)| \) (as \( \mathcal{T}'(1) < 0 \)), the fixation probability and unconditional MFT (11) become

\[ \phi = \frac{\mathcal{T}'(0)\pi_1}{\mathcal{T}'(0)\pi_1 + |\mathcal{T}'(1)|\pi_{N-1}}, \quad \tau = \frac{N}{\mathcal{T}'(0)\pi_1 + |\mathcal{T}'(1)|\pi_{N-1}}. \] \quad (25)

while the conditional MFTs of species A and B are respectively \( \tau^A = N[|\mathcal{T}'(1)|\pi_{N-1}]^{-1} \) and \( \tau^B = N[\mathcal{T}'(0)\pi_1]^{-1} \). Importantly, since we have assumed that \( \tau \) is exponentially large in \( N \), these results indicate that our theory is valid as long as \( N[S(1) - S(x^*)] \gg 1 \) and \( N[S(0) - S(x^*)] \gg 1 \).

2.2. Applications

As applications of the general results that we have derived, we now explicitly consider the four types of update rules mentioned above, i.e. the fMP, LMP, LUP and the FP (4)–(7). For each of them we obtain the QSD, the MFTs and the fixation probability under arbitrary (but finite) selection strength \( 0 < w \leq 1 \).

doi:10.1088/1742-5468/2010/09/P09009
2.2.1. Frequency-dependent Moran process. For the fMP, the birth and death rates (4) in terms of the variable $x$ become

$$T_+(x) = \frac{\{1 - w + w[ax + b(1 - x)]\} x(1 - x)}{1 - w + w[ax^2 + (b + c)x(1 - x) + d(1 - x)^2]}$$  
$$T_-(x) = \frac{\{1 - w + w[cx + d(1 - x)]\} x(1 - x)}{1 - w + w[ax^2 + (b + c)x(1 - x) + d(1 - x)^2]}$$  

(26)

and one can check that $T_+(0) = |T_+'(1)| = 1$. The action $S(x)$ is computed from equation (16) with the rates (26), yielding

$$S(x) = \int_0^x \ln \left\{ \frac{1 - w + w[cq + d(1 - q)]}{1 - w + w[aq + b(1 - q)]} \right\} \, dq.$$  

(27)

For further analytical treatment, it is convenient to introduce the following parameters (also used in [41]): $A = 1 - w + wA$, $B = 1 - w + wb$, $C = 1 - w + wc$ and $D = 1 - w + wd$, where for ACG, $C > A$ and $B > D$. Performing the integral (27), one obtains after some algebra

$$e^{-NS(x)} = [Ax + B(1 - x)]^{N_+ - N(B/(B-A))}[Cx + D(1 - x)]^{-N_+ - N(D/(C-D))}.  

(28)$$

It can also be checked that

$$S''(x) = \frac{BC - AD}{[Ax + B(1 - x)][Cx + D(1 - x)]}$$  

(29)

is positive over the entire region $0 \leq x \leq 1$. It therefore follows from (19), and equations (26), (28) and (29), that in the bulk, i.e. for $x \gg N^{-1/2}$ and $1 - x \gg N^{-1/2}$, the QSD is

$$\pi(x) = \sqrt{\frac{(C - A)(B - D)}{2\pi N(BC - AD) T_+(x) T_-(x)(B - A + C - D)}} \times \frac{[Ax + B(1 - x)]^{N_+ - N(B/(B-A))}}{[Cx + D(1 - x)]^{N_+ + N(C/(C-D))}} \left( \frac{BC - AD}{C - A + B - D} \right)^{N(B/(B-A))/(B-A)(C-D)} \frac{N_+}{N_+ + N(D/(C-D))}.  

(30)$$

Moreover, $\pi_1$ and $\pi_{N-1}$ are obtained from equations (24):

$$\pi_1 = \sqrt{\frac{N}{2\pi BD(BC - AD)}} \left( \frac{BC - AD}{C - A + B - D} \right)^{N(B/(B-A))/(B-A)(C-D)} B^{N(B/(B-A))} D^{-N(D/(C-D))}  

(31)$$

$$\pi_{N-1} = \sqrt{\frac{N}{2\pi AC(BC - AD)}} \left( \frac{BC - AD}{C - A + B - D} \right)^{N(B/(B-A))/(B-A)(C-D)} A^{-N(A/(B-A))} C^{-N(C/(C-D))}.$$

