Universal Lower Bound for Causal Structure Learning with Interventions

May 20, 2022

Abstract

A well-studied challenge that arises in the structure learning problem of causal directed acyclic graphs (DAG) is that using observational data, one can only learn the graph up to a “Markov equivalence class” (MEC). The remaining undirected edges have to be oriented using interventions, which can be very expensive to perform in applications. Thus, the problem of minimizing the number of interventions needed to fully orient the MEC has received a lot of recent attention, and is also the focus of this work. Our first result is a new universal lower bound on the number of single-node interventions that any algorithm (whether active or passive) would need to perform in order to orient a given MEC. Our second result shows that this bound is, in fact, within a factor of two of the size of the smallest set of single-node interventions that can orient the MEC. Our lower bound is provably better than previously known lower bounds. Further, using simulations on synthetic graphs and by giving examples of special graph families, we show that our bound is often significantly better. To prove our lower bound, we develop the notion of clique-block shared-parents (CBSP) orderings, which are topological orderings of DAGs without v-structures and satisfy certain special properties. We also use the techniques developed here to extend our results to the setting of multi-node interventions.

1 Introduction

Causal Bayesian Networks (CBN) provide a very convenient framework for modeling causal relationships between a collection of random variables (Pearl, 2009). A CBN is fully specified by (a) a directed acyclic graph (DAG), whose nodes model random variables of interest, and whose edges depict immediate causal relationships between the nodes, and (b) a conditional probability distribution (CPD) of each variable given its parent variables (in the DAG) such that the joint distribution of all variables factorizes as a product of these conditionals. The generality of the framework has led to CBN becoming a popular tool for the modeling of causal relationships in a variety of fields, with health science (Shen et al., 2020), molecular cell biology (Friedman, 2004), and computational advertising (Bottou et al., 2013) being a few examples.

It is well known that the underlying DAG of a CBN is not uniquely determined by the joint distribution of its nodes. In fact, the joint distribution only determines the DAG up to its Markov Equivalence Class (MEC), which is represented as a partially directed graph with well-defined combinatorial properties (Verma and Pearl, 1990; Chickering, 1995; Meek, 1995; Andersson et al., 1997). Information about which nodes are adjacent is encoded in the MEC, but the direction of several edges remains undetermined. Thus, learning algorithms based only on the observed joint distribution (Glymour et al., 2019) cannot direct these remaining edges. As a result, algorithms which use additional interventional distributions were developed (Squires et al. (2020) and references therein). In addition to the joint distribution, these algorithms also assume access to interventional distributions generated as a result of randomizing some target vertices in the original CBN (a process called intervention) and thereby breaking their dependence on any of their ancestors. A natural and well-motivated (Eberhardt et al., 2005) question, therefore, is to find the minimum number of interventions required to fully resolve the orientations of the undirected edges in the MEC.

Interventions, especially on a large set of nodes, however, can be expensive to perform (Kocaoglu et al., 2017). In this respect, the setting of atomic interventions, where each intervention is on a single node, is already very interesting and finding the smallest number of atomic interventions that can orient the MEC is well studied (Squires et al., 2020). A long line of work, including those cited above, has considered in various settings the problem of designing methods for finding the smallest set of atomic interventions that would fully orient all edges of a given MEC. An important distinction between such methods is whether they are active (He and Geng, 2008), i.e., where the directions obtained via the current intervention are available before one decides which further interventions to perform; or passive, where all the interventions to be performed have to be specified beforehand. Methods can also differ in whether or not randomness is used in selecting the targets of the interventions. An important question, therefore, is to understand how many interventions must be performed by any given method to fully orient an MEC.

Universal Lower Bounds While several works have reported lower bounds (on minimum number of atomic interventions required to orient an MEC) in different settings, a very satisfying solution concept for such lower bounds, called universal lower bounds, was proposed by Squires et al. (2020). A universal lower bound of $L$ atomic interventions for orienting a given MEC means that if a set of atomic interventions is of size less than $L$, then for every ground-truth DAG $D$ in the MEC, the set $S$ will fail to fully orient the MEC. Thus, a universal lower bound has two universality properties. First, the value of a universal lower bound depends only upon the MEC, and applies to every DAG in the MEC. Second, the lower bound applies to every set of interventions that would fully orient the MEC, without regards to the method by which the intervention set was produced.

In this work, we address the problem of obtaining tight universal lower bounds. The goal is to find a universal lower bound such that for any DAG $D$ in the MEC, the smallest set of atomic interventions...
that can orient the MEC into $D$ has size bounded above by a constant factor of the universal lower bound. Similar to Squires et al. (2020), we work in the setting of causally sufficient models, i.e. there are no hidden confounders, selection bias or feedback. To the best of our knowledge, this is the first work that addresses the problem of tight (up to a constant factor) universal lower bounds. We note that the best known universal lower bounds (Squires et al., 2020) so far are not tight and provide concrete examples of graph families that illustrate this in Section 3.2.

1.1 Our Contributions and Organization of the Paper

We prove a new universal lower bound on the size of any set of atomic interventions that can orient a given MEC, improving upon previous work (Squires et al., 2020). We further prove that our lower bound is optimal within a factor of 2 in the class of universal lower bounds: we show that for any DAG $D$ in the MEC, there is a set of atomic interventions of size at most twice our lower bound, that would fully orient the MEC if the unknown ground-truth DAG were $D$.

We also compare our new lower bound with the one obtained previously by Squires et al. (2020). We prove analytically that our lower bound is at least as good as the one given by Squires et al. (2020). We further give examples of graph classes where our bound is significantly better (in fact, it is apparent from our proof that the graphs in which the two lower bounds are close must have very special properties). We then supplement these theoretical findings with simulation results comparing our lower bound with the “true” optimal answer and with the lower bound in previous work.

Further, using the techniques developed in our work, we explore how tight our lower bound remains in the setting of multi-node interventions. See Section 4 for more details.

Our lower bound is based on elementary combinatorial arguments drawing upon the theory of chordal graphs, and centers around a notion of certain special topological orderings of DAGs without v-structures, which we call clique-block shared-parents (CBSP) orderings (Definition 3). This is in contrast to the earlier work of Squires et al. (2020), where they had to develop sophisticated notions of directed clique trees and residuals in order to prove their lower bound. We expect that the notion of CBSP orderings may also be of interest in the design of optimal intervention sets.

Many of the proofs are deferred to the appendix. In particular, Section B of the appendix gives, for the sake of completeness, proofs of many folklore observations concerning the notion of interventional Markov equivalence.

