Emergent anisotropy in the Fulde–Ferrell–Larkin–Ovchinnikov state

As theorized by Bardeen, Cooper, and Schrieffer (BCS), superconductivity occurs when itinerant electrons form pairs, so-called Cooper pairs, via an attractive force. Although many superconducting properties are well described by BCS theory, long-standing studies have found various superconductors beyond the BCS framework and many intriguing open questions. One of the exotic unconventional superconducting states, the Fulde–Ferrell–Larkin–Ovchinnikov (FFLO) state, was independently theorized by Fulde & Ferrell and Larkin & Ovchinnikov in 1964. An up-spin electron with momentum $k$ is coupled with a down-spin electron with momentum $-k + q$ in an FFLO pairing, leading to a finite center-of-mass momentum of Cooper pairs $q \neq 0$, whereas an ordinary superconducting state is formed by electrons whose momenta are $k$ and $-k$, as illustrated in Fig. 1a. For ordinary superconductivity, in which spins in paired electrons are antiparallel to each other, a magnetic field destabilizes the superconductivity through the orbital effect and the Zeeman effect. In most superconductors, superconductivity is suppressed by the orbital effect caused by the Lorentz force on vortices, which mainly determines the upper critical field $H_{c2}$. However, when the orbital effect is quenched, the Zeeman effect governs $H_{c2}$. In this case, the ordinary spin-singlet superconducting state is destroyed at the field where the Zeeman splitting energy reaches the superconducting energy gap $\Delta$, which is known as the Pauli paramagnetic limit $H_p$. In contrast, the FFLO state is stable even above $H_p$ due to a gain in spin polarization energy of the nonzero $q$. This finite $q$ adds a term, $\cos(q \cdot r)$, to the order parameter of the superconductivity $\Delta$. The modified gap function $\Delta \cos(q \cdot r)$ indicates that the order parameter spatially oscillates in real space, as shown in Fig. 1b. The oscillatory pattern composed of the normal state and the superconductivity endows the FFLO state with emergent anisotropy depending on the $q$ vector. Since disorder stunts the formation of the spatial modulation, the FFLO state appears only in the clean limit. Besides, as mentioned-above, the emergence of the FFLO state is allowed when the orbital effect is sufficiently weaker than the paramagnetic effect, as characterized by the Maki parameter $\alpha_M > 1.8$. Consequently, these restrictions narrow the candidate materials in the search for FFLO superconductivity and have disturbed experimental examination of FFLO physics despite numerous theoretical studies. In particular, spatial anisotropy, one of the main features of the FFLO state, has never been experimentally observed.

The organic superconductor $\kappa$-(BEDT-TTF)$_2$Cu(NCS)$_2$ (BEDT-TTF) is an abbreviation of bis(ethylenedithio)tetrathiafulvalene) is known as the prime candidate for exhibiting the FFLO state and has been examined by various measurements. As displayed in Fig. 1c, the layered structure formed by alternating stacking of conducting and insulating layers provides a quasi-two-dimensional (quasi-2D) electronic structure. This compound undergoes a superconducting transition at $-9.5 \, \text{K}$ and changes into a $d$-wave superconductivity, which is theoretically expected to manifest using nesting vectors including

Exotic superconductivity is formed by unconventional electron pairing and exhibits various unique properties that cannot be explained by the basic theory. The Fulde–Ferrell–Larkin–Ovchinnikov (FFLO) state is known as an exotic superconducting state in that the electron pairs have a finite center-of-mass momentum leading to a spatially modulated pattern of superconductivity. The spatial modulation endows the FFLO state with emergent anisotropy. However, the anisotropy has never been experimentally verified despite numerous efforts over the years. Here, we report detection of anisotropic acoustic responses depending on the sound propagation direction appearing above the Pauli limit. This anisotropy reveals that the two-dimensional FFLO state has a center-of-mass momentum parallel to the nesting vector on the Fermi surface. The present findings will facilitate our understanding of not only superconductivity in solids but also exotic pairings of various particles.
the predominant nesting vector $Q_\text{f}$ shown in Fig. 1d. When a magnetic field is parallel to the conducting plane, emergence of FFLO pairing is highly expected in $\kappa$-(BEDT-TTF)$_2$Cu(NCS)$_2$ because of the large Maki parameter, relatively long mean-free path, and quasi-2D Fermi surface. The heat capacity data show a 1st-order transition at $H \approx 21$ T. Tunnel diode oscillator (TDO) measurement also detect this anomaly, which is smeared out by a field dependence of the sound velocity $v(\nu)\alpha\nu^{-1/2}$ at 1.6 K and $\theta\approx 90^\circ$ as a function of magnetic field. The black arrow indicates the upper critical field of the superconductivity $H_c2$.

