Evaluating Protective Effects of Vaccination

6.1 Overview

In this and the next few chapters, we consider evaluating direct protective effects of vaccination in studies that do not condition on exposure to infection. Evaluating the direct protective effects of vaccines in the individuals who were vaccinated has been the focus of vaccine studies over the past century. Generally, interest has been in the ability of vaccination to prevent or to ameliorate disease rather than to prevent infection (Clements-Mann 1998). Ascertainment of cases is often done by surveillance for suspected cases in the population under study in people who exhibit a set of symptoms. The suspected cases are then tested for biological confirmation of the infectious agent of interest. Alternatively, surveillance can ascertain cases reported in central registries. However they are ascertained, usually clinical disease is the primary outcome of interest. When ascertainment is on clinical cases, most asymptomatic infections may go undetected. A different situation arises when infection is the primary outcome. To ascertain infections in asymptomatic people, tests need to be done on the asymptomatic people using an active follow-up method.

We have generally distinguished $V_{ES}$, the vaccine efficacy for susceptibility to infection, from $V_{ESP}$, the vaccine efficacy for susceptibility to disease. The third parameter was $V_{EP}$, the vaccine efficacy for progression. However, in this and the following chapters, ascertainment is most often on disease rather than infection. The methods in most cases apply equally well if ascertainment is on infection or clinical disease. The interest may be in some outcome such as level of severity in the ascertained clinical case, or if ascertainment is on infection, interest may be in some outcome that occurs after infection. Thus, in this and the next several chapters, the primary outcome to measure $V_{ES}$ can be either infection or disease, which is meant should be clear from the context. Most of the examples ascertain clinical cases, not infection. The meanings of $V_{ESP}$ and $V_{EP}$ will follow from the primary outcome to measure $V_{ES}$. 
6 Evaluating Protective Effects of Vaccination

In this chapter we consider estimation and inference for the VE parameters that do not condition on exposure to infection. We consider aspects of the design of such studies. Several examples of randomized, double blind controlled vaccine trials illustrate the standard approach to design and analysis of such studies. The choice of these studies was motivated largely because they are used to illustrate other aspects of vaccine studies in other sections of the book. The next two chapters include a few examples of observational studies. In Chapter 7, we discuss different conceptual models of protective effects of vaccine and the consequences for choosing and interpreting protective efficacy estimates. The chapter also discusses methods to estimate waning vaccine effects. In Chapter 8 we present further topics in evaluating protective effects. The evaluation of the effect of vaccination on post-infection outcomes is considered in Chapter 9.

6.2 Vaccine efficacy parameters

6.2.1 Estimands

The vaccine efficacy parameters of interest in this chapter are the Level II, III and IV parameters in Table 2.2. The level IV parameter VE_{S,CI}(T) is defined using the cumulative incidence or attack rates at the end of the study:

\[
VE_{S,CI}(T) = 1 - \frac{\text{vaccinated infection events/persons-at-risk}}{\text{unvaccinated infection events/persons-at-risk}} = 1 - \frac{C_I(T)}{C_I_0(T)}.
\]  

(6.1)

The level II parameters VE_{S,IR} based on the incidence rates and VE_{S,\lambda} based on the hazard rates require knowledge of the infection times:

\[
VE_{S,IR}(T) = 1 - \frac{\text{vaccinated events/person-time}}{\text{unvaccinated events/person-time}} = 1 - \frac{I_R(T)}{I_R_0(T)}.
\]  

(6.2)

The VE_{S,\lambda} based on the hazard rate ratio is

\[
VE_{S,\lambda}(t) = 1 - \frac{\lambda_1(t)}{\lambda_0(t)}.
\]  

(6.3)

The level III parameter VE_{PH} based on the proportional hazards model requires only the ordering of the infection times:

\[
VE_{S,PH} = 1 - \exp(\beta).
\]  

(6.4)

where \( \beta \) is the log hazard ratio. In Chapter 2 we showed the intrinsic relationship of the parameters to one another based on the depending happening
6.2 Vaccine efficacy parameters

relation. We also showed that they form a hierarchy based on the amount of information required for their estimation. The parameter based on the cumulative incidence is black-box estimator.

In this chapter, we treat $\text{VE}_{S,IR}(T)$, $\text{VE}_{S,\lambda}$ and $\text{VE}_{S,PH}$ somewhat interchangeably. The interpretation of $\text{VE}_{S,CI}(T)$ and $\text{VE}_{S,IR}(T)$ (or $\text{VE}_{S,\lambda}$ or $\text{VE}_{S,PH}$) differ. $\text{VE}_{CI}(T)$ is related to the number of cases saved over the period of the study, and $\text{VE}_{IR}(T)$ and the other two parameters measure a relative improvement in incidence rate or hazard. The choice between $\text{VE}_{CI}(T)$ and a vaccine efficacy based on incidence or hazard ratios could be influenced by the distribution of vaccine protection (Chapter 7).

6.2.2 Absolute versus Relative Efficacy

The control arm in a planned study is often another active vaccine that is assumed not to have an effect on the disease of interest. In the pneumococcal conjugate vaccine study below, a meningococcal conjugate vaccine is the control. In these studies, the goal is to show that the active vaccine of interest is superior to the control in preventing the primary outcome of interest. If a licensed (and recommended) vaccine is available, it is generally unethical to use a placebo or another vaccine in the control arm. Then the study must compare two (or more) active vaccines against the same disease. The relative rather than the absolute efficacy can be computed. The relative efficacy is the relative reduction in disease risk or incidence by the one vaccine compared with the other. An example is the pertussis vaccine study in Senegal presented below. The whole cell pertussis vaccine was recommended for infants in Senegal, so the acellular pertussis vaccine could not be compared to a placebo. In contrast, in Sweden, the whole cell pertussis vaccine had been discontinued so that there was no licensed pertussis vaccine in Sweden when they conducted the study of the acellular pertussis vaccine. In the Swedish study, the control was the diphtheria-tetanus toxoid without the pertussis component.

As new generations of vaccines are introduced, it is more common to be comparing a new vaccine candidate with an existing vaccine. If both vaccines are fairly efficacious and or the outcome of interest is fairly rare, then the size of the field study becomes prohibitively large and expensive. For example, the pneumococcal vaccines are highly efficacious against invasive disease, so that field studies of new pneumococcal vaccines with invasive disease are not possible. In this setting the hunt for immunological surrogates of protection becomes imperative. In the case of pneumococcal vaccines, there is also interest in developing pneumococcal nasopharyngeal carriage as a primary outcome for vaccine field study (Chapter 15).

Even when individuals cannot be randomized to a placebo, there may be individuals under surveillance who do not enroll in the trial, and thus do not receive either vaccine. The absolute efficacy of both vaccines can be computed by comparison with the individuals who happened not to be in either study arm. The study is then an observational cohort study, not a randomized study.
The Senegal pertussis vaccine study included surveillance of cases in people not in the study, so was able to compute the absolute efficacy of both vaccines though with the potential biases inherent in observational studies. With two active vaccines, the trial may be planned in a way to show that the efficacy of the new vaccine is not worse than the already licensed vaccine (a noninferiority study) or that the new vaccine has a higher efficacy than the other vaccine (a superiority trial), the usual approach in vaccine trials that compare a vaccine to a control.

6.2.3 Types of studies

Cohort studies for evaluating vaccines follow groups of people over time, some of whom are vaccinated, some of whom are not. Randomized vaccine studies are examples of cohort studies in which the vaccine has been randomly allocated. Cohort studies can be used to estimate any of the unconditional VE parameters if certain conditions are met. If all of the vaccine was administered before the beginning of the observation period, then the cohort is a fixed cohort. If, in addition, there is no loss to follow-up during the observation period, the cohort is a closed cohort. Then \( \text{VE}_{S,CI}(T) \) can be estimated by the cumulative incidence or attack rates. More generally, open or dynamic cohorts allow people to join and leave the population under study and for people to change their vaccination status. From these studies, estimates can be based on either cases per person-time at risk, the incidence rate, or using survival analysis methods in which the risk set can change over time. \( \text{VE}_{S,IR} \) and \( \text{VE}_{S,\lambda} \) can be estimated from either closed or open cohorts. Primary vaccine efficacy studies often report \( \text{VE}_{S,IR} \) based on relative events per person-time, or level II information.