Equation (30) determines the QSD for ACG evolving according to the fMP (close to the boundaries, one must use equations (20) and (21) instead). Clearly, the resulting QSD
Figure 1. Shown is $\ln \pi_n$ as a function of $n$ for $a = 0.1$, $b = 0.7$, $c = 0.6$, $d = 0.2$, $w = 0.4$ and $N = 150$, so that $n_* = 75$. The dynamics is implemented according to the fMP (4). We compare the analytical result (30) (solid line) with the numerical solution of the master equation (3) (dashed line) with rates (26), and with a Gaussian approximation of this distribution with mean $n_*$ and standard deviation $\sigma = \sqrt{N/S'(x^*)}$ (dashed–dotted line). Near the tails, one can clearly observe the non-Gaussian nature of the QSD. Note that, very close to the boundaries at $n = \mathcal{O}(1)$ and $N - n = \mathcal{O}(1)$ (see text), equation (30) has to be replaced by equations (20) and (21).

is non-Gaussian, which is especially evident near the tails. A typical example is shown in figure 1 where excellent agreement is observed between our analytical results and a numerical solution of the corresponding master equation (3). It is worth reminding the reader that our theory is applicable when $N[S(1) - S(x^*)] \gg 1$ and $N[S(0) - S(x^*)] \gg 1$, which imposes a lower bound on $w$. Hence, while it is inapplicable in the weak selection limit $Nw \ll 1$, recently investigated by other techniques (see, e.g., [23, 30] and references therein), our approach successfully applies to the more general case of finite selection intensity $0 < w \leq 1$.

The MFTs can now be found by using equations (25) and (31), with $T'(0) = |T'_+(1)| = 1$. As illustrated in figure 2, the unconditional MFT asymptotically exhibits an exponential dependence on the population size $N$. That is, $\tau \propto N^{1/2}e^{N[S(\Sigma - S(x^*))]}$, where $\Sigma \equiv \min[S(0), S(1)]$ depends on the entries of the payoff matrix and on the selection intensity $w$. It follows from equations (25), (28) and (31) that, in the biologically relevant case of small (but not too small) selection intensity $N^{-1} \ll w \ll 1$, the MFTs grow exponentially as $\tau^A \sim N^{1/2}e^{Nw(a-c)^2/[2(c-a+b-d)]}$, $\tau^B \sim N^{1/2}e^{Nw(b-d)^2/[2(c-a+b-d)]}$ and $\tau = \tau^A \tau^B / (\tau^A + \tau^B) \sim \min(\tau^A, \tau^B)$. In the opposite limit of large selection strength $w \to 1$, one can show that our results in the leading order coincide with those of [24]. For finite selection strength, the exponential dependence of $\tau$ is found to increase monotonically.
Large fluctuations and fixation in evolutionary games

Figure 2. Shown is ln τ⁻¹ as a function of the population size N, for a = 0.1, b = 0.7, c = 0.6 and d = 0.2, with w = 0.2 in panel (a) and w = 0.7 in panel (b). Excellent agreement is observed between the analytical solution (solid line), given by equations (25) and (31), and the numerical solution of the master equation (×s).

with w, as shown in figure 3. Note that, in this figure and in all other figures (except figure 5), when simulating the master equation (3), the initial number n of As was chosen to be sufficiently large to avoid immediate fixation prior to reaching the metastable state.

The ratio φᴬ/φᴮ = φ⁻¹ − 1 allows us to assess the influence of selection by comparing the fixation probability of species A and B for finite w. It follows from (11) and (31) that the fixation probability ratio φᴬ/φᴮ is given by

\[
\frac{\phi^A}{\phi^B} = \frac{\pi_{N-1}}{\pi_1} = \sqrt{BD \left( \frac{C - A}{B - D} \right) \frac{B^{N(B/(B-A))} D^{N(D/(C-D))}}{A^{N(A/(B-A))} C^{N(C/(C-D))}}.}
\]

(32)

In figure 4, the asymptotic expression (32) as a function of the selection strength is compared with the numerical solution of the master equation (3), demonstrating an excellent agreement. This figure illustrates the exponential dependence of the ratio φᴬ/φᴮ on w with a marked nonlinear behavior of the exponent. One can see a steep decay as the selection’s strength increases (the fixation of B is thus more likely), and for w close to 1 the fixation of A is almost improbable. In the neutral case arising when w = 0, the stochastic dynamics is diffusive and the ratio of the fixation probabilities then strongly depends on the initial number n of As. In stark contrast, for finite w the ratio φᴬ/φᴮ becomes independent of n (provided that n ≫ 1)⁵ and converges towards equation (32). This

⁵ When w → 0 (almost neutral dynamics) but Nw ≫ 1 (to ensure the validity of the WKB approach), n has to be sufficiently close to Nx∗ ≫ 1 to guarantee the convergence to the coexistence state prior to fixation.
is demonstrated in figure 5, where we have compared equation (32) with the numerical solution of the master equation (3) for various initial conditions. Note that, for $w > 0$ and $N \to \infty$, the fluxes to the absorbing states are vanishingly small and (32) becomes singular, with $\phi^A/\phi^B \to 0$ or $\phi^A/\phi^B \to \infty$ depending on the rest of the parameters. When $w \to 0$, one has $\phi^A/\phi^B \to x/(1-x)$.