**Results**

To discuss the anisotropy in the FFLO state, we arranged two pairs of transducers, generating and detecting longitudinal ultrasonic waves, on all sides of a cuboid-shaped single crystal, as shown in Fig. 1e. First, in Fig. 1f, we show the relative change in sound velocity $\Delta v/\nu$ and ultrasonic attenuation $\Delta$ at 1.6 K in magnetic fields perpendicular to the conducting plane $\theta\approx 90^\circ$. The polarization vector $\sigma$ (parallel to the ultrasound propagation vector for longitudinal waves) is along the $b$ axis. At low fields, the obtained data reproduce the reported behavior$^{25}$. As indicated by the arrow, $\Delta v/\nu$ exhibits an anomaly accompanied by suppression of the superconductivity at $3 \pm 0.5$ T when $\theta\approx 0^\circ$. From the equation $H_{c2}(90^\circ) = \nu_0(2n\xi)$, where $\nu_0$ is the flux quantum, an in-plane coherence length of $\xi\approx 10$ nm is determined. The gradual increase in $\Delta v/\nu$ between 3 T and 7 T reflects the suppression of fluctuating superconductivity above $H_{c2}$ since $\Delta v/\nu$ is a sensitive indicator of fluctuations of the superconducting order parameter in organic superconductors. At higher fields, both properties exhibit oscillations of the superconducting order parameter in the Supplementary Materials. For the $\alpha$ orbit, an estimation of the mean-free path $\ell$ from a fit to the typical Lifshitz-Kosevich formula leads to $\ell\approx 90$ nm. This value sufficiently larger than $\xi\approx 10$ nm indicates that the electronic system is in the clean limit, which meets one of the requirements for the emergence of the FFLO state. For the Maki parameter, the phase diagram, which is consistent with our results discussed later, indicates $\Delta v/\nu\approx 8^\circ$, which is approximately 4 times larger than required. Thus, the present sample satisfies the conditions required to form the FFLO state.

Since the FFLO state appears at low temperatures when the orbital effect is sufficiently suppressed, in Fig. 2, we show the magnetic field dependence of the elastic properties $\nu(\nu)$ at 2.1 K near the parallel direction, with $\theta\approx 1.2^\circ$. Note that no clear hysteresis was observed in our present measurements (see Supplementary Fig. 4). At $\theta\approx 0^\circ$, the field dependence of $\Delta v/\nu$ has two dips at $-21.3$ T (blue circle) and $-24.5$ T (black triangle), as indicated by the symbols in Fig. 2a. These anomalies are observed as peaks in $\Delta v$ in Fig. 2b. Based on the results of previous studies$^{26-30}$, these characteristic fields correspond to $H_{\text{FFLO}}$ and $H_{c2}$, respectively, and the FFLO state appears between $H_{\text{FFLO}}$ and $H_{c2}$. Upon tilting the sample away from $0^\circ$, $H_{c2}$ abruptly decreases, whereas $H_{\text{FFLO}}$ shows barely any change. Since these two anomalies finally merge into one sharp anomaly at $\theta\approx 1.2^\circ$, the FFLO state is completely suppressed by this slight tilt. This result is perfectly consistent with the report that the FFLO state at 2.0 K only exists for $\theta < 1.2^\circ$. To clearly examine the ultrasonic properties of the FFLO state, the datasets of $\theta = 0^\circ$ and $\theta = 1.2^\circ$ are enlarged in Fig. 2c, d.
light green area corresponds to the contribution of the FFLO state. This result indicates that the formation of the FFLO state leads to the lattice hardening in the $u \parallel b$ direction. For $\Delta \alpha$ in Fig. 2d, attenuation of the sound wave propagation by FFLO formation is natural because of the spatially inhomogeneity. Near $H_{c2}$, a flux flow gives excess attenuation appearing as a peak in $\Delta \alpha$, and therefore, the combination of the two peaks at $H_{\text{FFLO}}$ and $H_{c2}$ produces the observed behavior above $H_{\text{FFLO}}$. Note that the difference below $H_{\text{FFLO}}$ (gray area) originates from perpendicular components of the applied fields because it appears when a field is tilted away from $\theta = 0^\circ$. The perpendicular component, which penetrates the conducting plane and forms pancake vortices, induces excess dynamics of the pancake vortices. Therefore, when $\theta = 0^\circ$, the lattice is softened and $\Delta \alpha$ is enhanced, leading to the difference highlighted by the gray area.