1.2 Related Work

The theoretical underpinning for many works dealing with the use of interventions for orienting an MEC can be said to be the notion of “interventional” Markov equivalence (Hauser and Bühlmann, 2012), which, roughly speaking, says that given a collection $I$ of sets of targets for interventions, two DAGs $D_1$ and $D_2$ are $I$-Markov equivalent if and only if for all $S \in I$, the DAGs obtained by removing from $D_1$ and $D_2$ the incoming edges of all vertices in $S$ are in the same MEC (Hauser and Bühlmann, 2012, Theorem 10). Thus, interventions have the capability of distinguishing between DAGs in the same Markov Equivalence class, and in particular, “interventional” Markov equivalence classes can be finer than MECs (Hauser and Bühlmann, 2012, see also Theorem 1 below).

As described above, the problem of learning the orientations of a CBN using interventions has been studied in a wide variety of settings. Lower bounds and algorithms for the problem have been obtained in the setting of interventions of arbitrary sizes and with various cost models (Eberhardt, 2008; Shanmugam et al., 2015; Kocaoglu et al., 2017), in the setting when the underlying model is allowed to contain feedback
loops (and is therefore not a CBN in the usual sense) (Hyttinen et al., 2013a,b), in settings where hidden variables are present (Addanki et al., 2020, 2021), and in interventional "sample efficiency" settings (Agrawal et al., 2019; Greenewald et al., 2019). The related notion of orienting the maximum possible number of edges given a fixed budget on the number or cost of interventions has also been studied (Hauser and Bühlmann, 2014; Ghassami et al., 2018; AhmadiTeshnizi et al., 2020). However, to the best of our knowledge, the work of Squires et al. (2020) was the first to isolate the notion of a universal lower bound, and prove a lower bound in that setting.

2 Preliminaries

Graphs A partially directed graph (or just graph) \( G = (V, E) \) consists of a set \( V \) of nodes or vertices and a set \( E \) of adjacencies. Each adjacency in \( E \) is of the form \( a \rightarrow b \) or \( a \leftarrow b \), where \( a, b \in V \) are distinct vertices, with the condition that for any \( a, b \in V \), at most one of \( a \rightarrow b \), \( a \leftarrow b \) and \( b \leftarrow a \) is present in \( E \).

If there is an adjacency in \( E \) containing both \( a \) and \( b \), then we say that \( a \) and \( b \) are adjacent in \( G \), or that there is an edge between \( a \) and \( b \) in \( G \). If \( a \rightarrow b \in E \), then we say that the edge between \( a \) and \( b \) in \( G \) is undirected, while if \( a \leftarrow b \in E \) then we say that the edge between \( a \) and \( b \) is directed in \( G \). \( G \) is said to be undirected if all its adjacencies are undirected, and directed if all its adjacencies are directed. Given a directed graph \( G \), and a vertex \( v \) in \( G \), we denote by \( pa_G(v) \) the set of nodes \( u \) in \( G \) such that \( u \rightarrow v \) is present in \( G \). A vertex \( v \) in \( G \) is said to be a child of \( u \) if \( u \in pa_G(v) \). An induced subgraph of \( G \) is a graph whose vertices are some subset \( S \) of \( V \), and whose adjacencies \( E[S] \) are all those adjacencies in \( E \) both of whose elements are in \( S \).

This induced subgraph of \( G \) is denoted as \( G[S] \). The skeleton of \( G \), denoted skeleton \( (G) \), is an undirected graph with nodes \( V \) and adjacencies \( a \rightarrow b \) whenever \( a, b \) are adjacent in \( G \).

A cycle in a graph \( G \) is a sequence of vertices \( v_1, v_2, v_3, \ldots, v_n \) such that for each \( 1 \leq i \leq n, \) either \( v_i \rightarrow v_{i+1} \) or \( v_i \leftarrow v_{i+1} \) is present in \( E \). The length of the cycle is \( n \), and the cycle is said to be simple if \( v_1, v_2, \ldots, v_n \) are distinct. The cycle is said to have a chord if two non-consecutive vertices in the cycle are adjacent in \( G \), i.e., if there exist \( 1 \leq i < j \leq n \) such that \( j - i \neq \pm 1 \) (mod \( n \)) and such that \( v_i \) and \( v_j \) are adjacent in \( G \). The cycle is said to be directed if for some \( 1 \leq i \leq n, v_i \rightarrow v_{i+1} \) is present in \( G \). A graph \( G \) is said to be a chain graph if it has no directed cycles. The chain components of a chain graph \( G \) are the connected components left after removing all the directed edges from \( G \). A directed acyclic graph or DAG is a directed graph without directed cycles. Note that both DAGs and undirected graphs are chain graphs. An undirected graph \( G \) is said to be chordal if any simple cycle in \( G \) of length at least 4 has a chord.

A clique \( C \) in a graph \( G = (V, E) \) is a subset of nodes of \( G \) such that any two distinct \( u \) and \( v \) in \( C \) are adjacent in \( G \). The clique \( C \) is maximal if for all \( v \in V \setminus C \), the set \( C \cup \{v\} \) is not a clique.

A perfect elimination ordering (PEO), \( \sigma = (v_1, \ldots, v_n) \) of a graph \( G \) is an ordering of the nodes of \( G \) such that for all \( i \in [n], ne_G(v_i) \cap \{v_1, \ldots, v_{i-1}\} \) is a clique in \( G \), where \( ne_G(v_i) \) is the set of nodes adjacent to \( v_i \).

A graph is chordal if and only if it has a perfect elimination ordering (Blair and Peyton, 1993). A topological ordering, \( \sigma \) of a DAG \( D \) is an ordering of the nodes of \( D \) such that \( \sigma(a) < \sigma(b) \) whenever \( a \in pa_D(b) \), where \( \sigma(u) \) denotes the index of \( u \) in \( \sigma \). We say that \( D \) is oriented according to an ordering \( \sigma \) to mean that \( D \) has a topological ordering \( \sigma \).

A v-structure in a graph \( G \) is an induced subgraph of the form \( b \rightarrow a \leftarrow c \) (v-structures are also known as unshielded colliders). It follows easily from the definitions that by orienting the edges of a chordal graph according to a perfect elimination ordering, we get a DAG without v-structures, and that the skeleton of

\(^1\) \( a \rightarrow b \) and \( b \leftarrow a \) are treated as equal.

\(^2\) Our definition of a PEO uses the same ordering convention as Hauser and Bühlmann (2014).
a DAG without v-structures is chordal (see Proposition 1 of Hauser and Bühlmann (2014)). In fact, any topological ordering of a DAG $D$ without v-structures is a perfect elimination ordering of skeleton $(D)$.

**Interventions** An intervention $I$ on a partially directed graph $G$ is specified as a subset of target vertices of $G$. Operationally, an intervention at $I$ is interpreted as completely randomizing the distributions of the random variables corresponding to the vertices in $I$. We work here in the “infinite sample” setting, where, under standard assumptions, performing the intervention $I$ reveals at least the directions of all edges between vertices in $I$ and $V \setminus I$ (see Theorem 1 below for a more formal statement of the extent to which a set of interventions orients the edges of a partially directed graph). An intervention set is a set of interventions. In this paper, we make the standard assumption that the “empty” intervention, in which no vertices are intervened upon, is always included in any intervention set we consider: this corresponds to assuming that information from purely observational data is always available (see, e.g., the discussion surrounding Definition 6 of Hauser and Bühlmann (2012)). The size of an intervention set $I$ is the number of interventions in $I$, not counting the empty intervention.