2.2.2. Linear Moran and local update processes. The cases of the LMP and LUP, with rates $T_{\pm}(x)$ obtained respectively from equations (5) and (6), can be studied in the same manner as the fMP. Given the birth and death rates $T_{\pm}(x)$, one obtains the action (see equation (16)) and, with equations (19), (24) and (25), one can calculate the QSD, fixation probability and MFTs. This leads essentially to the same qualitative features as in the fMP with low selection intensity $w$. Our findings are summarized in figure 6, where our prediction for the unconditional MFT for the LUP is found to grow exponentially with $N$ and $w$, in excellent agreement with numerical results.

2.2.3. Fermi process. We now consider the FP that has recently received considerable attention (see, e.g., [23, 25, 30]). As above, the transition rates $T_{\pm}(x)$ for the FP are obtained from equation (7). With equation (16), the action in this case is quadratic:

$$S(x) = \int_x^w w[(c-a)q + (d-b)(1-q)] dq = wx(d-b)[1-x/(2x^*)].$$

Figure 3. Shown is $\ln \tau$ as a function of the selection strength $w$, for $a = 0.1$, $b = 0.7$, $c = 0.6$ and $d = 0.2$, with $N = 100$ in panel (a) and $N = 200$ in panel (b). Excellent agreement is observed between the analytical solution (solid line), given by equations (25) and (31), and the numerical solution of the master equation ($\times$s).
Large fluctuations and fixation in evolutionary games

**Figure 4.** Shown is the ratio $\phi_A/\phi_B$ of the fixation probabilities of species $A$ and $B$ as a function of the selection intensity $w$ in the fMP. The theoretical prediction (equation (32)) (solid) is compared with numerical solution ($\times$) of the master equation (3). The parameters are $a = 0.1, b = 0.7, c = 0.7$ and $d = 0.2$, with $N = 100$ in panel (a) and $N = 300$ in (b).

and $S''(x) = w(c - a + b - d) > 0$. Using equations (24) and (33), after some algebra one obtains the following expressions for $\pi_1$ and $\pi_{N-1}$:

$$
\pi_1 = \sqrt{\frac{Nw}{2\pi} \frac{(c-a)(b-d)}{(c-a+b-d)^{3/2}}} \sinh[(b-d)w]e^{(b-d)w/2} \exp \left[ -\frac{wN(b-d)^2}{2(c-a+b-d)} \right],
$$

$$
\pi_{N-1} = \sqrt{\frac{Nw}{2\pi} \frac{(c-a)(b-d)}{(c-a+b-d)^{3/2}}} \sinh[(c-a)w]e^{(c-a)w/2} \exp \left[ -\frac{wN(c-a)^2}{2(c-a+b-d)} \right].
$$

It follows from these results that, in the case of the FP, our approach is valid as long as $w \gg N^{-1}$, with $N \gg 1$. Therefore, our results are complementary to those of earlier works on this model which were carried out in the weak selection limit by treating selection as a linear perturbation to the neutral case $w = 0$ (see, e.g., [23, 25, 30]).

Using equations (19), (25), (33) and (34) one can explicitly obtain the QSD, the fixation probability and the (unconditional and conditional) MFTs. Here, one obtains the following asymptotic behavior of the conditional MFTs:

$$
\tau_A \sim N^{1/2} \exp \left[ \frac{wN(c-a)^2}{2(c-a+b-d)} \right], \quad \tau_B \sim N^{1/2} \exp \left[ \frac{wN(b-d)^2}{2(c-a+b-d)} \right],
$$

while the unconditional MFT satisfies $\tau = \tau_A\tau_B/($leading order, the MFTs for the FP coincide with those obtained for the fMP in the limit of small (but not too small) selection strength $N^{-1} \ll w \ll 1$. In addition to the MFTs,
Figure 5. Shown is the fixation probability of the A species versus the selection intensity $w$ for the fMP. The dashed line is the analytical prediction given by equations (11) and (24). The four solid lines are numerical solutions of the master equation (3) starting with $n = 5, 10, 20$ and $30$ (bottom to top) initial $A$s. The numerical results are found to converge towards the analytical prediction when $w$ increases, with a convergence that improves when $n$ increases. Inset: ratios of the above four numerical curves and the analytical prediction (top to bottom). One clearly observes that the smaller $w$ is, the larger $n$ must be to avoid fixation prior to reaching the coexistence state. The parameters are $a = 0.1$, $b = 0.7$, $c = 0.6$, $d = 0.2$ and $N = 300$.

