Abstract

Background: Scrub typhus is prevalent in India although definite statistics are not available. There has been only one study on scrub typhus meningitis 20 years ago. Most reports of meningitis/meningoencephalitis in scrub typhus are case reports.

Methods: A retrospective study done in Pondicherry to extract cases of scrub typhus admitted to hospital between February 2011 and January 2012. Diagnosis was by a combination of any one of the following in a patient with an acute febrile illness: a positive scrub IgM ELISA, Weil-Felix test, and an eschar. Lumbar puncture was performed in patients with headache, nuchal rigidity, altered sensorium or cranial nerve deficits.

Results: Sixty five cases of scrub typhus were found, and 17 (17/65) had meningitis. There were 33 males and 32 females. Thirteen had an eschar. Median cerebrospinal fluid (CSF) cell count, lymphocyte percentage, CSF protein, CSF glucose/blood glucose, CSF ADA were 54 cells/μL, 98%, 88 mg/dL, 0.622 and 3.5 U/mL respectively. Computed tomography was normal in patients with altered sensorium and cranial nerve deficits. Patients with meningitis had lesser respiratory symptoms and signs and higher urea levels. All patients had received doxycycline except one who additionally received chloramphenicol.

Conclusion: Meningitis in scrub typhus is mild with quick and complete recovery. Clinical features and CSF findings can mimic tuberculous meningitis, except for ADA levels. In the Indian context where both scrub typhus and tuberculosis are endemic, ADA and scrub IgM may be helpful in identifying patients with scrub meningitis and in avoiding prolonged empirical antituberculous therapy in cases of lymphocytic meningitis.

Introduction

Scrub typhus is an acute febrile illness caused by Orientia tsutsugamushi, and is characterized by an eschar, lymphadenopathy, multisystem involvement and a rapid response to doxycycline. Scrub typhus is seen in all terrains of the tsutsugamushi triangle, a geographical region of south and east Asia and the southwest Pacific and is related mostly to agricultural activities [1]. Although it was known in China in the 3rd century A.D, scrub typhus (tsutsugamushi fever) was described by Hakju Hashimoto in 1879 [3] as Japanese “flood fever” [4]. Tsutsugamushi describes a Japanese term for tsutsuga “illness” and mushi “insect/creature”. Taiwan is the centre of the tsutsugamushi triangle and the first case reported in that country was in 1915 [5]. The first and second cases in Korea were reported in 1951 and 1986 respectively [6] and it now has the highest reported incidence in the world [7]. About one million new cases are identified annually [8]. The first reported cases in India were in 1934, in Himachal Pradesh [4]. We do not have definite statistics in India due to lack of awareness, unavailability and high cost of diagnostic kits and the fact that it is not a reportable illness.

The larval forms (chiggers) of the trombiculid mite transmit the disease to humans and other vertebrates [9]. The mite has four life-cycle stages: egg, larva, nymph and adult [9]. Horizontal transmission occurs in rodents and humans get accidentally infected following bites of chiggers [10]. Vertical transovarial transmission occurs in mites [10] although one case of transplacental spread has been reported in a pregnant woman who delivered a preterm baby with hepatosplenomegaly, meningitis, sepsis and scrub IgM positivity [11]. Leptotrombidium delense and L. scutellare are the mites for the summer type (March to November) and winter type (September to December) scrub typhus respectively. Correspondingly, the reservoir hosts (rodents) include Rattus norvegicus, R. flavipes, and Apodemus agrarius for the former and A. agrarius, Cricetulus triton, and R. norvegicus for the latter [12]. There are more than 30 antigenically different strains apart from the 6 important serotypes of O. tsutsugamushi – Gilliam, Karp, Kato, Shimokoshi, Kawasaki, and Kuroki [13]. Infection spreads through both hematogenous and lymphatic routes [12]. Target site for multiplication are the endothelial cells of the various systems [14]. Both humoral and cell mediated immunity are important for combating scrub typhus [14].
Chills and fever occur by the 3–4th day of bite, and rash and lymphadenopathy appear at end of the first week [13]. Incubation period ranges from 6–20 days [15]. Serious complications occur during the second week of illness and comprise of pneumonitis, pleural effusion, hepatomegaly, edema, acute kidney injury (AKI), acute respiratory distress syndrome (ARDS) and meningitis [16]. Most studies of meningitis and meningocencephalitis in scrub typhus are case reports/series (Table 1). Silpapojakul et al., in 1991 described nine patients (9/72) presenting with meningitis in the earliest study of rickettsial meningitis [17]. CSF studies were similar to tuberculous meningitis (TBM) and viral etiologies [17]. Although literature describing various neurological complications in scrub typhus was available (Table 1), we could not find any previous studies on scrub typhus, from India or elsewhere that compared patients with and without meningitis.