$I$ is a set of atomic interventions if $|I| = 1$ for all non-empty $I \in I$ (an intervention $I$ is said to non-atomic if $|I| > 1$). With a slight abuse of notation, we denote a set of atomic interventions $I = \{\emptyset, \{v_1\}, \ldots, \{v_k\}\}$ as just the set $I = \{v_1, \ldots, v_k\}$ when it is clear from the context that we are talking about a set of atomic interventions. Given an intervention set $I$ and a DAG $D$, we denote, following Hauser and Bühlmann (2012), by $E_I(D)$ the partially directed graph representing the set of all DAGs that are $I$-Markov equivalent to $D$. $E_I(D)$ is also known as the $I$-essential graph of $D$ (see Fig. 2 of Hauser and Bühlmann (2014) for an example). For a formal definition of $I$-Markov equivalence, we refer to Definitions 7 and 9 of Hauser and Bühlmann (2012); we use instead the following equivalent characterization developed in the same paper.

**Theorem 1 (Characterization of $I$-essential graphs, Definition 14 and Theorem 18 of Hauser and Bühlmann (2012)).** Let $D$ be a DAG and $I$ an intervention set containing the empty set. A graph $H$ is an $I$-essential graph of $D$ if and only if $H$ has the same skeleton as $D$, all directed edges of $H$ are directed in the same direction as in $D$, all v-structures of $D$ are directed in $H$, and

1. $H$ is a chain graph with chordal chain components.
2. For any three vertices $a, b, c$ of $H$, the subgraph of $H$ induced by $a, b$ and $c$ is not $a \rightarrow b \leftarrow c$.
3. If $a \rightarrow b$ in $D$ (so that $a, b$ are adjacent in $H$) and there is an intervention $J \in I$ such that $|J \cap \{a, b\}| = 1$, then $a \rightarrow b$ is directed in $H$.
4. Every directed edge $a \rightarrow b$ in $H$ is strongly $I$-protected. An edge $a \rightarrow b$ in $H$ is said to be strongly $I$-protected if either (a) there is an intervention $J \in I$ such that $|J \cap \{a, b\}| = 1$, or (b) at least one of the four graphs in Figure 1 appears as an induced subgraph of $H$, and $a \rightarrow b$ appears in that induced subgraph in the configuration indicated in the figure.
3 Universal Lower Bound

In this section, we establish our main technical result (Theorem 4). Our new lower bound (Theorems 8 and 9) then follows easily from this combinatorial result, without having to resort to the sophisticated machinery of residuals and directed clique trees developed in previous work (Squires et al., 2020).

We begin with a definition that isolates two important properties of certain topological orderings of DAGs without v-structures. Given a DAG $D$ without v-structures, let $\gamma$ be the maximal-clique-sink vertices of $D$. Then, for every maximal clique $C$ of skeleton $(D)$, we denote by sink$_D(C)$ any vertex in $D$ such that $C = pa_D(\text{sink}_D(C)) \cup \{\text{sink}_D(C)\}$. The fact that sink$_D(C)$ is uniquely defined, and that sink$_D(C_1) \neq$ sink$_D(C_2)$ when $C_1$ and $C_2$ are distinct maximal cliques of skeleton $(D)$ is guaranteed by the following observation. (The standard proof of this is deferred to Section A.1.)

**Observation 2.** Let $D$ be a DAG without v-structures. Then, for every maximal clique $C$ of skeleton $(D)$, there is a unique vertex $v$ of $D$, denoted sink$_D(C)$, such that $C = pa_D(v) \cup \{v\}$. Further, for any two distinct maximal cliques $C_1$ and $C_2$ in skeleton $(D)$, we have sink$_D(C_1) \neq$ sink$_D(C_2)$.

We refer to each vertex $v$ of $D$ that is equal to sink$_D(C)$ for some maximal clique of skeleton $(D)$ as a maximal-clique-sink vertex of the DAG $D$. Note also that sink$_D(C)$ is also the unique node with out-degree 0 in the induced subgraph $D[C]$.

**Definition 3 (Clique-Block Shared-Parents (CBSP) ordering).** Let $\sigma$ be a topological ordering of a DAG $D$ without v-structures. Let $s_1, s_2, s_3, \ldots, s_r$ be the maximal-clique-sink vertices of $D$ indexed so that $\sigma(s_i) < \sigma(s_j)$ when $i < j$. (Here $r$ is the number of maximal cliques in skeleton $(D)$.) Then, $\sigma$ is said to be a clique-block shared-parents (CBSP) ordering of $D$ if it satisfies the following two properties:

1. **P1: Clique block property** Define $L_i(\sigma)$ to be the set of nodes which occur before or at the same position as $s_i$ in $\sigma$ i.e., $\sigma(u) \leq \sigma(s_i)$. Similarly, for $2 \leq i \leq r$, define $L_i(\sigma)$ to be the set of nodes which occur in $\sigma$ before or at the same position as $s_i$, but strictly after $s_{i-1}$ (i.e., $\sigma(s_{i-1}) < \sigma(u) \leq \sigma(s_i)$). Then, for each $1 \leq i \leq r$ the subgraph induced by $L_i(\sigma)$ in skeleton $(D)$ is a (not necessarily maximal) clique.

2. **P2: Shared parents property** If vertices $a$ and $b$ in $D$ are consecutive in $\sigma$ (i.e., $\sigma(b) = \sigma(a) + 1$), and also lie in the same $L_i(\sigma)$ for some $1 \leq i \leq r$, then all parents of $a$ are also parents of $b$ in $D$.

We illustrate the definition with an example in Figure 2. In the figure, vertices $b$, $e$, and $f$ are the maximal-clique-sink vertices of $D$, and are highlighted with an underbar. The orderings $\sigma'$, $\sigma$ and $\tau$ in
Theorem 4. If $D$ is a DAG without $v$-structures, then $D$ has a CBSP ordering.

Towards the proof of this theorem, we note first that the existence of a topological ordering $\sigma$ satisfying just P1 can be established using ideas from the analysis of, e.g., the “maximum cardinality search” algorithm for chordal graphs (Tarjan and Yannakakis (1984), see also Corollary 2 of Wienöbst et al. (2021)). We state this here as a lemma, and provide the proof in Section A.2.

Lemma 5. If $D$ is a DAG without $v$-structures, then $D$ has a topological ordering $\sigma$ satisfying P1 of Definition 3.

We now prove the theorem.

Proof of Theorem 4. Let $O$ be the set of topological orderings of $D$ which satisfy P1 of Definition 3. By Lemma 5, $O$ is non-empty. If there is a $\sigma \in O$ which also satisfies P2 of Definition 3, then we are done.