an interesting quantity to compute is the ratio of the fixation probabilities $\phi^A$ and $\phi^B$:

$$\frac{\phi^A}{\phi^B} = \frac{\sinh[(c-a)w]}{\sinh[(b-d)w]} \exp\left[\frac{(N-1)w(a+b-c-d)}{2}\right]. \quad (36)$$

This ratio is larger than unity if $b - d > c - a$, i.e. when $x^* > 1/2$, which simply means that the closer $x^*$ is to 1, the easier it is for species A to fixate. In figure 7, we show the ratio between $\phi^A$ and $\phi^B$ given by equation (36) as a function of $N$ for a low and high selection strength ($w = 0.2$ and $w = 0.7$, respectively) and find excellent agreement with the numerical solution of the master equation (3). One can easily show that our asymptotic result (36) coincides in the leading order with the exact result found from equation (8) (which takes a simple form in this case), whereas the different prefactor stems from self-interaction terms that were not excluded in our treatment (see equation (7) and footnote 3).

3. Coordination games: fixation probability

In this section we use the WKB method to asymptotically compute the fixation probability in CG for $N \gg 1$ and finite $w$. After the presentation of the general treatment, our theoretical results are applied to the fMP (4) and FP (7) update rules, and are compared with those obtained from the FPE.

doi:10.1088/1742-5468/2010/09/P09009

15
Figure 6. (a) For the LUP (6), $\ln \tau^{-1}$ is shown as a function of the population size $N$ and parameters $w = 0.5$, $a = 0.2$, $b = c = 0.9$ and $d = 0.1$. In (b), $\ln \tau^{-1}$ is shown for the LUP as a function of the selection intensity $w$ for the same process and same parameters as in (a) but $N = 100$. An excellent agreement between our analytical predictions (solid lines) and the numerical solution of the master equation (xs) is observed.

3.1. General treatment and results

In CG, the elements of the payoff matrix satisfy $d > b$ and $a > c$. Thus, within the realm of rate equations, the fixed point $x^+$ (2) is a repeller, whereas the absorbing states $x = 0$ and 1 are attractors. In the presence of noise, the fixation of the intruding species occurs rapidly [24] and therefore the main interest is in the fixation probability $\phi^A_n$: the probability that, starting from $n < n^*$ individuals of type $A$, the species $A$ will fixate the population. In terms of the transition rates $T^\pm(n)$, $\phi^A_n$ obeys the following difference equation [3, 24, 27, 28]:

$$T^+(n)\phi^A_{n+1} + T^-(n)\phi^A_{n-1} - [T^+(n) + T^-(n)]\phi^A_n = 0,$$

with boundary conditions $\phi^A_0 = 0$, $\phi^A_{N} = 1$. Here, the probability $\phi^A_n$ that the $A$s fixate starting from $n$ individuals of type $A$ is given by a sum of two components. The first is the probability to fixate starting from $n + 1$ $A$s multiplied by the probability to jump to state $n + 1$ from state $n$, which is $T^+(n)/[T^+(n) + T^-(n)]$. The second component is the probability to fixate starting from $n - 1$ $A$s multiplied by the probability to jump to state $n - 1$ from state $n$, which is $T^-(n)/[T^+(n) + T^-(n)]$. Note that in this section (and differently from the treatment of ACG), as there is no metastability, the results strongly depend on the initial condition, that is, on the initial number of $A$s.

As $\phi^A_n \equiv \phi^A(x)$ is a cumulative distribution function, it is more convenient to consider the corresponding PDF, defined as $P_n \equiv \mathcal{P}(x) \equiv \phi^A_{n+1} - \phi^A_n$. $\mathcal{P}(x)$ is
Figure 7. The ratio $\phi_A/\phi_B$ as a function of $N$ for the FP (7). Comparison between the analytical result given by equation (36) (solid line) and the numerical solution of the master equation (3) ($\times$). The parameters in (a) are $a = 0.5$, $b = c = 2$, $d = 0.4$, $i.e., x^* \simeq 0.516$, and $w = 0.2$, and in (b) $a = 0.3$, $b = c = 1$, $d = 0.2$, $i.e., x^* \simeq 0.533$, and $w = 0.7$. As $x^* > 1/2$, we notice that the fixation probability of species A increases with $w$ and $N$.