In a case-control study, cases are ascertained and controls selected from a source population. The goal of the case-control study is to estimate the same unconditional estimands of vaccine efficacy as in the cohort studies. The method of sampling the controls and the method of analysis determine whether the case-control study will provide good estimates for \( \text{VE}_{S,IR} \), \( \text{VE}_{S,\lambda} \), or \( \text{VE}_{S,CI}(T) \). A case-control study can be thought of as a sample of data from a hypothetical cohort study. The cohort can also thought of as a source population that gives rise to the cases (Chapter 8).

Randomized versus observational cohort studies

Randomization is supposed to ensure that potential confounders are balanced between the two groups. The three criteria stated by Greenwood and Yule (1915) about the conditions for a valid comparison are essentially met under randomization. Observational studies that do not assign vaccine randomly need to examine the three criteria carefully. The criteria can be thought of in terms of exposure to infection versus susceptibility to infection. First, the groups being compared are in all relevant aspects alike. Relevant covariates
can include pre-existing immune levels such as antibody titer, prior vaccination, prior disease history, age, gender, among others.

Second, randomization is supposed to ensure that effective exposure to infection of the two groups is the same. The two groups having the same exposure to infection is not the same as every person in the groups having the same exposure to infection. Even if, on average, exposure in the two groups is comparable, there may be heterogeneity of exposure to infection within the groups. Some participants might not be exposed at all to the infectious agent of interest. Since in field trials, exposure to infection is not under control of the investigator, in studies that do not condition on exposure to infection, the assumption of equal exposure in the two groups is a strong one, especially if a study is not randomized. For example, children of a higher socioeconomic status may be less exposed to a certain infection. If these children also tend to get vaccinated, then a study of the effect of vaccination will overestimate vaccine efficacy. Potential relevant covariates related to exposure to infection could include distance from potential environmental sources of infection, number of people living in the household, use of bednets, behavioral covariates such as number of sexual contacts or handwashing habits, among others. Going to work rather than working at home or attending school rather than either being too young to attend school or remaining at home for other reasons can affect exposure to infection.

Third, the chance of being vaccinated can not be associated with the probability of developing disease. Some of these elements are similar to those in the first group related to susceptibility to infection and disease. As an example, children of a higher socioeconomic status may have better nutrition, and therefore better immune systems and better resistance to infection or disease if exposed. If children of higher socioeconomic status also tend to be vaccinated, then a study of the effect of vaccination will overestimate the vaccine efficacy. In both of these situations, socioeconomic status could be used as a proxy covariate for either exposure or for susceptibility to infection.

If these three criteria are met, any differences in the rate of developing disease in the two groups is likely due to the biological effects of the vaccine. It is important to collect information on relevant covariates and potential confounders in both randomized and observational studies. Potential confounders will depend on the particular infections agent of interest and the setting of the study. Reports of randomized, cohort, and case-control studies usually include a comparison of the vaccine and control groups on any covariates considered relevant.

Nonrandomized cohort and case-control studies need to address these potential sources of bias. Although propensity scores (Rosenbaum 1995) and marginal structural models (Robins et al 2000) could be used to adjust for confounding in vaccine studies, these approaches have not found much use so far. Further details of epidemiologic study design can be found in Rothman et al (2008). Interactions of pre-existing immunity and level of exposure to
Table 6.1. Number of individuals, number of cases, and number of person-time at risk in vaccinated and control groups.

|               | Number of persons in group | Number of cases of disease | Person-time at risk |
|---------------|----------------------------|---------------------------|---------------------|
| Vaccinated    | $N_1$                      | $c_1$                     | $Y_1$               |
| Control       | $N_0$                      | $c_0$                     | $Y_0$               |

Infection can confound interpretation of vaccine efficacy estimates even when the study is randomized (Chapter 14).

6.2.4 Estimation and Inference

The statistical methods for analyzing the studies described in this chapter are fairly standard. Consistent with the focus of this book, estimation with a measure of uncertainty such as confidence intervals, likelihood intervals, or Bayesian posterior distribution is preferable over hypothesis testing. Our interest is in how efficacious a vaccine is and the interpretation of the estimate, not whether it is simply better than nothing. Consider a vaccine study with $N_1$ individuals in the vaccine group and $N_0$ in the control group, and $N = N_0 + N_1$.

The cohort can be observed either at time 0 and time $T$ or over the interval $[0, T]$. The number of cases observed in the unvaccinated group is $c_0$ and in the vaccinated group is $c_1$. The total person-time at risk in each group is denoted by $Y_0$ in the unvaccinated group and $Y_1$ in the vaccinated group (Table 6.1).

Estimating $VE_{S,CI}(T)$ based on the cumulative incidence or attack rates requires only information about whether persons are infected or not by the end of the study at time $T$, that is, final value data:

$$VE_{S,CI}(T) = 1 - \frac{c_1 / N_1}{c_0 / N_0}.$$  

Estimation of $VE_{S,CI}(T)$ based on the simple relative proportions of cases in each group assumes that there is no loss to follow-up, that is, no censoring.

Chick et al (2001) consider correcting for bias in risk ratio and vaccine effect estimators, especially when the number of cases is small. The standard maximum likelihood vaccine effect estimators are consistent, but they are biased because they are non-linear functions of other estimators. They show that the bias is small when the number of cases is relatively large, say $> 70$ in the placebo arm. However, with small numbers of cases, the bias can be substantial. Chick et al (2001) propose various bias correction options, and also include one suggested by Jewell (1986). Bias of both the $VE_{S,CI}$ under an all-or-none model and the $VE_{S,CI}$ under the leaky model are explored. Of the options considered, the best was to add one to the positive count in the control population, both to the case count and the population count. For example, they recommend
\[ \tilde{V}E_{S,CI}(T) = 1 - \frac{c_1/N_1}{(c_0 + 1)/(N_0 + 1)}. \] (6.5)

This addition in the control population increases the \( V_{S,CI}(T) \) estimates. As they point out, it may seem to “corrupt the data.” However, for small studies, the simulations are convincing. Clearly when \( c_0 \) is large, the addition of one count will have a small effect. They also provide bias corrections for Bayesian vaccine effect estimators, for \( V_I \) and \( V_S \) based on the secondary attack rates, and for the vaccine effect of the susceptibility and infectiousness effects on the reproductive number.

\( V_{S,IR}(T) \) is estimated by

\[ V_{S,IR}(T) = 1 - \frac{c_1/Y_1}{c_0/Y_0}. \] (6.6)

The usual assumption is that the numbers of events follow a Poisson distribution. Similarly, from time-to-event data, to estimate \( V_{S,\lambda} \) investigators may estimate the hazard rates in the vaccinated and unvaccinated \( \lambda_1(t) \) and \( \lambda_0(t) \), respectively, using survival analysis methods. When covariates such as age and gender are added, the analyses are stratified by the covariates or Poisson regression can be used.

Under the assumption that the effect of the vaccine is multiplicative, constant, and homogeneous, the Cox proportional hazards model can be used to estimate \( V_{S,PH} \). In this case, it is not necessary to estimate the hazard rate in the unvaccinated group, but only the relative hazard rate. Covariates including time-dependent covariates can easily be incorporated using standard software. The proportional hazards model with covariates can be used to investigate possible confounding factors. Since the proportional hazards model assumes that the baseline hazard is the same in both the vaccinated and the unvaccinated groups, for studies including different communities, it may be possible to include a covariate for each community. The model would then assume that the incidence varies by community, but the vaccine effect is the same in each community (Section 6.4.1).