We now proceed to show by contradiction that such a $\sigma$ must indeed exist. So, suppose for the sake of contradiction that for each $\sigma$ in $O$, P2 is violated. Then, for each $\sigma \in O$, there exist vertices $a, b$ and an index $i$ such that $a, b \in L_i(\sigma), \sigma(b) = \sigma(a) + 1$, and there exists a parent of $a$ in $D$ that is not a parent of $b$. For any given $\sigma \in O$, we choose $a, b$ as above so that $\sigma(a)$ is as small as possible. With such a choice of $a$ for each $\sigma \in O$, we then define a function $f: O \rightarrow [n - 1]$ by defining $f(\sigma) = \sigma(a)$. Note that by the assumption that P2 is violated by each $\sigma$ in $O$, $f$ is defined for each $\sigma$ in $O$. But then, since $O$ is a finite set, there must be some $\sigma \in O$ for which $f(\sigma)$ attains its maximum value. We obtain a contradiction by exhibiting another $\tau \in O$ for which $f(\tau)$ is strictly larger than $f(\sigma)$. We first describe the construction of $\tau$ from $\sigma$, and then prove that $\tau$ so constructed is in $O$ and has $f(\tau) > f(\sigma)$.

Construction. Given $\sigma \in O$, let $f(\sigma) = j \in [n - 1]$. Let $\sigma(a) = j, \sigma(b) = j + 1$ and suppose that $a, b \in L_i(\sigma)$. By the definition of $f$, there is a parent of $a$ that is not a parent of $b$. Define $C^a$ to be the set $\{a\} \cup \text{pa}_D(a)$. Since $D$ has no $v$-structures, $C^a$ is a clique in skeleton $(D)$. Define $S^a := \{z | C^a \subseteq \text{pa}_D(z)\}$. Let $Y_a$ be the set of nodes occurring after $a$ in $\sigma$ that are not in $S^a$ (note that $b \in Y_a$, and, in general, $z \in Y_a$ if and only if $\sigma(z) > \sigma(a)$ and there is an $x \in C^a$ that is not adjacent to $z$).

We now note the following easy to verify properties of the sets $S^a$ and $Y_a$ (the proof is provided in Section A.3).

Proposition 6. 1. If $y \in Y_a$ and $z$ is a child of $y$ in $D$, then $z \in Y_a$.

2. Suppose that $x \in \{a\} \cup S^a$ is not a maximal-clique-sink node of $D$. Then there exists $y \in S^a$ such that $x \in \text{pa}_D(y)$ and such that $y$ is a maximal-clique-sink node in $D$. In particular, $S^a$ is non-empty.

3. Suppose that $x$ is a maximal-clique-sink node in the induced DAG $H := D[S^a]$. Then $x$ is also a maximal-clique-sink node in $D$.

The ordering $\tau$ is now defined as follows: the first $j$ nodes in $\tau$ are the same as $\sigma$. After this, the nodes of $S^a$ appear according to some topological ordering $\gamma$ of the induced DAG $H := D[S^a]$ that satisfies P1 of
Definition 3 in $H$ (such a $\gamma$ exists because of Lemma 5 applied to the induced DAG $H$, which also cannot have any $v$-structures). Finally, the nodes of $Y_a$ appear according to their ordering in $\sigma$.

Proof that $\tau \in O$ and $f(\tau) > f(\sigma)$. Note first that $\tau$ is a topological ordering of $D$: if not, then there must exist $u \in Y_a$ and $v \in S^a$ such that the edge $u \rightarrow v$ is present in $D$, but this cannot happen by item 1 of Proposition 6 above.

To show that $\tau \in O$ (i.e., that $\tau$ satisfies P1), the following notation will be useful. For each maximal-clique-sink vertex $s$ in $D$, denote by $\lambda(s)$ the unique $L_\alpha(\sigma)$ such that $s \in L_\alpha(\sigma)$. Similarly, denote by $\mu(s)$ the unique $L_\beta(\tau)$ such that $s \in L_\beta(\tau)$. Since $\sigma \in O$, we already know that $\lambda(s)$ is a clique for each maximal-clique-sink node $s$ of $D$. In order to show that $\tau \in O$, all we need to show is that $\mu(s)$ is also a clique for each maximal-clique-sink node $s$ of $D$.

Let $J$ be the set of maximal-clique-sink vertices of $D$ present in $S^a$. By item 2 of Proposition 6, the last vertex in $\gamma$ must be an element of $J$. Note also that $s_i \notin J$ since $b \in Y_a$ and the edge $b \rightarrow s_i$ in $D$ together imply that $s_i \in Y_a$ by item 1 of Proposition 6. We also observe that $\lambda(s) \subseteq S^a$, for all $s \in J$. For if there exists $u \in \lambda(s) \cap Y_a$ then the edge $u \rightarrow s$ in $D$ implies that $s \in Y_a$, contradicting that $s \in S^a$.

From the construction of $\tau$, we already have $\mu(s_j) = \lambda(s_j)$ for all maximal-clique-sink vertices $s_j$ that precede $s_i$ in $\sigma$. From the fact that all vertices in $S^a$ precede $Y_a$ in the ordering $\tau$, and from the observations above that (i) the sink node $s_i \in Y_a$, and (ii) $\lambda(s) \subseteq S^a$, for all sink nodes $s \in S^a$, we also get that for any maximal-clique-sink node $s$ of $D$ such that $s \in Y_a$, $\mu(s) \subseteq \lambda(s)$. Thus, when $s$ is a maximal-clique-sink node of $D$ that is not in $J \subset S^a$, we have that $\mu(s)$ is a clique in skeleton $(D)$, since $\mu(s) \subseteq \lambda(s)$, and $\lambda(s)$ is a clique in skeleton $(D)$. It remains to show that $\mu(s)$ is a clique when $s \in J$.

Let $t_1, t_2, \ldots, t_j$ be the maximal-clique-sink nodes of $H = D[S^a]$, arranged in increasing order by $\gamma$. Since $\gamma$ satisfies P1 in $H$, each $L_i(\gamma)$, $1 \leq i \leq k$, is a clique in $H$ (and thus also in $D$). Now consider a maximal-clique-sink node $s \in J \subseteq S^a$. Since the $t_i$ are maximal-clique-sink nodes of $D$ (from item 3 of Proposition 6), it follows that $\mu(s) \subseteq L_i(\gamma)$ (if $s \in L_i(\gamma)$ for $i \geq 2$) or $\mu(s) \subseteq L_i(\gamma) \cup C^a$ (if $s \in L_1(\gamma)$). In the former case, $\mu(s)$ is automatically a clique, since $L_i(\gamma)$ is a clique in $D$. In the latter case also $\mu(s)$ is a clique since $L_i(\gamma) \subseteq S^a$, so that $L_i(\gamma) \cup C^a$ is a clique in $D$ (since $L_1(\gamma)$ and $C^a$ are cliques, and (ii) by definition of $S^a$, every node of $S^a$ is adjacent to every node in $C^a$).