peaked in the vicinity of $x^* = n_*/N$ (see the insets of figure 8) and can be shown to satisfy $P_0 = \phi_A^1$, $P_{N-1} = 1 - \phi_A^{N-1}$ and $\sum_{0}^{N-1} P_n = 1$. Rewriting equation (37) as $T_+(x)[\phi_A(x + N^{-1}) - \phi_A(x)] - T_-(x)[\phi_A(x) - \phi_A(x - N^{-1})] = 0$ and using the definition of $P(x)$, one obtains the following equation for $P(x)$:

$$T_+(x)P(x) - T_-(x)P(x - N^{-1}) = 0.$$  

This equation is similar in form to the QSME (12) and is treated using the WKB ansatz

$$P(x) = A_{CG} e^{-N S(x) - S_1(x)}.$$  

Substituting (39) into (38), one obtains in the leading $O(1)$ order $T_+(x) - T_-(x)e^{S'(x)} = 0$, whose solution is

$$S(x) = -S(x) = \int x \ln[T_+(\xi)/T_-(\xi)] d\xi.$$  

Here, $S(x)$ is the negative of the expression (16), and thus $S''(x^*) < 0$. In the subleading $O(1/N)$ order, one obtains $S_1(x) = (1/2)S'(x) = (1/2)\ln[ T_+(x)/ T_-(x) ]$. As in section 2, the constant $A_{CG}$ in equation (39) is found by normalizing the Gaussian asymptote of $P(x)$ in the vicinity of $x^*$. With equation (40), the final result for $P(x)$ is

$$P(x) = \sqrt{\frac{[S''(x^*)]}{2\pi N}} \sqrt{ \frac{T_-(x)}{T_+(x)} } e^{N[S(x) - S(x^*)]}.$$  

$$\text{doi:10.1088/1742-5468/2010/09/P09009}$$
Figure 8. Fixation probability of species A evolving according to the fMP (4): comparison between the expression (42) (dashed), its approximation (44) (xs) and numerical results (solid) as a function of \(x\). Note that the theoretical (42) and numerical results are indistinguishable. The parameters are \(N = 100\), \(a = 1.2\), \(b = 0.1\), \(c = 0.3\) and \(d = 1.1\), with \(w = 0.2\) and \(w = 0.7\) in the left and right panels, respectively. The quality and range of validity of the approximation (44) improves as \(w\) is increased. In the left panel the small-\(w\) approximation (43) is also reported (dashed–dotted). In this case, as \(S'(x) \ll 1\), the approximation (43) is superior to (44), see text. In the insets of both panels, we show a comparison between the analytical (equation (41)) (dashed) and numerical (solid) results for \(P(x)\), and excellent agreement is found over the entire range \(0 \leq x \leq 1\).

As shown in the appendix, this result coincides up to subleading-order corrections with the exact solution of equation (38). In particular, this implies that the recursion solution of equation (38) near the boundaries \(x = 0\) and \(1\) exactly coincides with the WKB result at \(x \ll 1\) and \(1 - x \ll 1\), respectively, and no special treatment is thus required near those boundaries (see also [37]). With equation (41), we can write down the fixation probability, \(\phi_A = \sum_{i=0}^{n-1} P_i\), as

\[
\phi_A = \sqrt{\frac{|S''(x^*)|}{2\pi N}} \sum_{i=0}^{n-1} \sqrt{\frac{T^-(i)}{T^+(i)}} e^{N[S(i/N) - S(x^*)]}.
\]

This expression gives the fixation probability of species A for any finite \(w\) (see figures 8), where its accuracy holds in the entire region of \(x\) including the boundaries.

Importantly, the summation in equation (42) can be drastically simplified for \(x \ll x^*\), i.e. \(n \ll n_\ast\). This corresponds to the biologically important limit of the fixation probability of a few intruders of type A in a sea of Bs [3, 11, 30]. It is now convenient to split our discussion into two cases. For small (but not too small) selection intensity \(N^{-1} \ll w \ll 1\), \(P(x)\) is slowly varying and the sum (42) can be safely transformed into an integral. In this case, the term \(\sqrt{T_-(x)/T_+(x)} \simeq 1\) can be omitted from the integration, yielding

\[
\phi_A(x) \simeq \sqrt{\frac{N|S''(x^*)|}{2\pi}} \int_0^x e^{N[S(\xi) - S(x^*)]} \, d\xi.
\]

This approximation is valid when \(|P_{n+1}/P_n - 1| \ll 1\), i.e. when \(|S'(x)| \ll 1\), which ensures that \(T_+(x) \simeq T_-(x)\) and holds excellently for \(w \ll 1\).
In the second case, $w = \mathcal{O}(1)$, the sum (42) is dominated by its last term when $1 \ll n \ll n_\ast$. In this case, denoting $k = n - 1 - i$, one can Taylor-expand the summand about $i = n$ in equation (42), yielding $e^{-N S(i/N) - S_1(i/N)} \approx e^{-N S(n/N) - S_1(n/N) + (k + 1) S'(n/N) + \mathcal{O}(1/N)}$. Plugging this expression into the sum (42), one has (with $S'(x) = -S'(x)$)

$$
\phi^A(x) \approx \mathcal{P}(x) \sum_{k=0}^{n-1} e^{-(k+1) S'(x)} \approx \frac{\mathcal{P}(x)}{\phi^{S'(x)} - 1},
$$

(44)

where $S'(x) > 0$ for $x < x^\ast$, and we have replaced the upper limit of the sum by infinity. Results (43) and (44) are valid for $N^{-1} \ll x \ll x^\ast$. Clearly, similar approximations can be made near $x = 1$ in the region $N^{-1} \ll 1 - x \ll 1$.