In Fig. 3a, b, we show the $H_{\text{FFLO}}$ and $H_{c2}$ of the detected anomalies at 2.1 K and 6.3 K as an $H$ vs. $\theta$ plot. The cusp-like angular dependence of $H_{c2}$ at 6.3 K can be described by the Tinkham 2D model. Indeed, the interlayer coherence length $\xi \approx 1.4$ nm (= $\phi_{0}/2\pi c H_{c2}(0^\circ)$) is smaller than the interlayer distance of 1.5 nm, indicating that the interlayer coupling of the superconductivity is weak. This anisotropic behavior and the values of $H_{c2}$ agree well with the results reported in refs. 22,24,33. However, this model cannot reproduce $H_{c2}$ at 2.1 K because of the emergence of the FFLO state. The $H_{c2}$ determined by the resistivity (see Supplementary Materials) at 1.6 K also exhibits similar behavior, as shown by the pink triangles (right axis) in Fig. 3a. The abrupt suppression of $H_{c2}$ when moving away from $\theta = 0^\circ$ means that the FFLO state is easily destabilized even by the small orbital effect induced by the slight tilt. This fragility to the orbital effect is also a well-known characteristic peculiar to the FFLO state. In contrast, the angle dependence of $H_{\text{FFLO}}$ is not significant. As $H_{\text{FFLO}}$ corresponds to $H_{c2}$ determined by the paramagnetic effect, the angle-insensitive behavior is suggestive of isotropic Pauli paramagnetism. This fact is also consistent with the almost isotropic $g$-factor in the organic compounds composed of light atoms with weak spin-orbit coupling. In Fig. 3c, we organize the present results as the obtained $H$-$T$ superconducting phase diagram at $\theta = 0^\circ$. For comparison, we additionally show the data of earlier reports (blank symbols)20,23,24. Our results are in good agreement with the reported data. In addition, the temperature dependence of the reduced superconducting gap amplitude $\Delta(0)/\Delta(0K)$ calculated by the basic BCS theory is also shown on the right axis. Since the $\alpha$ model, a simple extension of the BCS theory, well describes the thermal variation in $\Delta(0)/\Delta(0K)$41, the behavior roughly reconciling with the temperature dependence of $H_{c2}$ for the homogeneous superconducting state is reasonable. Above we assumed that the FFLO state would appear between $H_{\text{FFLO}}$ and $H_{c2}$ according to the results of previous studies, this consistency certainly confirms that the high-field phase is non-BCS superconductivity emerging above $H_{c2}$.

Apart from the phase diagram, examination in further detail of the pinning effect enhanced in the FFLO state is interesting. In Fig. 4a, we compare the field dependence of $\Delta \nu/\nu$ at $\theta = 0^\circ$ taken for the parallel (u) and perpendicular (u $\parallel b$) configurations under the same conditions. There is only a small difference depending on the sound wave direction below $H_{\text{FFLO}}$. The difference becomes significantly larger in the FFLO region $H_{\text{FFLO}} < H < H_{c2}$ (green area). Since the acoustic response for $\theta = 90^\circ$ is almost isotropic in the whole field region, as shown in Fig. 4b, the behavior is clear evidence of the emergent anisotropy of the FFLO state.