Thus, we get that $\tau$ also satisfies P1, so that $\tau \in O$. Consider the node $b' := (j + 1)$ next to $a$ in $\tau$. Since $S^a$ is non-empty, the construction of $\tau$ implies $b' \in S^a$, so that $b'$ is adjacent to all parents of $a$. Since $\sigma$ and $\tau$ agree on the ordering of all vertices up to $a$, we thus have $f(\tau) \geq f(b') = j + 1 > j = f(\sigma)$. This gives the desired contradiction to $\sigma$ being chosen as a maximum of $f$. Thus, there must exist some ordering in $O$ which satisfies P2.

At the heart of our lower bound proof is the following important property of CBSP orderings. Our lower bound for atomic interventions on DAGs without $v$-structures, Theorem 8, immediately follows once we isolate this property.

**Lemma 7.** Let $D$ be a DAG without $v$-structures, and let $\sigma$ be a CBSP ordering of nodes in $D$ (at least one such $\sigma$ exists by Theorem 4). Let $a$ and $b$ be any nodes in $D$ that are consecutive in $\sigma$ (i.e., $\sigma(b) = \sigma(a) + 1$) which lie in the same clique block $L_\beta(\sigma)$ of $\sigma$ (in particular the edge $a \rightarrow b$ is present in $D$). Let $I$ be an intervention set containing the empty intervention. Then, the edge $a \rightarrow b$ is directed in $E_I(D)$ if and only if there is an intervention $I' \in I$ such that $|I' \cap \{a, b\}| = 1$.

**Proof.** In case there exists an $I \in I$ such that $|I \cap \{a, b\}| = 1$, the edge $a \rightarrow b$ is directed in $E_I(D)$ by item 3 of Theorem 1.

We now show that if $|I \cap \{a, b\}| \neq 1$ for every $I \in I$, then the edge $a \rightarrow b$ is not directed in $E_I(D)$. Suppose, for the sake of contradiction, that $a \rightarrow b$ is directed in $E_I(D)$. Then, by item 4 of Theorem 1,
a → b must be strongly I-protected in E_I(D). Since |I ∩ \{a, b\}| ≠ 1 for every I ∈ I, one of the graphs in Figure 1 must therefore appear as an induced subgraph of E_I(D). We now show that none of these subgraphs can appear as an induced subgraph of E_I(D).

First, subgraphs (ii) and (iv) cannot be induced subgraphs of E_I(D) since they have a v-structure at b while D (and therefore also E_I(D)) has no v-structures. For subgraph (iii) to appear as an induced subgraph, the vertex c must lie between a and b in any topological ordering of D, which contradicts the fact that a and b are consecutive in the topological ordering σ. For subgraph (i) to appear, we must have a parent c of a that is not adjacent to b. However, since σ is a CBSP ordering, it satisfies property P2 of Definition 3, so that, since a, b are consecutive in σ and belong to the same L_i(σ), any parent of a must also be a parent of b. We thus conclude that a → b cannot be strongly I-protected in E_I(D), and hence is not directed in it. □

**Theorem 8.** Let D be a DAG without v-structures with n nodes. Then, any set I of atomic interventions that fully orients skeleton (D) when the ground-truth DAG is D must be of size at least \(\left\lceil \frac{n-r}{2} \right\rceil\) (skeleton (D) is also the MEC of D, since D has no v-structures). Here \(r\) is the number of distinct maximal cliques in skeleton (D). In other words, if I is a set of atomic interventions such that E_I(D) = D, then \(|I| ≥ \left\lceil \frac{n-r}{2} \right\rceil\).

**Proof.** Lemma 7 implies that any set I of atomic interventions that fully orients D starting with skeleton (D) (i.e., for which E_I(D) = D) must contain at least one node of each pair of consecutive nodes (in σ) of L_i(σ), for each \(i ∈ [r]\). Thus, for each \(i ∈ [r]\), I must contain at least \(\left\lfloor (|L_i(σ)| - 1)/2 \right\rfloor\) nodes of L_i(σ). We therefore have,

\[
|I| ≥ \sum_{i=1}^{r} \left\lceil \frac{|L_i(σ)| - 1}{2} \right\rceil ≥ \sum_{i=1}^{r} \left\lfloor \frac{|L_i(σ)| - 1}{2} \right\rfloor = \sum_{i=1}^{r} \frac{|L_i(σ)| - r}{2} = \left\lceil \frac{n-r}{2} \right\rceil.
\]

The following corollary for general DAGs (those that may have v-structures) follows from the previous result about DAGs without v-structures in a manner identical to previous work (Squires et al., 2020), using the fact that it is necessary and sufficient to separately orient each chordal chain component of an MEC in order to fully orient an MEC (Hauser and Bühlmann, 2014, Lemma 1). We defer the standard proof to Section C.1.

**Theorem 9.** Let D be an arbitrary DAG and let E(D) be the chain graph with chordal chain components representing the MEC of D. Let CC denote the set of chain components of E(D), and \(r(S)\) the number of maximal cliques in the chain component \(S ∈ CC\). Then, any set of atomic interventions which fully orients E(D) must be of size at least

\[
\sum_{S ∈ CC} \left\lceil \frac{|S| - r(S)}{2} \right\rceil ≥ \left\lceil \frac{n-r}{2} \right\rceil,
\]

where \(n\) is the number of nodes in D, and \(r\) is the total number of maximal cliques in the chordal chain components of E(D) (including chain components consisting of singleton vertices).

### 3.1 Tightness of Universal Lower Bound

We now show that our universal lower bound is tight up to a factor of 2: for any DAG D, there is a set of atomic interventions of size at most twice the lower bound that fully orients the MEC of D. In fact, as the proof of the theorem below shows, when D has no v-structures, this intervention set can be taken to be the set of nodes of D that are not maximal-clique-sink nodes of D.
Theorem 10. Let $D$ be a DAG without $v$-structures with $n$ nodes, and let $r$ be the number of distinct maximal cliques in skeleton $(D)$. Then, there exists a set $I$ of atomic interventions of size at most $n - r$ such that $I$ fully orients skeleton $(D)$ (i.e., $E_I(D) = D$).

Proof. Fix any topological ordering $\sigma$ of $D$. Let the maximal cliques of $D$ be $C_1, \ldots, C_r$, and let $s_i := \text{sink}_D(C_i)$, for $i \in [r]$. Observation 2 implies that each node of $S = \{s_1, \ldots, s_r\}$ is distinct. We re-index these nodes according to the ordering $\sigma$, i.e. $\sigma(s_i) < \sigma(s_j)$ when $i < j$. Consider the set $I := V \setminus S$ of atomic interventions (note that $|I| = n - r$). We show that $E_I(D) = D$. Note that every edge of $D$, except those which have both end-points in $S$, has a single end-point in one of the interventions in $I$, and hence is directed in $E_I(D)$ (by item 3 of Theorem 1). We show now that all edges with both end-points in $S$ are also oriented in $E_I(D)$.