In figure 8, for the fMP, we compare the numerical results for $\phi^A$ with the WKB solution (42) and with its approximation (44), and an excellent agreement is observed. The latter improves as $w$ is increased. From (44), we infer that the fixation probability is exponentially small for finite selection intensity and therefore one generally has $\phi^A(x) < x$ when $x \ll 1$. In stark contrast with the weak selection limit [3, 11, 23, 30, 31], this implies that, when $w$ is finite, selection *always* opposes the replacement of the wild species (B) by mutants (A).

### 3.2. Applications

We now apply the above general results to the cases of CG evolving according to the fMP (4) and FP (7) and compare our theoretical results with those of the FPE. For the fMP, the rates are given by (26), with $A > C$ and $D > B$. In this case the action $S(x)$ is given by equation (28). The fixation probability of species A starting with $n = N x \ll n_\ast$ individuals, is given by equations (43) and (44), i.e.

$$
\phi^A(x) \approx N \int_0^x \mathcal{P}_{\text{fMP}}(\xi) \, d\xi \quad \text{for } N^{-1} \ll w \ll 1
$$

$$
\phi^A(x) \approx \frac{\mathcal{P}_{\text{fMP}}(x)}{e^{S(x)} - 1} \quad \text{for } w = \mathcal{O}(1),
$$

(45)

where $\mathcal{P}_{\text{fMP}}(x)$ is given by equation (41) and $S(x)$ given by (28). In figure 8, we compare (for $w = 0.2$ and $w = 0.7$) the theoretical predictions (equation (45)) with the numerical results and find an excellent agreement over the entire range $0 < x < 1$. Results (45) generalize the results of [24] by considering arbitrary (finite) selection strength $0 < w \leq 1$ and by including the subleading-order correction.

For the FP (7) starting with $n \ll n_\ast$ mutants, equations (43) and (44) can be explicitly calculated. Using (33) one finds

$$
\phi^A(x) = \frac{1}{2} \left\{ \text{erf} \left[ \sqrt{N x^\ast} \alpha(x/x^\ast - 1) \right] + \text{erf} \left( \sqrt{N x^\ast} \alpha \right) \right\} \quad \text{for } N^{-1} \ll w \ll 1
$$

$$
\phi^A(x) = \sqrt{\frac{\alpha}{\pi N x^\ast}} \frac{e^{-\alpha(x/x^\ast - 1)/[N(x-x^\ast)+1]}}{e^{-2\alpha(x/x^\ast - 1)/[N(x-x^\ast)+1]} - 1} \quad \text{for } w = \mathcal{O}(1)
$$

(46)

where $\text{erf}(x) = (2/\sqrt{\pi}) \int_0^x e^{-y^2} \, dy$ denotes the usual error function and $\alpha = w(d-b)/2 > 0$. The small-$w$ result coincides with the exact results in the continuum limit (see, e.g., [25, 30]).

doi:10.1088/1742-5468/2010/09/P09009 19
Fixation probabilities are often computed using diffusion approximations, like the Fokker–Planck equation (FPE) [16], [29]–[31], that can be obtained from a van Kampen size expansion. This expansion implicitly assumes that \( \mathcal{P}(x) \) varies slowly over the entire range of \( 0 < x < 1 \) [27, 28]. Here, we are interested in comparing the predictions of the FPE with those of the WKB approach when the selection intensity is small (but not too small) \( N^{-1} \ll w \ll 1 \). In this case, the fixation probability in both the WKB and Fokker–Planck treatments [29, 30, 32] is conveniently rewritten as

\[
\phi^A(x) = \frac{\Psi(x)}{\Psi(1)}, \quad \text{where} \quad \Psi(x) = \int_0^x e^{-\int_0^x \Theta(z) \, dz} \, d\xi. \tag{47}
\]

Here, by comparing equations (43) and (47), one has \( \Theta_{\text{WKB}}(x) = N \ln [\mathcal{T}_+(x)/\mathcal{T}_-(x)] \), while

\[
\Theta_{\text{FPE}}(x) = 2N \left[ \frac{\mathcal{T}_+(x) - \mathcal{T}_-(x)}{\mathcal{T}_+(x) + \mathcal{T}_-(x)} \right]. \tag{48}
\]