Materials and Methods

The Pondicherry Institute of Medical Sciences is a 550-bedded teaching hospital serving the coastal town of Pondicherry and surrounding districts of Tamil Nadu with a population of nearly seven million. We did a retrospective analysis of all adult cases (≥16 years) of scrub typhus that were admitted in the hospital between February 2011 and January 2012. Computerized records of the Medical Records Department were searched using the terms, “scrub typhus”, “typhus”, “scrub typhus meningitis” and “rickettsial meningitis”. Confirmed cases of scrub typhus were selected based on a positive scrub IgM ELISA (Scrub Typhus Detect™ IgM ELISA, InBios India, detecting IgM antibodies to Orientia tsutsugamushi derived recombinant antigens), a positive Weil-Felix test (WFT), the presence of an eschar or a combination of the three in a patient with an acute febrile illness. Probable cases of scrub typhus without any of the above three were excluded from the study even if recovery following doxycycline was noted. Sixty nine adult cases were found- 65 of scrub typhus, three of Indian tick typhus and one of endemic typhus with none of the four having meningitis. There were no pediatric cases found during the study period. Sixty five cases were included in the study and divided into two groups based on the presence or absence of meningitis. The remaining four patients without scrub typhus (but positive titers of WFT OX:2, OX:19) were excluded from the study.

Ethics statement: Only demographic data of patients were stored in the hospital database to enable retrieval of files manually based on patient codes. Charts and discharge summaries were perused. All data were anonymously analysed without individual patient consent due to the retrospective nature of the study. The Institute Ethics Committee of the Pondicherry Institute of Medical Sciences waived the need for individual informed consent and approved the study.

Meningitis was defined by the presence of headache or nuchal rigidity with either altered sensorium or focal neurological deficits on history or examination and with CSF pleocytosis ≥5. Hypotension was defined by a systolic blood pressure of <90 mmHg. Tachycardia and tachypnea were identified if the pulse and respiratory rates were >100/min and >20/min respectively. Respiratory symptoms included sore throat, cough, expectoration, hemoptysis, wheeze and breathlessness. Abdominal symptoms consisted of nausea, vomiting, diarrhea, abdominal pain, constipation, jaundice and hematemesis. Urinary symptoms comprised of frequency, dysuria, and haematuria. Hepatic injury was defined by the presence of transaminases elevation (>3times).

Results

Seventeen (26%) patients had clinical and laboratory evidence of meningitis and male: female ratio for this group was 10:7 (Table 2). The meningitis group also had a significantly higher percentage of patients with low grade fever and a lower percentage with respiratory symptoms. On examination the temperature, pulse and respiratory rates and incidence of crackles were significantly lower in patients with meningitis. Arthralgia, fatigue, edema, lymphadenopathy, pleural effusions, crakcles and rhonchi were seen only in the control group but were not statistically significant. Mean duration of hospital stay was lower in patients without meningitis. Elevated urea, elevated total WBC counts in blood and a normal chest X-ray (CXR) were significantly associated with the presence of scrub meningitis (Table 3). A higher percentage of patients in the control group had elevated ESR, AST (>3times), bilirubin, GGT and WFT positivity (>1:80) but without statistical significance. A positive WFT (≥1:20) was seen in 33 patients (10/15 patients with meningitis) but only 7/15 patients had WFT titers >1:80.

December had the maximum admissions of scrub typhus, while the highest number of admissions with meningitis was in February (5/17). Unilateral and bilateral sixth cranial nerve palsies were the only cranial nerve deficits observed (Table 4). Altered sensorium was seen in five, while limb weakness was seen in three patients. Computed tomography (CT) brain of patients with altered sensorium was normal. Magnetic resonance imaging (MRI) could not be done due to lack of availability. Median cerebrospinal fluid (CSF) cell count, lymphocyte percentage, CSF protein, CSF glucose/blood glucose, CSF ADA was 54 cells/μL, 98%, 88 mg/dL, 0.622 and 3.5 U/mL respectively. All CSF samples were negative for gram stain, India ink, aerobic culture and acid fast bacilli. CSF pressure recordings were not performed.