Suppose, if possible, that there exist $s_i, s_j \in S$, with $i < j$ such that $s_i$ and $s_j$ are adjacent in skeleton $(D)$, so that the edge $s_i \to s_j$ is present in $D$, but for which $s_i - s_j$ is not directed in $E_I(D)$. We derive a contradiction to this supposition. To start, choose $s_i, s_j$ as above with the smallest possible value of $i$. In particular, this choice implies that every edge of the form $u \to s_i$ in $D$ is directed in $E_I(D)$.

Note that, by Observation 2, $C_i = \{s_i\} \cup \text{pa}_D(s_i)$ and $C_j = \{s_j\} \cup \text{pa}_D(s_j)$ are distinct maximal cliques in skeleton $(D)$. Thus, there must exist an $x \in C_i$ that is not a parent of $s_j$ in $D$. Further, since $\sigma(s_i) < \sigma(s_j)$, all vertices of $C_i$ appear before $s_j$ in $\sigma$. Thus, $x \in C_i$ that is not a parent of $s_j$ in $D$ is also not adjacent to $s_j$ in skeleton $(D)$. Further, by the choice of $i$, the edge $x \to s_i$ is directed in $E_I(D)$. Thus, we have the induced subgraph $x \to s_i - s_j$ in $E_I(D)$. However, according to item 2 of Theorem 1, such a graph cannot appear as an induced subgraph of an $I$-essential graph $E_I(D)$, and we have therefore reached the desired contradiction. It follows that $E_I(D)$ has no undirected edges, and is therefore the same as $D$. $\square$

Using again the fact that it is necessary and sufficient to separately orient each of the chordal chain components of an MEC in order to fully orient an MEC, the following result for general DAGs follows immediately from Theorem 10, and implies that the lower bound for general DAGs is also tight up to a factor of 2 (see Section C.2 for a detailed statement and proof).

Theorem 11. Let $D$ be an arbitrary DAG on $n$ nodes and let $E(D)$ and $r$ be as in the notation of Theorem 9. Then, there is a set of atomic interventions of size at most $n - r$ that fully orients $E(D)$.

3.2 Comparison with Known Lower Bounds

To compare our universal lower bound with the universal lower bound of Squires et al. (2020), we start with the following combinatorial lemma, whose proof can be found in Section C.3.

Lemma 12. Let $G$ be an undirected chordal graph on $n$ nodes in which the size of the largest clique is $\omega$. Then, $n - |C| \geq \omega - 1$, where $C$ is the set of maximal cliques of $G$.

Lemma 12 implies that $\left\lfloor \frac{n - |C|}{2} \right\rfloor \geq \left\lfloor \frac{\omega - 1}{2} \right\rfloor$ in chordal graphs which shows that our universal lower bound is always equal to or better than the one by Squires et al. (2020). The proof of Lemma 12 makes it apparent that two bounds are close only in very special circumstances. ($\text{Split graphs}$ and $k$-trees are some special families of chordal graphs for which $\left\lfloor \frac{n - |C|}{2} \right\rfloor = \left\lfloor \frac{\omega}{2} \right\rfloor$). We further strengthen this intuition through theoretical analysis of special classes of graphs and via simulations.

Examples where our Lower Bound is Significantly Better  We provide two constructions of special classes of chordal graphs in which our universal lower bound is $\Theta(k)$ times the $\left\lfloor \frac{2}{5} \right\rfloor$ lower bound by Squires et al. (2020) for any $k \in \mathbb{N}$. Further discussion of such examples can be found in Section D.
Construction 1. First, we provide a construction by Shanmugam et al. (2015) for graphs that require about $k$ times more number of interventions than their lower bound, where $k$ is size of the maximum independent set of the graph. This construction of a chordal graph $G$ starts with a line $L$ consisting of vertices $1, \ldots, 2k$ such that each node $1 \leq i < 2k$ is connected to $i - 1$ and $i + 1$. For each $1 \leq p \leq k$, $G$ has a clique $C_p$ of size $\omega$ which has exactly two nodes $2p - 1, 2p$ from the line $L$. Maximum clique size of $G$ is $\omega$, number of nodes, $n = k\omega$, and number of maximal cliques, $|C| = 2k - 1$. Thus, for $G$, we have, $n - |C| = k(\omega - 2) + 1$ which implies \(\frac{n - |C|}{2} = \Theta(k) \cdot \frac{\omega}{2}\) for $\omega > 2$.

Construction 2. $G$ has $k$ cliques of size $\omega$, with every pair of cliques intersecting at a unique node $v$. The number of nodes in $G$ is $k(\omega - 1) + 1$, maximum clique size is $\omega$, and number of maximal cliques is $k$, thus, $n - |C| = k(\omega - 2) + 1$ which implies \(\frac{n - |C|}{2} = \Theta(k) \cdot \frac{\omega}{2}\) for $\omega > 2$.

### 4 Multi Node Interventions

In this section, we explore the applicability of the techniques developed in the previous section to the setting of non-atomic interventions, where each intervention can potentially randomize more than one node. We begin with the lower bound in Proposition 13, which is a direct corollary of our lower bound for single-node interventions. Then, in Theorem 16, we explore how tight this lower bound is. The technical core of this result is Theorem 14, which uses some of the ideas behind the notion of CBSP orderings.

**Proposition 13.** Let $D$ be an arbitrary DAG on $n$ nodes and let $E(D)$ and $r$ be as in the notation of Theorem 9. If $I$ is a set of interventions of size at most $k$ that fully orients $E(D)$ (i.e., $E_I(D) = D$), then $|I| \geq \left\lceil \frac{n - r}{2} \right\rceil$. 

**Construction 2.** Let $I$ be a set of interventions of size at most $k$ such that $E_I(D) = D$. Consider the set $I^*$ of single node interventions obtained from $I$ by braking each intervention $I \in I$ into its constituent vertices. Formally, $I^* := \{\emptyset\} \cup \{\{v\} \mid v \in I \text{ for some } I \in I\}$.

Then, (recalling that the empty intervention is not counted when reporting the size of the intervention set), we have $|I^*| \leq k |I|$, since each intervention in $I$ is of size at most $k$. Further, from Corollary 23 in Section B, we also have $E_{I^*}(D) = D$ (since $E_I(D) = D$).

However, from Theorem 9 we know that since $I^*$ is a set of single node interventions which fully orients $E(D)$, we must have $|I^*| \geq \left\lceil \frac{n - r}{2} \right\rceil$. Thus, we get that

\[|I| \geq \left\lceil \frac{|I^*|}{k} \right\rceil = \left\lceil \frac{n - r}{2} \right\rceil.