Several approaches are available for the confidence interval for \( V_{S,CI}(T) \). O’Neill (1988) favored the method based on the log of the ratio of two binomial random variables (Katz et al 1978) because of its simplicity of interpretation and the symmetry of the confidence interval on the log scale. Let \( \theta(T) = CI_1(T)/CI_0(T) \), so that \( V_{S,CI}(T) = 1 - \theta(T) \), and let \( \beta(T) = \ln \theta(T) \). Assume for now that the follow-up is over the interval \( T \), so that we can drop the \( T \) from the notation. The estimate of \( \theta \) is \( \hat{\theta} = (c_1/N_1)/(c_0/N_0) \) and \( \hat{\beta} = \ln \hat{\theta} \). An estimate of the variance of \( \beta \) is

\[ \sigma^2 = \frac{N_1 - c_1}{N_1c_1} + \frac{N_0 - c_0}{N_0c_0} = \frac{1}{c_1} + \frac{1}{N_1} + \frac{1}{c_0} + \frac{1}{N_0}. \] (6.7)

In vaccine studies, \( N_0 \) and \( N_1 \) are usually large, so that the variance of \( \beta \) is approximated by a function of the number of cases in the vaccinated and
unvaccinated groups, \(1/c_1 + 1/c_0\). The 100(1 – \(\alpha\)) percent confidence interval for \(VE_{S,CI}(T) = 1 – \theta\) is

\[
[1 - \exp(\hat{\beta} + z\hat{\sigma}), 1 - \exp(\hat{\beta} - z\hat{\sigma})],
\]

(6.8)

where \(z\) is the \((1 – \alpha)\) percentage point of the standard normal distribution. One can also use Taylor series approximations (Hightower 1988). Ewell compared Bayesian posterior regions with frequentist exact and large sample confidence intervals for intermediate (Phase IIb) trials (Ewell 1996). Generally two-sided intervals are recommended, and even required by some journals. The lower confidence bound on the vaccine efficacy estimate is sometimes of primary interest, especially in proof-of-concept studies, or Phase IIb studies.

An approximate confidence interval for \(VE_{S,IR}\) can be obtained similarly as in (6.8). An estimate of the approximate variance of the log of the ratio of the incidence rate in the vaccinated group and the incidence in the unvaccinated group is again

\[
\hat{\sigma}^2 = \frac{1}{c_1} + \frac{1}{c_0}.
\]

(6.9)

If now \(\theta = (c_1/Y_1)/(c_0/Y_0)\) and \(\beta = \ln \theta\), then the 100(1 – \(\alpha\)) percent confidence interval for \(VE_{IR} = 1 – \theta\) is

\[
[1 - \exp(\hat{\beta} + z\hat{\sigma}), 1 - \exp(\hat{\beta} - z\hat{\sigma})],
\]

(6.10)

where \(z\) is the \((1 – \alpha)\) percentage point of the standard normal distribution.

If there is loss to follow-up, then \(VE_{S,CI}(T)\) also requires knowledge of the time of onset of cases. In a hepatitis B vaccine study, Szmuness et al (1980) calculated cumulative attack rates using a life-table method. The statistical significance of the differences between observed numbers of trial end points in different groups was calculated from the life tables by the log-rank summary chi-square test. In another hepatitis B vaccine study, Francis et al (1982) also used a life table approach based on person months of follow-up to get cumulative attack rates. Hudgens et al (2004) suggest using nonparametric maximum likelihood estimators of \(c_1\) and \(c_0\) in the presence of censoring (Kaplan and Meier 1958, Peto 1973). Standard survival analysis methods can be used for inference for \(VE_{S,\lambda}\) and \(VE_{S,PH}\):

\[
\hat{VE}_{S,PH} = 1 - \exp(\hat{\beta}).
\]

(6.11)

where \(\hat{\beta}\) is the partial likelihood estimate of the log hazard ratio (Cox 1972).

The methods for the analyses in this chapter are available on most statistical analysis packages such as SAS (REF), R (REF) and Splus (REF).

When the number of cases in the study is small, exact confidence intervals may be used. Again, many approaches are available for exact confidence intervals. Randomized trials in this chapter used the Clopper-Pearson (1934) or
Koopman’s (1984) method. Agresti and Coull (1998) compare exact and approximate confidence intervals and find that sometimes approximate intervals are better than exact. The software StatXact (http://www.cytel.com/Products/StatXact/) is able to do most for exact computations and explains the methods in its manuals.

6.3 Design considerations

In this section, we consider some of the design considerations of a vaccine study, with the studies in the next section serving as illustrations.

6.3.1 Vaccines and vaccination schedule

The vaccine of interest and the comparison needs to be specified. If the study is designed to actively administer doses of vaccines, the number of doses and the schedule for administering the doses needs to be specified. Many vaccines require two or more doses for complete vaccination. For example, usually complete pertussis vaccination requires three doses. It is important when possible to record the number of doses of a vaccine that a person has received to determine if the person has complete or incomplete vaccination. In addition, the immune response requires some time to develop. Thus, many studies include only cases in the analysis that occur a certain time interval after the completion of vaccination. In a randomized study, participants who receive the number of doses according to protocol are included in the per-protocol analysis. In the intent-to-treat analysis, any person randomized to a particular arm regardless of how many doses received is included in the analysis. Analyses can also be broken down by the actual number of doses received.

In observational studies, the study can specify what the recommended dose schedule is for that vaccine, then ascertain the extent to which participants are vaccinated according to the recommended schedule.

6.3.2 Study population

The study needs to specify the usual person, time and place of any field study, whether randomized or observational. Eligibility and exclusion criteria need to be specified.

Recruitment and vaccination

Recruitment into a vaccine study can be through a population-based study, a local census, by attendance at clinics or physician’s offices, schools, workplaces, health maintenance organizations or public advertisements. The method of recruitment will depend on the societal context and the target age of vaccination. Vaccination can take place in clinics or by teams going to the field for vaccination.
6.3.3 Case definition

The case definition is an essential element for the study. In randomized studies, there will usually be a primary endpoint for the primary analysis. The case definition can be defined by clinical criteria alone or require biological confirmation of evidence of the infectious agent of interest. Several secondary endpoints may be based on different case definitions, other clinical endpoints related to the infectious agent of interest, or laboratory endpoints related to either the immune response or the course of the infection.

6.3.4 Ascertainment of cases

Methods for ascertaining potential clinical cases include active surveillance such as through phone calls at specified intervals or visits to the homes. Suspect cases may be ascertained in clinical settings, whereby only cases that seek medical attention will be ascertained. If the case definition includes biological confirmation, then the relevant tests will be performed.

Ascertainment of infected people rather than clinical cases requires testing of all of the study participants at regular intervals.

Safety and Immunogenicity

If a study actively administers vaccine, usually study participants will be directly observed for a period of time for short-term adverse events such as anaphylactic reaction. Parents or adults can be given diaries to keep track of adverse events. Investigators may make visits or phone calls to the homes of participants to register any adverse events.

Immunogenicity of the vaccine could be measured on all or a subset of participants. It may not be measured on anyone. In observational studies, immunogenicity measures may not be available.

6.3.5 Sample size calculations

It happens often that vaccine studies go to the field, then suddenly there is no or little transmission, so there are few events. Someone once said that for vaccine studies, one should calculate the sample size then multiply by five or possibly 10. Here are a few formulae for simple sample size calculations as guidelines, but most sample size calculations for vaccine studies will need computer simulations. Careful, sometimes lengthy, baseline studies to understand the local epidemiology and transmission of the infection, seasonal and yearly variation in incidence, and other characteristics may be required before sample size calculations can be considered reliable.

Hayes and Bennett (1999) provide simple formulae for individually randomized studies as well as parallel design cluster randomized studies (Chapter 13). Let $z_{\alpha/2}$ and $z_{\beta}$ be the standard normal distribution values corresponding
to upper tail probabilities of $\alpha/2$ and $\beta$. The corresponding sample size will give a power of $100(1 - \beta)\%$ of obtaining a significant difference ($P < \alpha$ on a two-sided test), assuming that the true (population) rates in the vaccine and control groups are $\lambda_1$ and $\lambda_0$. If the outcome is based on person-time, let $y$ denote the person-time of follow-up in each group. Then the amount of person-time required in each group is (Smith and Morrow 1996, Hayes and Bennett 1999)

$$y = \left(z_{\alpha/2} + z_{\beta}\right)^2 \frac{\lambda_0 + \lambda_1}{\left(\lambda_0 - \lambda_1\right)^2}.$$  

(6.12)

If the outcome is based on proportions, let $\pi_0$ and $\pi_1$ be the true population proportions in the presence and absence of the intervention. Let $n$ be the number of individuals in each group. Then the number of individuals required in each arm is

$$n = \left(z_{\alpha/2} + z_{\beta}\right)^2 \frac{\pi_0(1 - \pi_0) + \pi_1(1 - \pi_1)}{(\pi_0 - \pi_1)^2}.$$  