Pleural effusion was observed in two females aged 23 and 40 years; thoracentesis revealed cell counts of 720 and 450 with lymphocyte percentages of 80% and 98%, pleural fluid protein 2 g and 2.2 g, fluid LDH/scrum LDH values of 468/691[67%] and 527/1000[52.7%] and ADA values of 28 U and 76 U respectively. The first subject also had a posterior pericardial effusion. There was one woman (28 y) with 28 weeks gestation, one case of acute pancreatitis following co-infection with dengue [18], one man with a papular rash, one woman (38 y) admitted under surgery for an acute abdomen and another woman (53 y) on antiretroviral therapy. HIV testing performed for lymphocytic meningitis was negative in all the 17 patients. All patients with meningitis had been treated with doxycycline (100 mg BD for 14 days) and a

51 year old patient was given chloramphenicol in addition to doxycycline due to lack of defervescence.

Discussion

In India, scrub typhus has been reported in at least 16 states (Jammu & Kashmir, Himachal Pradesh, Rajasthan, Haryana, Maharashtra, Karnataka, Andhra Pradesh, Kerala, Tamil Nadu, Pondicherry, West Bengal, Sikkim, Uttarakhand, Assam, Arunachal Pradesh, and Nagaland) [8],[19],[20]. Although most studies from Tamil Nadu are from one institute [21], documentation has been done in at least 15 districts [8],[21].

The differential diagnoses of scrub typhus in our setting include enteric fever, dengue, leptospirosis and malaria [22] all of which had been ruled out in our patients save one, who had a co-infection with dengue [18]. Clinical diagnosis is often made/confirmed by the presence of an eschar and clinical improvement following doxycycline therapy [22]. Eschars are seen in 7 to 80% of patients, with a higher percentage seen in children [14],[5]. Japan and Korea have a higher reportage of eschars when compared to Taiwan and Thailand [7]. Identification of eschars in the Indian population is difficult due to dark skin with incidence ranging from 4% to 46% [23],[24] and it was 20% in our study. Absence of an eschar was a risk factor for mortality [6].

### Table 2. Demography and clinical features of scrub typhus patients with and without meningitis at admission.

tions in one study [5]. In our setting hepatomegaly and hepatic dysfunction were seen in 41.8% and 24.6% of subjects respectively while CXR abnormalities were observed in 20(30.8%) patients. Unusual manifestations include ARDS, myocarditis, pancreatitis, hemophagocytic syndrome, disseminated intravascular coagulation (DIC) and meningoencephalitis [25],[18]. Myocarditis, pleural effusion and gastrointestinal (GI) hemorrhage are more common with winter scrub typhus [12]. We had only one case each of myocarditis and hematemesis and two cases of pleural effusion. Hypoalbuminemia can be seen in one-fourth to three-fourths of patients of scrub typhus [26]. Perivasculitis, endothelial damage predisposes to capillary leak and hypoalbuminemia.

Scrub typhus involves both the central and peripheral nervous system. Tsutsugamushi is the rickettsia with the most meningeal involvement [27] but central nervous system(CNS) involvement is higher in epidemic typhus than that of scrub typhus [9]. CNS complications include infarction [28], cerebellitis [17], hemorrhages [29], encephalitis, demyelination [30], subdural hematoma [31], typhus nodules [32] and meningitis causing altered sensorium, agitation, motor weakness, seizures, neck stiffness, cranial nerve deficits(CND) [33]. Low platelets and DIC contribute towards haemorrhage [29]. Microglial nodules suggested cortical invasion [34]. The involved cranial nerves are the optic [17], abducens, facial and cochlear [35] nerves. Peripheral nervous system involvement reported are mononeuritis multiplex [36], brachial plexus neuropathy [37], polyneuropathy [28], myelitis [30,38] and Guillain-Barre syndrome (GBS) [25].