We conclude that any intervention set of interventions of size at most $k$ that fully orients $E(D)$ must have at least $\left\lceil \frac{n - r}{2} \right\rceil$ interventions.

In Theorem 16 below we show that the above lower bound is tight up to an additive term of roughly $R/k$, where $R$ is the total number of maximal cliques in all “non-singleton” chordal chain components of the MEC, and $k$ is the maximum size of each intervention. The main technical ingredient of that result is the theorem below for a single chain component.

**Theorem 14.** Let $D$ be an DAG on $n$ nodes without v-structures and let $\sigma$ be a topological ordering of $D$ that satisfies the clique block property $P1$ of Definition 3. Suppose that $D$ has $r$ maximal-clique-sink nodes, and let...
Let $L_i(\sigma), 1 \leq i \leq r$ be as in P1 of Definition 3. Then, there is a set $I$ of at most $\sum_{i=1}^{r} \left\lceil \frac{|L_i(\sigma)|}{2} \right\rceil$ nodes such that the intervention set $I := \{\varnothing, I\}$ fully orients $D$ starting from its MEC (which is the same as skeleton $(D)$ as $D$ has no v-structures). In other words, $E_T(D) = D$.

Proof of Theorem 14. The proof is similar to that of Theorem 10. Let $L_i(\sigma)$, for $1 \leq i \leq r$ (where $r$ is the number of maximal-clique-sink nodes of $D$), be as in P1 of Definition 3. For each $1 \leq i \leq r$, order the nodes of $L_i(\sigma)$ as $L_i(\sigma)_j$, $1 \leq j \leq |L_i(\sigma)|$, according to $\sigma$. For each node $v$, let $p(v)$ denote the parent of $v$ that has the highest index according to $\sigma$ (i.e., such that $\sigma(u) \leq \sigma(p(v))$ for every parent $u$ of $v$). $I$ is defined using the following procedure:

**Input:** A DAG $D$ without v-structures  
**Output:** A set $I$ of nodes such that $E_{I}(D) = D$

1. $I \leftarrow \varnothing$;
2. $\sigma \leftarrow$ A topological ordering of $D$ satisfying the clique block property P1 of Definition 3;
3. For $j \in [r]$ do
   4. \[ \text{if } j = 1 \text{ or } p(L_j(\sigma)_1) \notin I \text{ then} \]
   5. \[ I \leftarrow I \cup \{L_j(\sigma)_{2\ell-1} | 1 \leq \ell \leq \left\lceil \frac{|L_j(\sigma)|}{2} \right\rceil \}; \]
   6. \[ \text{else} \]
   7. \[ I \leftarrow I \cup \{L_j(\sigma)_{2\ell} | 1 \leq \ell \leq \left\lceil \frac{|L_j(\sigma)|}{2} \right\rceil \}; \]
4. End
5. Return $I$.

By construction, $|I| \leq \sum_{i=1}^{r} \left\lceil \frac{|L_i(\sigma)|}{2} \right\rceil$. We will now complete the proof by showing that $E_T(D) = D$, where $T := \{\varnothing, I\}$. To do this, we will show that any edge $a \rightarrow b$ in $D$ is directed in $E_T(D)$.

Consider first the case when $a$ and $b$ are in the same $L_i(\sigma)$. If they are also consecutive in $\sigma$, then, by construction, $|I \cap \{a, b\}| = 1$, so that the edge $a \rightarrow b$ would be directed in $E_T(D)$ (by item 3 of Theorem 1). Now, suppose that $a, b$ are in the same $L_i(\sigma)$, but are not consecutive in $\sigma$. Let $v_1, v_2, \ldots v_\ell$ be the vertices (all of which must be in $L_i(\sigma)$) between $a$ and $b$ in $\sigma$, ordered according to $\sigma$. By the previous argument, $a \rightarrow v_1$, $v_1 \rightarrow v_{i+1}$ (for $1 \leq i \leq \ell - 1$) and $v_\ell \rightarrow b$ are all directed edges in $E_T(D)$ (here we are also using the fact that $L_i(\sigma)$ is a clique in skeleton $(D)$). But then, if $a \rightarrow b$ were not directed in $E_T(D)$, the undirected edge $a - b$ along with the above directed path from $a$ to $b$ would form a directed cycle in $E_T(D)$, contradicting item 1 of Theorem 1 (which says that $E_T(D)$ must be a chain graph). Thus, we conclude that if $a$ and $b$ are in the same $L_i(\sigma)$, then $a \rightarrow b$ is directed in $E_T(D)$.

Now, suppose, if possible, that there is some edge $a \rightarrow b$ in $D$ which is not directed in $E_T(D)$. Among all such edges, choose the one for which the pair $(a,b)$ is lexicographically smallest according to $\sigma$. By the previous paragraph, $a$ and $b$ cannot belong to the same $L_i(\sigma)$, so that there must exist $j > i$ such that $a \in L_i(\sigma)$ and $b \in L_j(\sigma)$. We consider the possibilities $b = L_j(\sigma)_1$ and $b \neq L_j(\sigma)_1$ separately.

Suppose first, if possible, that $b \neq L_j(\sigma)_1$. Then, there must exist a vertex $c \in L_j(\sigma)$, such that $c \rightarrow b$ is directed in $E_T(D)$ (here again we use the fact that $L_j(\sigma)$ is a clique). Now, $a$ must be adjacent to $c$ in skeleton $(D)$, for otherwise, $E_T(D)$ would contain the induced graph $c \rightarrow b \rightarrow a$, contradicting item 2 of Theorem 1. Further, the edge $a \rightarrow c$ must be directed in $E_T(D)$, by the choice of $(a,b)$ as the lexicographically smallest undirected edge in $E_T(D)$ (for otherwise, $(a,c)$ would be a lexicographically smaller undirected edge compared to $(a,b)$, since $c$ comes before $b$ in $\sigma$). But we then have the directed cycle $a \rightarrow c \rightarrow b \rightarrow a$ in $E_T(D)$, thereby contradicting item 1 of Theorem 1 (which says that $E_T(D)$ must be a chain graph). Thus, we conclude that $b \neq L_j(\sigma)_1$ is not possible.
This leaves only the possibly that \( b = L_j(\sigma)_1 \). We now show that this also leads to contradiction. Consider first the case that \( b \in I \). Then, since the edge \( a \to b \) is undirected in \( E_I(D) \), we must have \( a \in I \) also (by item 3 of Theorem 1).

From the construction of \( I \), it then follows that \( p(b) \neq a \) and also that \( p(b) \notin I \) (to see this consider line 4 of the process above, and note that by our choice of \( a \) and \( b \), \( b = L_j(\sigma)_1 \) and \( a \in L_i(\sigma) \) with \( j > i \geq 1 \)). Thus, \( |I \cap \{a,p(b)\}| = 1 \) and \( |I \cap \{b,p(b)\}| = 1 \). Similarly, if \( b \notin I \), then, since the edge \( a \to b \) is undirected in \( E_I(D) \), we must have \( a \notin I \) also (by item 3 of Theorem 1).