(6.13)

If the outcome is based on a continuous response, such as malaria parasite density, then the objective is to compare the mean of that variable in the intervention and control groups. Let $\mu_1$ and $\mu_0$ be the true population means and $\sigma_0$ and $\sigma_1$ be the standard deviations of the outcome variable in the vaccine and control groups. Let $n$ be the number of individuals in each group. Then the number of individuals required in each arm is

$$n = \left(z_{\alpha/2} + z_{\beta}\right)^2 \frac{\sigma_0^2 + \sigma_1^2}{(\mu_0 - \mu_1)^2}.$$  

(6.14)

Fay, Halloran, Follmann (2007) consider sample size calculations for testing differences in means between two samples and allowing for different variances in the two groups. The approach accounts for two sources of variability. One source of variability is in parameter estimates that are estimated from prior data. The second source of variability is if the vaccine fails in some of the people who are vaccinated. The sample size calculation needs to take the possible failure of the vaccine into account. The research was motivated by the design of a Phase II trial of a *Plasmodium falciparum* blood-stage malaria vaccine candidate in Africa. Baseline data on malaria in children had been gathered in a village in Mali in 1999 and 2000. Children were visited weekly and blood smears were done monthly. Data on malaria symptoms and blood smears were available. Several different primary endpoints for the trial were explored. The goal of vaccination was to elicit an immune response comparable to the immune response in older children, all of whom had had repeated exposure to malaria infection. For each candidate primary endpoint, the effect measure was defined as the difference in the malaria outcome in the older compared to the younger children. Instead of choosing an effect size arbitrarily, the observational data were used to estimate the standardized effect size and
variances. The variability in the variance estimate can be accounted for simply by using a slightly larger nominal power in the usual sample size calculation, called calibrated power. Fay et al (2007) provide a table of calibrated power by sample size.

The second problem in designing the trial was that some of the children might not respond to the vaccine, for genetic or other reasons. For the second problem, the proportion expected not to respond to the vaccine could be obtained from expert opinion, as in traditional sample size computations. Fay et al (2007) provide simple closed form sample size calculations. In general, the sample size will be greater if a proportion of the population does not respond to the vaccine than if all respond to the vaccine.

### 6.4 Examples of randomized trials

#### 6.4.1 Relative efficacy of pertussis vaccines in Senegal

A randomized, double-blind trial comparing a diphtheria-tetanus-acellular pertussis vaccine (DTaP) (pertussis toxoid and filamentous hemagglutinin) with a whole-cell vaccine (DTwP) was conducted in the Niakhar area of Senegal (Simondon et al 1997) (See Chapter 10.2.3 for more details about the area). The comprehensive ongoing surveillance in the Niakhar area allowed a prospective, nested case-contact study and a cohort study to be conducted during the trial to estimate absolute efficacy of each vaccine.

Eligible infants were those born between February 1, 1990, and April 30, 1994 to mothers residing in the Niakhar area who attended the vaccination sessions. From 1990 through 1994, 4,181 children were randomized to receive one of the vaccines at 2, 4, and 6 months. Surveillance by weekly home visits looked for cough illness persisting more than 7 days in all children under 15 years of age, including children not in the study. Adverse events were screened in the first two weekly visits following each vaccine dose using a standardized questionnaire. Any positive answer was followed-up by a physician. The physicians doing the examinations took samples for culture and serologic testing blinded to vaccination status. The primary protocol definition of a case of pertussis was defined as 21 or more days of cough confirmed by (a) positive bacterial culture from nasopharyngeal aspirates, (b) serology (IgG against pertussis toxoid and filamentous hemagglutinin), or (c) contact with a culture-confirmed person in the same compound and coughing had started within 28 before or after onset of illness in the culture confirmed child (epilink). Polymerase chain reaction (PCR) amplification was used to detect *B. pertussis* DNA in nasopharyngeal aspirates.

The study sample size had been determined assuming that the efficacy of the whole-cell vaccine was 75% and allowed detection of the relative ratio of 1.5 in the two arms of the study at the 0.05 significance level. The overall ratio of pertussis incidence in the DTaP group relative to the DTwP group (RR<sub>ac/wc</sub>)
Table 6.2. Incidence rate ratio of DTaP (acellular pertussis) vaccine compared with DTwP (whole cell pertussis) vaccine for different case definitions in the Niakhar, Senegal study (Simondon et al 1997).

| Case Definition | Protocol confirmation criteria \(^a\) | Intention-to-treat | With PCR \(^b\) | Incidence rate ratio [95% CI] |
|-----------------|---------------------------------------|-------------------|------------------|-------------------------------|
| ≥21 days of cough (protocol definition) | Protocol confirmation criteria \(^a\) | 123 | 197 | 1.54 [1.23–1.94] |
|                 | Intention-to-treat                      | 162 | 233 | 1.43 [1.16–1.74] |
|                 | With PCR \(^b\)                       | 65  | 128 | 1.87 [1.38–2.52] |
| ≥21 days of paroxysmal cough (WHO definition) | Protocol confirmation criteria \(^a\) | 16  | 41  | 2.42 [1.35–4.34] |
|                 | Intention-to-treat                      | 23  | 49  | 2.06 [1.25–3.39] |
|                 | With PCR \(^b\)                       | 10  | 31  | 2.80 [1.36–5.74] |

and confidence interval were estimated in a proportional hazards model with calendar time as the time-scale and stratified by village. Pertussis is epidemic and the proportional hazards model assumes that the baseline hazard is equal in the comparisons groups. The model allows the incidence to vary by village, but assumes that the rate ratio is the same across villages. A multivariate proportional hazards model was used to investigate confounding factors. A secondary intent-to-treat analysis included all children receiving at least one dose of the study vaccines. After the study began, the WHO recommended that the case definition be 21 or more days of paroxysmal cough, not just cough. For each child, surveillance ended either at the onset of pertussis, additional pertussis immunization, emigration, death, or refusal to continue in the investigation. All surveillance for the study ended December 31, 1994.

Comparability between children receiving three doses was checked for age at inclusion, gender, weight at first dose, rank of birth number, age of mother, number of persons in the compound, and the number of persons <15 years of age in the compound. No significant differences were found. During the period of surveillance, physicians confirmed at least one episode of >7 days cough in 837 of 2,567 compounds reporting such episodes to field workers. The total duration of follow-up was 3,165 person-year at risk in the DTwP group and 3,193 person-year at risk in the DTaP group. Table 6.2 contains the number of cases for different case definitions. The primary analysis considered cases that occurred ≥28 days after the third dose. The overall ratio of pertussis incidence in the DTaP group relative to the DTwP group (RR\(_{ac/wc}\)) using the protocol case definition was 1.54 (95% CI, 1.23–1.93). A multivariate proportional hazards analysis including the comparability factors revealed that children in
compounds with more than 30 members had a higher rate of pertussis, but the value of \( RR_{\text{wc/wc}} \) did not change.

In a cohort analysis of 229 unvaccinated children, using the same proportional hazards model and the protocol case definition, absolute efficacy was 66% (95% CI, 46-78) for DTwP and 48% (95% CI, 18-66) for DTaP. Using the WHO case definition, the absolute efficacies were 91% (95% CI, 81-96) for DTwP and 79% (95% CI, 58-89) for DTaP.

This study illustrates several points. First, vaccine studies sometimes report the relative risk or rate ratios rather than the vaccine efficacies. Vaccine efficacy has the awkward property that it ranges from \(-\infty\) to \(\infty\). Reporting the relative risk or rate ratios range from 0 to \(\infty\) with the value of 1 being associated with no relative effect. Secondly, different case definitions can substantially alter the estimates. In the comparison of the DTaP to DTwP, the point estimates of the rate ratios were higher with the WHO definition, though the confidence intervals overlap. The absolute efficacy of both vaccines in the cohort analysis were higher with the WHO definition. The choice of case definition in pertussis is the subject of ongoing international discussion. The pertussis study in the next section uses a slightly different definition.