Cranial nerve deficits are seen in 25% of patients with the sixth being most commonly involved [39]. Unilateral or bilateral abducens palsies occur with or without meningitis and facial palsies ensue singly or in association with GBS. Facial nerve palsy has also been described with *R. typhi* and *R. conorii* infections [25]. There is a ~19% incidence of ear symptoms in scrub typhus that includes sensorineural hearing loss, otalgia and tinnitus [35]. Direct central nervous system invasion and involvement of the cochlear division or a secondary immune mediated effect in the

### Table 3. Investigations of patients of scrub typhus with and without meningitis at admission.

Rifampicin is also used to treat severe scrub typhus in patients with suspected TBM due to ready accessibility and low costs. CSF ADA levels may be helpful in differentiating scrub meningitis from TBM with sensitivity and specificity of 84% and 88% respectively [45]. Both models were based on studies in developing countries, but a single model may not predict TBM in all populations. Hence ADA levels may be helpful in differentiating scrub meningitis from tuberculous meningitis but more studies are necessary in that direction. Comparison with another group consisting of patients with tuberculous meningitis was not possible due to the retrospective study of scrub typhus patients alone. Prospective studies with cryptococcal antigen testing and PCR based kits like Xpert MTB/RIF (which were not performed in our patients due to unavailability) is needed in scrub meningitis to rule out other differential diagnoses. Scrub typhus meningitis can also be differentiated from TBM by the shorter period taken towards normalization [46]. Rifampicin is also used to treat severe scrub typhus in patients with suspected TBM due to ready accessibility and low costs.

Most reports of meningitis are from Korea, India and Taiwan (Table 1). Meningeal signs were seen in 14% of patients with scrub typhus in a study conducted in Assam and Burma way back in 1946 [4]. In a study by Pai et al., on 25 patients with CNS involvement, only half of them had CSF lymphocytosis and only a third had elevated protein [38]; O. tsutsugamushi DNA was isolated in six CSF samples. All our patients had CSF lymphocytic pleocytosis and a similar one-third had elevated protein (>60 mg). TBM remains the closest differential in our setting. India is one among the five countries that have the highest prevalence of TBM with an estimated mortality of 1.5/100,000 population [41]. Staining for acid fast bacilli(AB) in CSF has low sensitivity [42] and CSF culture for AFB takes up to 8 weeks and are positive only in 50–75% of cases [43],[44]. Hence other markers are necessary. Adenosine deaminase(ADA) >10 increases the post-test probability of TBM [43]. Even though ADA is useful in a setting where TBM prevalence is low [43], we have used a similar cut-off in our patients with suspected TBM due to ready accessibility and low costs. CSF ADA levels for our patients were <10 U. Fever >7 days, CSF polys <50%, focal deficits, abnormal movements and optic atrophy had predicted the likelihood of TBM in a Lancet study [42]. Specificity and sensitivity were 98.3% and 54.5% if more than 3 variables were present and 98-4% and 43-5% if one or more predictors were present. Twelve of our patients had fever >7 days' duration, six had focal deficits and all of them had <50% CSF polys. In another model, disease duration>5 days, CSF lymphocytosis>70%, age>30 years and cells<1000 may predict TBM with sensitivity and specificity of 84% and 88% respectively [45]. Both models were based on studies in developing countries, but a single model may not predict TBM in all populations. Hence ADA levels may be helpful in differentiating scrub meningitis from tuberculous meningitis but more studies are necessary in that direction. Comparison with another group consisting of patients with tuberculous meningitis was not possible due to the retrospective study of scrub typhus patients alone. Prospective studies with cryptococcal antigen testing and PCR based kits like Xpert MTB/RIF (which were not performed in our patients due to unavailability) is needed in scrub meningitis to rule out other differential diagnoses. Scrub typhus meningitis can also be differentiated from TBM by the shorter period taken towards normalization [46]. Rifampicin is also used to treat severe scrub
typhus and presence of lymphocytic CSF in a given patient, with improvement following antituberculous therapy (ATT) may mask the diagnosis of scrub typhus. Doxycycline remains the drug of choice, but azithromycin is used in pregnant patients and those with renal failure. In some instances, progressive neurological damage has occurred despite treatment [47,48] with doxycycline either due to resistance, immune-mediated injury or due to drug interaction with oral antacids [49]. Doxycycline is bacteriostatic to O. tsutsugamushi and does not cross the blood brain barrier beyond 15–30%. Only one patient required chloramphenicol after 4 days of doxycycline therapy, but he had not been prescribed antacids.