Furthermore, the FPE is often considered within the linear noise approximation [27, 28, 31]. In this case, \( \Theta_{\text{FPE}}(x) \) (48) is expanded to linear order in \( x - x^* \), yielding

\[
\Theta_{\text{FPE}}(x) = 2N(x - x^*) \left[ \frac{\mathcal{T}_+(x^*) - \mathcal{T}_-(x^*)}{\mathcal{T}_+(x^*) + \mathcal{T}_-(x^*)} \right]. \tag{49}
\]

To see how the WKB approximation compares with that of the FPE, we Taylor-expand the functions \( \Theta \) around \( x^* \), and compute \( \Delta \Theta_{\text{FPE}}(x) = \Theta_{\text{WKB}}(x) - \Theta_{\text{FPE}}(x) \) and \( \Delta \Theta_{\text{FPE}}(x) = \Theta_{\text{WKB}}(x) - \Theta_{\text{FPE}}(x) \). For the FMP one finds

\[
\Delta \Theta_{\text{FPE}}(x) \simeq C_{\text{FPE}} N w^3 (x - x^*)^3, \quad \Delta \Theta_{\text{FPE}}(x) \simeq C_{\text{FPE}} N w^2 (x - x^*)^2, \tag{50}
\]

where \( C_{\text{FPE}} = (1/12)(a - b - c + d)^6 / [(a - b - c + d)(1 - w) + (ad - bc)w]^3 \) and \( C_{\text{FPE}} = (1/2)(a - b + c - d)(a - b + c - d)^2 / [(a - b + c - d)(1 - w) + (ad - bc)w]^2 \) are both \( \mathcal{O}(1) \). Results (50) demonstrate that the exponent \( \Theta \) of our theory and those obtained from the FPE significantly deviate from each other when \( x - x^* = \mathcal{O}(1) \) (e.g. when \( x \ll 1 \) or \( 1 - x \ll 1 \)) and \( w \) is finite. Looking at equation (50), the results of the full and linear FPE agree with the WKB theory and numerical calculations (see also figures 9 and 10) when \( N^{-1} \ll w \ll N^{-1/3} \) and \( N^{-1} \ll w \ll N^{-1/2} \), respectively. This implies that demanding that \( w \ll 1 \) does not guarantee the applicability of the FPE, as the results of the full and linear FPE are plagued by exponentially large errors already when \( w \gtrsim N^{-1/3} \) and \( w \gtrsim N^{-1/2} \), respectively. While the predictions of the FPE further deteriorate when \( w \) increases, our theory improves and allows the accurate calculation of the exponentially small fixation probability for any finite value of \( w \) (see figure 9).

### 4. Summary and conclusion

In this work, we have studied large-fluctuation-induced fixation in (2×2) anti-coordination and coordination evolutionary games using a WKB-based approach. In both classes of

\[\text{doi:10.1088/1742-5468/2010/09/P09009}\]
Figure 9. Fixation probability $\phi^A(x)$ evolving according to the fMP (4) versus $w$: comparison between the WKB result (equation (45)) (solid), results of the full (equations (47) and (48)) (dashed) and linearized (equations (47) and (49)) (dashed–dotted) FPE, and numerical solution of equation (3) ($\times$s). Parameters are $a = 2$, $b = 0.2$, $c = 0.3$, $d = 1.8$ and $N = 150$, with initial condition $x = n/N = 10/150$. The WKB solution agrees excellently with the numerical results, while the FPE approximations systematically deviate from the WKB result as $w$ increases. Inset: ratios between the WKB and the results of the full (dashed) and linearized (dashed–dotted) FPE as a function of $w$. The linearized FPE has a narrower region of applicability, see text.

games, the deterministic description is characterized by the existence of an interior fixed point separating two absorbing fixed points. The latter are the only possible outcomes of the dynamics when internal stochasticity is taken into account. Yet, for ACG, the mean time necessary to reach one of the absorbing fixed points (mean fixation time) is typically very large as the system typically spends an exponentially long time in the metastable coexistence state. On the other hand, in CG fixation occurs rapidly and the quantity of interest is the (small) probability that a system comprising of a few mutants takes over the entire population, causing the extinction of the wild species. As the stochastic dynamics of evolutionary games is formulated in terms of one-dimensional single-step birth–death processes (with frequency-dependent rates), there exist exact formulae for the mean time and probability of fixation. However, these unwieldy expressions are nontrivial to analyze and cannot be generalized to multi-step processes or higher dimensions. To circumvent this difficulty, one popular approach is to resort to diffusion approximations, such as those based on the Fokker–Planck equation (FPE). However, the latter are ill-suited to describe phenomena like fixation that result from large fluctuations.