### 6.4.2 Absolute efficacy of pertussis vaccine in Sweden

Because of its limited efficacy, the Swedish-made whole cell pertussis vaccine was withdrawn in 1979. After that, Sweden had no licensed pertussis vaccine, so it was possible to conduct a randomized, placebo-controlled trial (Trollfors et al 1995). Infants were randomly assigned to receive DT toxoids or the same DT toxoids with pertussis toxoid (DTaP toxoids). The vaccine contained only the single component of the pertussis toxoid. About 99% of children in Sweden visit publicly financed child health clinics, where information about the study was given to the parents of infants. Full term healthy infants in the Göteborg area were eligible if the family had a telephone and at least one parent spoke Swedish. The vaccinations and follow-up were performed at five study sites. The parents of 3,450 of 5,964 eligible children agreed to participate. Of these 1,724 and 1,726 were randomly assigned to DTaP and DT toxoids. There were 817 recipients of DTP toxoids and 850 recipients of DT toxoids with one or more older siblings.

The three vaccine doses were administered intramuscularly at 3, 5, and 12 months. First vaccinations occurred between September 1991 and September 1992, third vaccinations between May 1992 and July 1993. There were 52 children withdrawn from the study for various reasons. Coughing episodes between the first vaccination and July 24, 1994 were included in the study analysis. The surveillance period for each child was divided in two parts. The first part was between the first vaccination until 29 days after the third during which time the children were considered to be incompletely vaccinated. The second part began at the end of the first part for each child and lasted until July 24, 1994. Parents were asked to monitor adverse events for seven days,
after which they were interviewed. They were contacted once a month by telephone for further surveillance of adverse events.

Parents were asked to contact the study nurse if anyone in the family coughed for seven or more days. Biological confirmation was done by culture or PCR of a nasopharyngeal sample and serology. Follow-up of each case continued for at least 60 days or until the cough ended. PCR was able to distinguish pertussis from parapertussis. The case definitions were similar to those of the Niakhar study, but the Göteberg group had their own classifications in addition to the WHO criteria. Essentially the Göteberg group allowed that household contacts for the epilink could be confirmed either by culture or serology, whereas the WHO definition allows only culture. The Göteberg group also distinguished two levels of biological evidence. Confirmed cases required two confirmation criteria, while probable cases required only one (Trollfors et al 1995). To measure immunogenicity, serum was obtained from 3,361 children at least four weeks after the third vaccination. IgG antibodies against pertussis toxin and toxin-neutralizing antibodies were measured.

Vaccine efficacy, $\text{VE}_{SIR}$, was based on the ratio of the incidence rates in the DTaP compared to the DT group. Confidence intervals were estimated by an exact calculation based on the conditional binomial distribution that follows from the assumption of a Poisson distribution for cases in each group (Clopper and Pearson 1934). Proportions were compared using a two-sided Fisher’s exact test.
Of the 2,037 coughing episodes lasting at least seven days, 465 (160 in the DTap-toxoids group and 305 in the DT-toxoids group) met the criteria for confirmed or probable pertussis, including 368 that met the WHO definition. Another 14 children had clinical pertussis without laboratory confirmation. Thirty days after the third vaccination, 1,670 and 1,665 recipients of the DTap and DT toxoids were still at risk for pertussis. The incidence of pertussis according to the WHO definition was 2.96 cases per 100 person-years among the DTap toxoids recipients and 10.32 cases per 100 person-years in the DT toxoids recipients. The efficacy of the pertussis vaccine was 71%. The results are in Table 6.3.

As in the Niakhar pertussis study, the number of cases and the vaccine efficacy estimates vary with the case definitions. The estimates using $\geq 21$ days of paroxysmal cough had the highest estimates, $\geq 21$ days of any cough the middle estimates, and $\geq 7$ days of cough the lowest estimates, reflecting the differing specificity of the case definition. Depending on the case definition used, over 15% of the children in the DT toxoids group developed pertussis during the trial. Although not discussed in detail in this book, the pertussis-toxin testing for defining a case had much lower sensitivity in recipients of DTP toxoids than in recipients of DT toxoids because the DTP-toxoid recipients already had high values for IgG antibodies against pertussis toxin in the acute-phase serum samples. Cultures and PCR were also less sensitive in vaccinated children. A study to estimate the indirect effects of vaccination was nested in this trial (Chapter 10.2.5 and 12.4.1).

The acellular pertussis component of the vaccine in the Trollfors et al. (1995) study had just the pertussis toxoid. Further acellular vaccine candidates were developed that contained additional antigens. Pertussis toxoid (PT) was included. Other antigens included were filamentous haemagglutinin (FHA), pertactin (PRN), and fimbriae types 2 and 3 (FIM). Two coordinated trials were conducted in Sweden as part of an international effort. Trial I was conducted during the years 1992-1995 (Gustafsson et al. 1996). Two acellular pertussis vaccines, one whole cell pertussis vaccine and one placebo were used. The placebo group ($n = 2574$) received diphtheria and tetanus toxoid (DT). The second group ($n = 2566$) received DTap2 with two antigens, PT and FHA. The third group ($n = 2587$) received DTap5 with PT, FHA, PRN, and the two FIM antigens. The fourth group received DTwP. A study to evaluate immunological surrogates of protection after household exposure to pertussis was nested in the primary efficacy study Trial I (Storsaeter et al. 1998). The study is discussed in Chapter 15.4.3.

Trial II was conducted during the years 1993-1996 (Olin et al. 1997). It had no placebo group. The DTap5 contained higher amounts of PT and FHA than the DTap5 of Trial I. The DTap2 had the same composition as in Trial I. The source for DTwP in Trial II was different than in Trial I.
6.4.3 Absolute efficacy of live attenuated influenza vaccine in children

Belshe et al (1998) conducted a randomized, double-blind placebo-controlled multicenter study of the efficacy of live attenuated cold-adapted trivalent influenza virus vaccine in children. Healthy children who were 15 to 71 months of age at time of recruitment and who had no contraindication were enrolled. The vaccine contained that year’s recommended strains of influenza A (H1N1), influenza A (H3N2), and influenza B. Children were randomized 2:1 to receive vaccine or placebo. Vaccine was given either as a one or two dose regimen, with some of the sites using one or the other. Vaccine and placebo were administered with an intranasal spray applicator.

To evaluate side effects of vaccination, parents were asked to monitor and to record certain symptoms for 10 days after vaccination. They were given a thermometer to measure the temperature. Serious adverse events were followed throughout the trial. Strain specific immunogenicity of the vaccine was measured in a substudy of 203 participants, approximately the first 21 children recruited at each site. The serum samples were assayed for presence of hemagglutination-inhibiting antibodies to the three viral strains contained in the vaccine.

The primary efficacy end point was the first episode of culture-confirmed influenza for subjects who became ill 28 days or more after the receipt of the first dose of vaccine or placebo or at any time after the second dose during the influenza season. Parents were contacted by telephone every two to three weeks until the beginning of an influenza outbreak in their community. Then weekly contact was made to remind the parents to report any relevant symptoms as soon as possible. Study staff attempted to collect specimens for culture for influenza virus confirmation within four days of the onset of symptoms. A case of influenza was defined as any illness detected by active surveillance that was associated with a positive culture for wild-type influenza virus.

The analysis was based on the $VE_{S,CL}(T)$, using the observed proportions of cases in vaccine recipients and placebo recipients. Koopman’s method for the ratio of two binomials (StatXact) was used to estimate 95% confidence intervals. A logistic generalized estimating equation with an exchangeable covariance matrix was used to rule out the possibility of an effect within families on the results, since more than half the children in the study were in households with at least two children in the household.