**Discussion**

Since the anisotropy appears only in the reported field-temperature region of the FFLO state, the present results demonstrate that the
emergent anisotropy originates from the formation of the FFLO state. Given an additional periodicity of the spatial modulation, it seems natural that the stiffness of the lattice in the direction across that modulation pattern should increase. Thus, sound velocity measures the stiffness of crystal lattice. Namely, the \( \mathbf{q} \) vector is oriented along the \( b \)-axis, perpendicular to the field direction in the present setup. Nevertheless, how this manifests as a change in \( \Delta \omega / \nu \) must be discussed. The most likely possibility is flux pinning because vortices have a strong influence on elastic properties in the superconducting state\(^{46,47}\). Typically, suppression of vortex motion results in lattice hardening through increase in spring constant. As shown in Fig. 2a, the enhancement of \( \Delta \omega / \nu \) with increasing magnetic field in the lower-field region indicates compression of the flux-line lattice, which reduces the vortex dynamics. When the vortex lattice melts, \( \Delta \omega / \nu \) decreases and shows a minimum. In Figs. 2c and 4a, the lattice hardening observed in \( \mathbf{u} \parallel \mathbf{b} \) suggests that the spatial modulation when \( H \parallel \mathbf{c} \) reinforces pinning of the flux lines. When this spatial modulation traps the flux lines, the Josephson vortices should be pinned at nodes of the spatial modulation of the FFLO state because the Josephson supercurrent is the Josephson vortices should be pinned at nodes of the spatial

Next, we need to consider the question of why the orientation of the \( \mathbf{q} \) vector is mainly along the \( b \)-axis, perpendicular to the field direction in the present configuration. Note, here, that the effect of the spin-orbit interaction on the FFLO state in the present salt is negligible because the organic salt is composed of light elements. In the case of ideal isotropic 3D superconductors, the \( \mathbf{q} \) vector always points in the field direction\(^{29,30}\). Since the \( \mathbf{q} \) vector can be oriented in any direction in 3D, the anisotropy can be discussed in the Heisenberg-type model. According to this framework, in the present measurement with \( H \parallel \mathbf{c} \), the \( \mathbf{q} \) vector should be parallel to the \( c \)-axis, not the \( b \)-axis. However, the present superconductivity is described by the 2D model (Fig. 3b). For 2D superconductors, the better nesting vectors on the Fermi surface make the FFLO state more stable, and the anisotropy of the Fermi surface often locks the direction of the \( \mathbf{q} \) vector according to the predominant nesting vectors\(^{9,42}\). Namely, the FFLO state in the anisotropic 2D superconductor is expected to show Ising-type behavior. Indeed, theoretical studies\(^{29,30}\) suggest that the nesting vector \( \mathbf{Q}_n \) parallel to the \( k_c \)-axis (green arrow in Fig. 1d), always strongly relates to the Cooper pairing in \( k \)-type organic salts regardless of the emergent pairing symmetry. Thus, the \( \mathbf{q} \) vector parallel to the \( b \)-axis in the FFLO state should be reasonable for the present 2D superconductor. This result suggests that the direction of the emergent anisotropy and the model describing it, such as Ising, XY, and Heisenberg, can be controlled by changing the shape of the Fermi surface and dimensionality. Future studies of the in-plane field angle dependence of the emergent anisotropy will allow for further detailed discussions of the relation between the \( \mathbf{q} \) vector and nesting vector. Furthermore, similar measurements in other FFLO candidates would also be interesting, as different anisotropies using other nesting vectors should occur in other FFLO candidates.
The present multidirectional ultrasound measurements demonstrate the emergent anisotropy of the FFLO state induced by the spatial modulation of the order parameter. Since $\kappa$-(BEDT-TTF)$_2$Cu(NCS)$_2$ is a 2D clean superconductor, the FFLO state shows Ising anisotropy originating from the anisotropic Fermi surface. Further studies of other FFLO candidates with various features, such as 3D and slight dirtiness, will facilitate a deeper understanding of the FFLO state.

**Methods**

**Sample preparation**

Single crystals of $\kappa$-(BEDT-TTF)$_2$Cu(NCS)$_2$ measured in this study were synthesized by typical electrochemical process and crystallized as black hexagonally-shaped blocks. The shape of the crystals used in the ultrasonic measurements was modified as described in the Supplementary Materials. Ultrasound measurements: Using the typical pulse-echo methods, the ultrasonic properties were measured. Longitudinal ultrasound waves, whose frequencies were in the range of $37$–$39$ MHz, were generated and detected by LiNbO$_3$ piezoelectric transducers (90 µm thickness) attached on side surfaces of the crystals. Further details of the setup are presented in the Supplementary Materials.

**Data availability**

All data needed to evaluate the conclusions in the paper are present in the paper and/or the Supplementary Information. Additional data related to this paper may be requested from the authors.