Here we have presented an alternative approach based on the WKB theory, which we have generalized to account for the existence of multiple absorbing states. Within this approach, the stochastic dynamics of the system is formally mapped, in the leading order, onto a Hamiltonian system, whose nontrivial zero-energy trajectory encodes, with
Figure 10. Shown are the ratios of the WKB result for $\phi^A(x)$ (equation (45))
with the numerical result (solid), with the full FPE (equations (47) and (48))
(dashed), and with the linearized FPE (equations (47) and (49)) (dashed–dotted),
as a function of $N$, for the fMP (4). Here $x = 10/N$ (i.e. $n = 10$), $a = 2$, $b = 0.2$,
c. $d = 1.8$ and $w = 0.5$. The WKB predictions agree excellently with the
numerical results, while there are systematic deviations (that increase with $N$)
between the latter and the predictions of the diffusion approximations (full and
linearized FPE), see text.

the maximum probability, the rare event in question. By using the WKB approach
complemented by recursive solutions of the master equation near the two absorbing
boundaries, we have obtained general results, for the complete statistics including large
fluctuations, of generic one-dimensional birth–death systems possessing two absorbing
states. Our results have been obtained including important pre-exponential factors that
are found to scale as some power of the population size. Along with the generic treatment,
we have also considered the most frequently used microscopic dynamics, based on
the frequency-dependent Moran process (fMP), the linear Moran and local update processes,
as well as the Fermi process (FP). In particular we have focused on the fMP and FP
and have obtained explicit analytical results for the complete metastable probability
distribution function of population sizes and for the fixation probability and times in
ACG, as well as for the fixation probability in CG. All these results were obtained for
arbitrary and finite $w$, which has allowed us to shed further light on the combined influence
of selection and random fluctuations in evolutionary processes. Finally, by comparing our
analytical results to those of the FPE, we have explicitly found the region of applicability
of the FPE and have shown that the WKB approach is vastly superior over the FPE when
the selection strength is finite.

While we have here focused on $2 \times 2$ evolutionary games, the WKB-based method
presented in this work can be generalized and is expected to be useful for multi-species
problems, like the rock–paper–scissors games that have recently received considerable
attention (see, e.g., [1, 42]).

Appendix

In this appendix, we show that the WKB result (41) asymptotically coincides with the exact solution of (38). Indeed by using recursion, the exact solution of (38) is

$$ \mathcal{P}_n^{\text{exact}} = \mathcal{P}_0 \prod_{i=1}^{n} \left( \frac{T^{-}(i)}{T^{+}(i)} \right) = \mathcal{P}_0 \exp \left[ \sum_{i=1}^{n} \ln \left( \frac{T^{-}(i)}{T^{+}(i)} \right) \right]. $$ \hspace{1cm} (A.1)

Here, \( \mathcal{P}_0 \) is a constant to be found by normalization. For \( N \gg 1 \), the sum in the exponent of equation (A.1) can be transformed into an integral using the Euler–Maclaurin formula

$$ \sum_{i=0}^{n} f(i) = \int_{0}^{n} f(x) \, dx + (1/2)[f(n) + f(0)] + (1/12)[f'(n) + f'(0)] - \cdots. $$

As the sum is in the exponent of (A.1), such a transformation should be done carefully and subleading-order corrections to the integral may be significant. Indeed, for \( N \gg 1 \) and \( x = n/N \), one has

$$ \sum_{i=1}^{n} \ln \left( \frac{T^{-}(i)}{T^{+}(i)} \right) \approx N \int_{0}^{x} \ln \left( \frac{T^{-}(\xi)}{T^{+}(\xi)} \right) \, d\xi + \frac{1}{2} \ln \left( \frac{T^{-}(x)/T^{+}(x)}{T^{-}(0)/T^{+}(0)} \right), $$ \hspace{1cm} (A.2)

up to \( \mathcal{O}(1/N) \) corrections, where we used the fact that \( T^{-}(0)/T^{+}(0) = T^{-} (0)/T^{+} (0) \). Thus, equation (A.1) becomes

$$ \mathcal{P}_n^{\text{exact}}(x) \approx \mathcal{P}_0 \sqrt{\frac{T^{-}(x)/T^{+}(x)}{T^{-}(0)/T^{+}(0)}} e^{N[S(x)-S(0)]} $$ \hspace{1cm} (A.3)

where we have used the definition of \( S(x) \) from equation (40). Finally, \( \mathcal{P}_0 \) is determined by demanding that \( \sum_{0}^{N-1} \mathcal{P}_n = 1 \). As before, for \( N \gg 1 \) we approximate this sum by an integral, whose main contribution arises from the Gaussian region around \( x \simeq x^* \), where the function \( \mathcal{P}(x) \) varies slowly. By doing so, one obtains

$$ \mathcal{P}_0 = \sqrt{\frac{|S''(x^*)|}{2\pi N}} \sqrt{\frac{T^{+}(0)/T^{+}(0)}} e^{N[S(0)-S(x^*)]}.$$ \hspace{1cm} (A.4)

With this result, (A.3) coincides with equation (41) obtained directly from our WKB treatment.