Enrollment began in August 1996 with 1,314 children enrolled in the two-dose cohort and 288 in the one-dose cohort. Surveillance ended April 1997 at the end of the influenza outbreaks at the study sites. Among children in the immunogenicity substudy, younger children were more likely to be seronegative before entering the study than older children. Only 29 percent of children one or two years of age had antibodies to influenza A (H3N2) compared with 70 percent of children three years of age or older. Pre-existing antibody to influenza in an influenza vaccine study is considered an important potential
Table 6.4. Efficacy (VE\(S.C1(T)\)) of one or two doses of live attenuated, cold-adapted influenza virus vaccine for the prevention of culture-confirmed influenza (Belshe et al 1998)

| Influenza type | Assigned to one dose | Assigned to two doses who received two doses | All participants |
|---------------|----------------------|--------------------------------------------|-----------------|
|               | No. of cases         | Efficacy [95% CI]                           | No. of cases    | Efficacy [95% CI]                           | No. of cases    | Efficacy [95% CI]                           |
|               | Vaccine (n = 189)    | Placebo (n = 99)                           | Vaccine (n = 849) | Placebo (n = 410)                           | Vaccine (n = 1070)| Placebo (n = 532)                           |
| A(H3N2)       | 2                    | 87 [47–97]                                 | 4               | 49 [90–99]                                  | 1               | 64 [88–97]                                  |
| B             | 1                    | 91 [46–99]                                 | 6               | 31 [78–96]                                  | 7               | 37 [79–96]                                  |
| Any           | 3                    | 89 [65–96]                                 | 10              | 74 [88–97]                                  | 14              | 95 [88–96]                                  |

confounder. Of the 3,009 illnesses in the study subjects, 71 cases of influenza A (H3N2) and 44 cases of influenza B were confirmed. No cases of wild-type influenza A (H1N1) were identified in the study participants or the communities at large during the 1996-1997 influenza season. Table 6.4 shows the results. Vaccination was quite effective against culture-confirmed influenza. Although the data are not presented here, the spectrum of illness in the vaccinated children who developed influenza was milder than that in unvaccinated children.

In influenza vaccine studies for vaccines directed against annual influenza, there is generally an attempt to get all of the participants vaccinated before the beginning of the influenza season. Then given the short duration of the season, influenza vaccine studies can often use an analysis based on the simple cumulative incidence or attack rates. The trial continued beyond the first year. Longini et al (2000) analyzed the first and second year of the trial, allowing for site specific attack rates. There was some evidence that study sites with high attack rates the first year had lower attack rates the second year and vice versa, suggesting a possible herd immunity effect.

6.4.4 Live attenuated influenza vaccine in adults without biological confirmation

A randomized, double blind, placebo-controlled trial of live attenuated trivalent influenza virus vaccine in health adults was conducted from September 1997 through March 1998 in 13 centers across the United States (Nichol et al 1999). Three of the main outcome measures were episodes of febrile illness, severe febrile illness, and febrile upper respiratory tract illness. Cultures were not performed for confirmation of influenza illness and culture-confirmed influenza was not an outcome in contrast to the Belshe et al (1998) study in young children. Nichol et al (1999) called this an effectiveness study, not an efficacy study. Participants were enrolled mid-September to mid-November 1997. Recruitment strategies varied across sites. Persons were eligible if they
were 18 to 64 years old, worked at least 30 hours per week outside the home, had health insurance, and were reachable by telephone. There were the usual exclusion criteria. The vaccine contained the three viruses corresponding to those recommended for the 1997-1998 influenza season in the United States. Vaccines were administered intranasally between September 18 and November 15, 1997.

Participants were randomized 2:1 to receive the vaccine or placebo in the fall of 1997. A total of 3,041 adults received vaccine and 1,520 received placebo. Reactogenicity and safety were assessed by asking each participant to keep a record of daily symptoms on the evening of vaccination and seven days afterwards. Participants were called at day 28 to identify serious adverse events. Assessment of any serious adverse events continued to the end of the study.

Influenza virus surveillance is conducted in many places across the United States. The surveillance identifies the influenza season and the strains of circulating wild-type virus. In Nichol et al (1999), they identified two influenza outbreak periods. The first was the site-specific peak outbreak, using the modal week at each site to begin an algorithm that identified the weeks in which at least 80% of the positive influenza isolates for the season were included. The total outbreak period was identified by a panel of experts from the surveillance information from all of the sites. The motivation for choosing the site-specific outbreak period was that the identified cases would have a higher probability of being influenza.

Bivariate comparisons for the proportions of subjects experiencing study outcomes were conducted using the Cochran-Mantel-Haenszel test controlling for site. Generalized linear models were used to calculate the variance of the event rates (PROC GENMOD SAS).

At the different sites, peak outbreak periods lasted from 4 to 12 weeks. The surveillance cultures revealed that nearly all of the isolates that year were influenza A (H3N2), 80% of which were a drifted variant of the vaccine strain, so that the vaccine was not well-matched to a large portion of the circulating viruses.

Table 6.5 contains the results for three of the main outcome measures. For the most specific case definition of febrile upper respiratory tract illness, the efficacy of the vaccine is 23.6% (95% CI, 12.7-33.2), much lower than in the Belshe et al (1998) study the previous year in young children (Table 6.3). There are three possible explanations for the lower efficacy. First, the circulating strain was a drifted variant of the vaccine strain. Secondly, some investigators believe that adults do not respond to the intranasal live attenuated vaccine as well as children. Thirdly, the case definition is not confirmed influenza, so that many of the illnesses captured in the analysis are likely not influenza, causing the efficacy estimates to be much lower than efficacy estimates of culture-confirmed influenza. This latter reason certainly played an important role. In Chapter 8 we show how to estimate vaccine efficacy for a biologically confirmed outcome when only a small subsample of the non-specific cases are biologically confirmed.
Table 6.5. Efficacy (effectiveness) of live attenuated, cold-adapted influenza virus vaccine for the prevention of some clinical outcomes (not culture-confirmed influenza) in adults (Nichol et al 1999).

| Outcome                        | Vaccine Group | Placebo Group | Reduction in rates, % [95% CI] | p-value |
|--------------------------------|---------------|---------------|-------------------------------|---------|
|                                | Total episodes| Rate per 1000 persons per 7-week outbreak | Total episodes | Rate per 1000 persons per 7-week outbreak | |
| Febrile illness                | 406           | 151.3         | 225                          | 168.1   | 10.0 [−2.1–20.7] | .10     |
| Severe febrile illness         | 298           | 111.0         | 183                          | 136.7   | 18.8 [7.4–28.8]  | .002    |
| Febrile upper resp tract illness| 248           | 92.4          | 162                          | 121.0   | 23.6 [12.7–33.2] | <.001   |

6.4.5 Relative efficacy of live and killed influenza vaccine in young children

Soon after universal vaccination of children 6 to 59 months of age was recommended by the U.S. advisory bodies, a double-blind randomized trial in infants and young children to compare live-attenuated influenza vaccine with with inactivated influenza vaccine was conducted (Belshe et al 2007).

The study was conducted at 249 sites in 16 countries in the U.S., Europe, the middle East, and Asia. The sites were physicians’ offices and primary care clinics. Children were randomly assigned on a 1:1 basis to receive one of the two vaccines. Subjects were stratified in the randomization to age on receipt of the first dose, presence or absence of previous influenza vaccination, presence or absence of wheezing, and country of residence. The usual exclusion criteria applied. Children with mild or moderate asthma or wheezing more than 42 days before the trial were included. Children not previously vaccinated for influenza received two doses of the assigned study vaccine. To preserve blinding, children assigned the intranasal live attenuated vaccine received an intramuscular injection of salt solution, and analogously for children assigned the intramuscular killed vaccine.

Parents recorded local and systemic reactions until 42 days after vaccination. Medically significant events were collected throughout until the end of the surveillance period, May 31, 2005. Study staff contacted the parents every 7 to 10 days during the surveillance period. Nasal swabs for viral cultures were obtained either at the child’s home or at the study site. The study was powered assuming a 3.0% attack rate in children receiving killed vaccine and a 1.8% attack rate in the children receiving live attenuated vaccine, for a relative efficacy of 40%. Assuming that 90% of the children would be able to be included in the per-protocol analysis, 8,500 children would be needed for
Table 6.6. Relative reduction in attack rate with live attenuated, cold-adapted influenza virus vaccine compared to inactivated vaccine regardless of match for the prevention of culture-confirmed influenza in infants and young children (Belshe et al 2007)

| Virus      | Live attenuated vaccine (N=3916) | Inactivated vaccine (N=3936) | Reduction in attack rate with live vaccine |
|------------|---------------------------------|-----------------------------|-------------------------------------------|
|            | Cases no. | Attack rate % | Cases no. | Attack rate % | % [95% CI]               |
| All        | 153       | 3.9          | 338       | 8.6          | 54.9 [45.4–62.9]         |
| A/H1N1     | 3         | 0.1          | 27        | 0.7          | 89.2 [67.7–97.4]         |
| A/H3N2     | 37        | 0.9          | 178       | 4.5          | 79.2 [70.6–85.7]         |
| B          | 115       | 2.9          | 136       | 3.5          | 16.1 [−7.7–34.7]         |

90% power to demonstrate superiority of the live attenuated to the inactivated vaccine. The primary end point was the relative efficacy in preventing culture-confirmed influenza-like illness caused by well-matched influenza strains. The definition of influenza-like illness was an oral temperature of 37.8° C or higher or the equivalent in the presence of cough, sore throat, or runny nose or nasal congestion occurring on the same or consecutive days.