Recovery in meningoencephalitis is brisk with appropriate therapy. All neurological abnormalities in our study recovered within 2–5 days of doxycycline therapy. Patients were additionally administered dexamethasone and mannitol if they had altered sensorium or cranial nerve deficits. Delayed recovery over months in a case of isolated abducens palsy [48] and long term care in a patient with ADEM [30] have been described.

Specific tests for scrub typhus include indirect immunofluorescence test (IFT), immunoperoxidase test (IPT) and complement fixation test (CFT) [38]. IFA is the standard test for diagnosis, but lack of fluorescent microscopes makes it difficult for most hospitals [26]. IgM ELISA, based on the detection of 56 Da antigen [50] is a dot blot test which has high specificity (~90%) and sensitivity (~90%) when compared to IFA and IPT [26]. Scrub IgM was positive in all our patients. This test is expensive and ours is the only centre with this facility in this locality and surrounding districts. A two week course of doxycycline costs less than 50 cents, while scrub IgM ELISA costs about 10–12 dollars and hence a cost-effectiveness trial in the future would be useful in our setting.

On the other hand, a serological diagnosis may prevent prolonged treatment with ATT for suspected TBM. Also, a correct diagnosis could pre-empt a label of tuberculosis. A four-fold rise in titre is diagnostic, but it is retrospective and could not be performed due to costs. Thoracentesis in two patients revealed transudative fluid, but with a lymphocytic response and elevated ADA levels in one and borderline levels in the other. In such instances, differentiation from tuberculosis may be difficult. Leptospiral serology (IgM), malarial antigen testing, Widal, dengue IgM, IgG, NS1 and blood culture was performed in all patients without an eschar. Since scrub IgM was performed in batches, and WFT was done in patients in whom a scrub IgM could not be expected within the next 1–3 days. At a titre of ≥1:80, sensitivity was 30% but specificity was nearly 100% for the WFT [50]. Also WFT is not useful until the second week of illness. Other advanced tests that have been used are the Sta56 gene amplification from eschars [51] and real time PCR studies based on the 56 kDa omp gene of the rickettsia, both of which would be difficult in the community setting. Pre antibiotic era mortality was >60% [52] and ~30% in a 2006 series from Vellore [53] but with prompt diagnosis and therapy, the mortality now is very low. There were no deaths arising from scrub typhus during the duration of our study, partly contributed by earlier institution of doxycycline in patients with fever and multisystem involvement. Empirical treatment of fevers with chloramphenicol and tetracyclines and insect eradication measures could have led the disease to insignificance [30] after initial reports in India in the 1930s. But currently with increasing awareness, facilities for diagnosis, more literature is being published from India.

This study had some drawbacks. It was a retrospective study and data regarding occupation and place of origin were not available which would have given us the district-wise breakup of scrub typhus and the occupational risks associated with this illness. Also, time to defervescence has not been documented in most patients. Scrub IgM can be negative with some serotypes and hence cases of probable scrub typhus responsive to doxycycline that were excluded could have contributed numbers to the study. There was a referral bias due to availability of neurology/neurosurgery facility, intensive care services and platelet transfusion accessibility that resulted in sicker patients and thrombocytopenic fevers being referred to our hospital especially by general practitioners and nursing homes. Differences in severity or differences in virulence occur among the various serotypes; confirming whether meningitis is caused only by some serotypes would have been ideal but could not be done due to dearth of facilities. Opening CSF pressure was not checked and whether they are elevated as in TBM is not known. Viral encephalitis, especially HSV related was not ruled out due to lack of diagnostic kits.

Conclusion

Scrub typhus meningitis is a milder complication compared to respiratory or gastrointestinal problems even if it is associated with altered sensorium or cranial nerve deficits and generally resolves completely with doxycycline therapy. Due to the presence of lymphocytic pleocytosis with increased CSF protein, TBM is a close differential diagnosis. This may result in rifampicin based ATT masking the diagnosis of scrub typhus and sometimes results in patients continuing long term therapy for TBM. Since India is endemic for both TB and scrub typhus, awareness of simple-to-treat scrub typhus with access to specific tests like scrub IgM and CSF ADA may go a long way in avoiding unwarranted treatment in patients.