Secondary endpoints included relative efficacy against mismatched influenza viruses and all influenza viruses, as well as several other clinical outcomes, such as otitis media.

From October 20 to October 29, 2004, a total of 8,475 children were enrolled. Of these, 7,852 were included in the per-protocol analysis. Table 6.6 shows the overall number of cases regardless of match of the vaccine with the circulating strains. The paper presents analysis by well-matched vaccine, well-matched by age group, well-matched by previous vaccination status, and not well matched. In this trial, of the 3,936 children who received inactivated vaccine, 338 developed culture-confirmed cases of influenza. Of the 3,916 children who received live-attenuated vaccine, 153 cases developed. Relative reduction in attack rate by the live vaccine compared to the killed vaccine was 54.9% (95% CI 45.4–62.9).

6.4.6 Oral cholera vaccines in Bangladesh

Interest in oral cholera vaccines developed because parenteral vaccination had not been very successful. Cholera is a disease in the intestine, so it seemed that local mucosal immunity stimulated by an oral vaccine might be better. A randomized, double-blind trial of two oral killed cholera vaccines and one placebo arm was conducted in the Matlab field studies area of the International Centre for Diarrheal Research, Bangladesh (ICDDR,B) (Clemens et al 1986). The oral vaccines consisted of killed cholera whole cells (WC) either
with or without the B subunit (BS) component of cholera toxin. The placebo arm received a heat inactivated *E. coli* K12 strain.

Potentially eligible subjects for the trial were the 124,035 persons aged 2 to 15 years and females aged over 15 years residing in the vaccine trial area at the onset of vaccination. These are the groups at highest risk for cholera in Matlab. After exclusion criteria, 89,596 persons took at least one dose of vaccine or placebo. A census of the vaccine trial population was conducted three months prior to vaccination. Persons were randomized in the census to one of the three groups before teams went to the field. Vaccination occurred in three six-week rounds starting in January, 1985, with a short one-week round in May, 1985. Vaccines and placebo were delivered by 69 vaccination teams who were assigned to particular villages and visited people in their homes.

The estimated fraction of the oral dose swallowed was recorded. Physicians in the trial area were stationed during vaccination to manage side-effects.

Surveillance for diarrhea was maintained at the three diarrheal treatment centers serving the Matlab population. Stool samples or rectal swabs were processed to identify *V. cholerae* O1, and to determine the biotype (El Tor or classical) and serotype of each isolate. To be considered fully vaccinated, a person needed to have three doses, and have swallowed all of the first dose and at least 3/4 of the second and third doses. Later follow-up analyses focused on those participants who had completely ingested all three doses (Clemens et al 1988; Clemens1990). The case definition was that the participant presented for treatment of diarrhea whose onset was ≥14 days after receipt of the third dose, had various diarrheal symptoms not detailed here, *V. cholerae* was isolated, and a field check at the person’s home confirmed that the person had indeed sought treatment on the specified date.

The vaccine efficacy measure after one year of follow-up was based on the proportion of vaccinees compared to the proportion of controls becoming ill with cholera, \( VE_{S,CL}(T) \). Table 6.7 presents the analysis of one year of follow-up (Clemens et al 1988). Cases were those that presented with onset between 14 and 365 days after the third dose. In this analysis, only those who ingested three complete doses are included. Of those initially enrolled in the study, 62,285 participants took three complete doses of either placebo, whole cell or B-subunit whole cell vaccine, with 20,837, 20,743, and 20,750 in each group. The group reported one-sided confidence intervals, which are not included in Table 6.7 (see Problem 6.1 and Table 7.3). In subsequent years of follow-up, the efficacy of the vaccines appeared to wane. In Section 7.3 we present a method to analyze vaccine efficacy that wanes over time using the example of the cholera vaccine trial.

### 6.4.7 Pneumococcal conjugate vaccine in California

A randomized, double blind trial of a heptavalent pneumococcal vaccine was conducted at 23 medical centers within Northern California Kaiser Permanente (NCKP), a health maintenance organization (Black et al 2000). Healthy
infants were randomized 1:1 to receive either heptavalent pneumococcal conjugate or the meningococcus type C conjugate vaccine at 2, 4, 6 and 12 to 15 months of age. Infants with specific risk factors were excluded. The heptavalent vaccine contained saccharides of the serotypes 4, 9V, 14, 18C, 19F, 23F, and 6B conjugated to a protein carrier made of nontoxic mutant diphtheria toxin. At that time, the seven serotypes were responsible for 83% of invasive disease in children younger than 4 years of age. The control meningococcal conjugate vaccine has the same carrier.

The primary endpoint was invasive pneumococcal disease caused by the vaccine serotypes. Secondary endpoints included otitis media. The outcome pneumonia was reported separately from the primary analysis. Active surveillance for cases in the study population was conducted using automated clinical and laboratory databases of the NCKP system. Invasive pneumococcal disease was defined as a positive culture of *Streptococcus pneumoniae* from a normally sterile body fluid (blood, spinal fluid) obtained from a child presenting with an acute illness compatible with pneumococcal illness.

Between October 1995 and August 1998, 37,868 children were enrolled into the trial. Of the 18,927 children who received at least one dose of pneumococcal conjugate, 17,174 received at least 2 doses, 15,565 received at least 3 doses, and 10,940 received at least 4 doses. Of the 18,941 children who received at least one dose of meningococcal conjugate, 17,196 received at least 2 doses, 15,536 received at least 3 doses, and 10,995 received at least 4 doses.

In this trial, protective efficacy was estimated by 1 minus the ratio of the number of cases of invasive disease in the pneumococcal vaccine arm compared to the meningococcal arm. In other words, the computation does not use the denominators. Efficacy was evaluated with the binomial test of the null hypothesis that the vaccine has no efficacy for the seven serotypes. The analysis incorporated a sequential design. An interim analysis had been planned when 17 cases had occurred. The null hypothesis was to be rejected if the case split was 15:2 or more favorable, \( p = 0.0023 \), with a final evaluation planned when 26 cases had occurred and an overall two-tailed \( p \) value of <0.05. Exact binomial confidence intervals were calculated by the Clopper-Pearson method.

### Table 6.7. Occurrence of cholera and VE \(_{SV}(T) \) during the first year of follow-up after the third dose among participants who ingested three complete doses of the vaccine or placebo assigned. (Clemens et al 1988)

| Group     | Outcome | BS-WC | VE no. | WC no. | VE no. | K12 no. |
|-----------|---------|-------|--------|--------|--------|---------|
|           | Cholera | 41    | 62     | 52     | 53     | 110     |
|           | No cholera | 20,664 | 20,691 | 20,727 |
|           | Total   | 20,705 | 20,743 | 20,837 |
Table 6.8. Efficacy of heptavalent pneumococcal vaccine against invasive pneumococcal disease results as of April 20,1999 (Black et al 2000)

| Analysis for serotypes contained in the vaccine | Cases split | Efficacy % [95% CI] | p-value |
|-------------------------------------------------|-------------|---------------------|---------|
| Per protocol fully vaccinated                    | 39:1        | 97.4 [82.7–99.9]    | <0.001  |
| Intent to treat                                   | 49:3        | 93.9 [79.6–98.5]    | <0.001  |
| Partially vaccinated only                         | 7:1         | 85.7 [0–100]        | 0.05    |
| All cases regardless of serotype                 | 55:6        | 89.1 [73.7–95.8]    | <0.001  |

(StatXact). An intent-to-treat analysis included all invasive disease caused by a pneumococcal serotype regardless of number of doses completed. Safety of the vaccine was assessed by telephone follow-up on subsets of the study population, one receiving DTwP, one receiving DTaP. The computerized utilization data of the NCKP was also used to compare rates of events in the two groups. Immunogenicity of the conjugate vaccine was evaluated in a subset of children receiving DTwP concurrently and in a subset given DTaP in the first year of life. Serum IgG to the seven serotypes was measure using ELISA from samples collected before the first vaccination and one month after the third dose.

At the interim analysis, all 17 of the cases of invasive disease in fully vaccinated children were in the control group. At the interim intent-to-treat analysis of children receiving at least one dose, all 22 cases were in the control group. The Study Advisory Group recommended termination of the trial at the interim analysis because of the high efficacy. Enrollment was discontinued at the end of August 1998. Blinded follow-up and per protocol vaccination of the two groups continued until April 20,1999. After that, all children in the control group were offered pneumococcal conjugate vaccine. The vaccine was highly efficacious against invasive pneumococcal disease (Table tab:yes:black2000). During the trial, concern grew that there would not be enough events for the definitive analysis. This motivated the design and implementation of the group randomized study to estimate the total effects of using the pneumococcal vaccine (Chapter 13.4.2).

6.5 Report of a study

In the preceding examples we have not included every aspect of the report of the studies. A report should tell the type of study, whether randomized, cohort, or case-control. The entities that reviewed the study protocol should be listed. These could include local institutional review boards, regulatory bodies, such as the US Food and Drug Administration, medical products committees, and ethics boards. Details of the vaccines and placebos, their manufacturers,
6.6 Reduction in burden of illness

Most of the studies of VE present in this chapter have a case definition that is a 0,1 dichotomous outcome. Although several different case definitions, some more and some less severe, may be considered in separate analyses, they are all scored 0,1 in any given analysis. Chang et al. (1994) suggest a measure of efficacy that takes into account both the incidence of disease and severity. A severity score is assigned to each incident case, then the total is summed over all cases to have a burden of illness score. When the severity score for each case is one, the burden-of-illness score reduces to the vaccine efficacy based on the number of cases in the vaccine compared with the unvaccinated group. When different cases have different severity scores, the burden-of-illness score for a group is a weighted sum of all of the cases in the group, where the severity scores serve as the weights. The burden-of-illness score divided by the number of subjects randomized to the group yields the burden-of-illness per randomized participant. The difference between the mean burden-of-illness in the two groups, or the relative difference is a measure of the net reduction in morbidity per participant. A number of vaccine studies have developed severity scores. In a rotavirus vaccine study, the severity of each case of diarrhea was given a severity score between 0 and 20 (Ruuska and Vesikari 1990).

Let $N_0$ and $N_1$ be the number randomized to vaccine and control, and $c_0$ and $c_1$ the number of cases in the vaccine and control arms. The severity scores for the cases are $S_{i0}, \ldots, S_{i0}$ and $S_{i1}, \ldots, S_{i1}$ in the two groups with means $\mu_0$, $\mu_1$ and variances $\sigma_0^2$, $\sigma_1^2$. One design option is that the trial runs for a fixed time, after which it is stopped and analyzed. A second option is that the trial is stopped after a number of total cases $c$, where $c = c_0 + c_1$. If $\lambda_0$ and $\lambda_1$ are the hazards of disease in the two groups, then the expected number of cases in the two groups are $\lambda_0 N_0 t$ and $\lambda_1 N_1 t$, where $t$ is the duration of follow-
up. The number of cases in the control group, $c_0$, has a binomial distribution $\text{Binom}(c, p_0)$, where $p_0 = \lambda_0 N_0 t / (\lambda_0 N_0 t + \lambda_1 N_1 t)$, and $p_1 = 1 - p_0$. In the design with fixed time, the null hypothesis is that $\mu_0 = \mu_1$ and $p_0 = p_1$. In the design with fixed number of events, the null hypothesis is that $\mu_0 = \mu_1$ and $\lambda_0 = \lambda_1$. A test statistic $T$ for both models is the difference in the mean burden of illness scores per participant:

$$T = \frac{1}{N_0} \sum_{i=1}^{n_0} S_{0i} - \frac{1}{N_1} \sum_{i=1}^{n_1} S_{1i}. \quad (6.15)$$

For both designs, under the null hypothesis, $\mu_0$ and $\mu_1$ are estimated by

$$\overline{x} = \left( \sum_{i=1}^{n_0} S_{0i} + \sum_{i=1}^{n_1} S_{1i} \right) / (n_0 + n_1) = (n_0 \overline{s}_0 + n_1 \overline{s}_1) / (n_0 + n_1). \quad (6.16)$$

The variances $j = 0, 1$ are estimated by

$$s_j^2 = \left( \sum_{i=1}^{n_j} (S_{ji} - \overline{S}_j)^2 \right) / (n_j - 1). \quad (6.17)$$

In the fixed time design, $\hat{p} = (n_0 + n_1) / (N_0 + N_1)$ estimates both $p_0$ and $p_1$. In the fixed number of events design, $\hat{p}$ is estimated by $N_0 / (N_0 + N_1)$, and $p_1$ by 1 minus the estimate of $p_0$. The observed standard test statistics are obtained from

$$\hat{V}_H(T) = \frac{[\overline{x}^2 \hat{p}(1 - \hat{p}) / (1 / N_0 + 1 / N_1) + \hat{p}(s_0^2 / N_0 + s_1^2 / N_1)]}{\sqrt{\hat{V}_H(T)})}$$

$$\hat{V}_H(T|n) = c[\overline{x}^2 / N_0 N_1 + (s_0^2 / N_0 + s_1^2 / N_1) / (N_0 + N_1)].$$

The two-sided rejection region of the null hypothesis for the fixed time design is $|T / \sqrt{\hat{V}_H(T)}| > z_{\alpha/2}$ and for the fixed number of events design is $|T / \sqrt{\hat{V}_H(T|n)}| > z_{\alpha/2}$. Chang et al (1994) also present a method to calculate sample size. Because the scores combine incidence with severity per case, one might think that the burden-of-illness scores can provide a more comprehensive measure of overall efficacy than would a separate analysis based simply on either incident cases, $\text{VE}_S$, or the per case severity, $\text{VE}_P$, with a continuous outcome, (Chapter 9) alone. However, because there may be a large number of zeros in each group, the test can have poor power.

Mehrotra et al (2006) compared eight methods for a dual endpoint evaluation of efficacy in a proof-of-concept trial, including that of Chang et al (1994). The motivation for the comparison was the design of the first trial of an HIV vaccine based on cell-mediated immunity. The vaccine was expected to have very low efficacy against infection, but it was hoped that it would reduce viral load as a surrogate for progression to disease. The question was whether it was better to test the composite null hypothesis of no vaccine effect on either the
incidence of HIV infection or the viral load set point among those who become infected relative to the placebo using just a single composite test or using two separate tests, one for the infection endpoint and one for viral load endpoint. They found that combining separate tests for the infection and viral load endpoints is generally more powerful than the unconditional burden-of-illness test of Chang et al (1994), especially at low or zero VE$_S$. At VE$_S = 0.60$ or higher, all methods and combinations of methods performed comparably. They recommended using either the unweighted Simes’ or Fisher’s combination test for the trial.

One of the problems in vaccine studies is that usually most of the participants do not become infected. Follmann et al (2008) took a different approach than that of Chang et al (1994) by introducing chop-lump Wilcoxon and t-tests. The approach again assigns a score $S$ to each participant, 0 for uninfected participants, and a measure $S > 0$ of the post-infection outcome such as severity or parasite density in the infected participants. When the number of participants in each group are equal, the chop-lump test removes an equal number of zeros from both groups, then performs the test on the remaining $S$s, most of which are greater than 0. A permutation approach then provides a null distribution. The chop-lump Wilcoxon test is shown to be always more powerful than the usual Wilcoxon test when the true infection rates in the vaccine and the control group are the same. The R package choplump is available at http://cran.r-project.org/.

Problems

6.1. One- versus two-sided confidence intervals
(a) Cholera study: compute one sided and two sided 95% confidence intervals for VE in Table 6.7. (b) Compare the results

6.2. Sample size calculation with person-time
(a) Niakhar pertussis study

6.3. Sample size calculation with proportions
(a) Relative efficacy of two influenza vaccines

6.4. Compute VE$_S$ for proportions
The problem is described here. The problem is described here. The problem is described here.

6.5. Compute VE$_S$ with person-time
(a) The first part of the problem is described here.
(b) The second part of the problem is described here.