By the condition on line 4 of the construction of \( I \), we must then have \( p(b) \in I \) (since \( b \notin I \)), and hence again that \( a \neq p(b) \) and \( |I \cap \{a,p(b)\}| = 1 \), \( |I \cap \{b,p(b)\}| = 1 \).

Thus, we obtain that if \( b = L_j(\sigma)_1 \), then \( a \neq p(b) \), and further that \( |I \cap \{a,p(b)\}| = 1 \) and \( |I \cap \{b,p(b)\}| = 1 \). Since \( D \) has no \( v \)-structures, we must have the edge \( a \to p(b) \) in \( D \) (by the definition of \( p(b) \)), and also in \( E_I(D) \) (by item 3 of Theorem 1, since \( |I \cap \{a,p(b)\}| = 1 \)). Also \( p(b) \to b \) in \( E_I(D) \) (by item 3 of Theorem 1, since \( |I \cap \{b,p(b)\}| = 1 \)). But then \( E_I(D) \) contains the directed cycle \( a \to p(b) \to b \to a \), which contradicts item 1 of Theorem 1 (which says that \( E_I(D) \) must be a chain graph). We conclude that \( b = L_j(\sigma)_1 \) is also not possible. This concludes the proof.

\[ \square \]

**Corollary 15.** Let \( D \) be an arbitrary DAG and let \( E(D) \) be the chain graph with chordal chain components representing the MEC of \( D \). Let \( CC \) denote the set of chain components of \( E(D) \), and \( r(S) \) the number of maximal cliques in the chain component \( S \in CC \). Let \( \sigma(S) \) be a topological ordering of \( D[S] \) satisfies the clique block property \( P1 \) of Definition 3 (note that \( D[S] \) is a DAG without \( v \)-structures since \( S \) is a chain component of \( E(D) \)). Let \( L_i(\sigma(S)), 1 \leq i \leq r(S) \) be as in \( P1 \) of Definition 3. Then, there is a set \( I \) of at most \( \sum_{S \in CC} I(|S| > 1) \sum_{i=1}^{r(S)} \left\lfloor \frac{L_i(\sigma(S))}{2} \right\rfloor \) nodes such that the intervention set \( I := \{\emptyset, I\} \) fully orients \( D \) starting from its MEC. In other words, \( E_I(D) = D \).

**Proof of Corollary 15.** We use Corollary 22, which says that it is sufficient to orient all chain components of \( E(D) \) in order to fully orient \( E(D) \). Formally, for each \( S \in CC, D[S] \) is a DAG without \( v \)-structures. Thus, for each \( S \in CC \) with \( |S| > 1 \), we see from Theorem 14 that there is a set \( I_S \subseteq S \) of size at most \( \sum_{i=1}^{r(S)} \left\lfloor \frac{L_i(\sigma(S))}{2} \right\rfloor \) such that \( E_{(\emptyset, I_S)}(D[S]) = D[S] \). We now define

\[
I := \bigcup_{S \in CC, |S| > 1} I_S \quad \text{and} \quad I := \{\emptyset, I\}.
\]

In the notation of Corollary 22, we thus have \( I_S = \emptyset, S \) for every \( S \in CC \) with \(|S| > 1 \). Thus from the above discussion, we have \( E_I(D[S]) = D[S] \) for every \( S \in CC \) (this equation is trivially true for those \( S \in CC \) for which \(|S| = 1 \), since in that case \( D[S] \) does not have any edges to direct). Corollary 22 thus implies that \( E_I(D) = D \). The claim now follows from the definitions of \( I \) and \( I_S \) above.

\[ \square \]

**Theorem 16.** Let \( D \) be an arbitrary DAG on \( n \) nodes and let \( E(D) \) and \( r \) be as in the notation of Theorem 9. Then, there exists a set \( I \) of interventions of size at most \( k \) such that \( I \) fully orients \( E(D) \) \( (i.e., E_I(D) = D) \) and \( |I| \leq \left\lceil \frac{n^r}{k} \right\rceil + \left\lceil \frac{r^*}{k} \right\rceil \). Here, \( r^* \) is the total number of maximal cliques in the chordal chain components of \( E(D) \), excluding chain components of singleton vertices.

**Proof of Theorem 16.** From Corollary 15, we get that there exists a set \( I \) with \(|I| \leq \sum_{S \in CC} I(|S| > 1) \sum_{i=1}^{r(S)} \left\lfloor \frac{L_i(\sigma(S))}{2} \right\rfloor \) such that \( I^* := \{\emptyset, I\} \) fully orients \( D \) starting from \( E(D) \). Now, write the elements of \( I \) as \( I_1, I_2, \ldots, I_{|I|} \), and define the partitions

\[
I_i := \{I_1 \cup \cdots \cup I_{i-1} \cup I_i \}.
\]
for \( i \in \{1, 2, \ldots, \left\lceil \frac{|I|}{k} \right\rceil \} \). Then, Corollary 23 implies that if \( I^* = \{\emptyset, I\} \) fully orients \( E(D) \), then \( I := \{\emptyset, I^1, I^2, \ldots, I^{|I|}\} \) also fully orients \( E(D) \). Thus, we conclude that \( I \) indeed fully orients \( E(D) \) (i.e., \( \mathcal{E}_I(D) = D \)). Now, we have,

\[
|I| \leq \sum_{S \in \mathcal{C}} I(|S| > 1) \sum_{i=1}^{r(S)} \left\lfloor \frac{|L_i(\sigma(S))|}{2} \right\rfloor \leq \sum_{S \in \mathcal{C}} I(|S| > 1) \left( \sum_{i=1}^{r(S)} \left\lfloor \frac{|L_i(\sigma(S))|}{2} \right\rfloor + 1 \right) \leq \sum_{S \in \mathcal{C}} I(|S| > 1) \left( \sum_{i=1}^{r(S)} \left\lfloor \frac{|L_i(\sigma(S))|}{2} - \frac{1}{2} \right\rfloor + r(S) \right) \leq \sum_{S \in \mathcal{C}} \left\lfloor \frac{|S| - r(S)}{2} \right\rfloor + r^* = \left\lfloor \frac{n - r}{2} \right\rfloor + r^*.
\]

Therefore, recalling that the empty intervention is not counted when reporting the size of an intervention set, we see that the size of the intervention set \( I \) satisfies

\[
|I| = \left\lfloor \frac{|I|}{k} \right\rfloor \leq \left\lfloor \frac{n - r}{2k} \right\rfloor + \frac{r^*}{k} \leq \left\lfloor \frac{n - r}{2k} \right\rfloor + \left\lfloor \frac{r^*}{k} \right\rfloor.
\]

Thus, we get that \( |I| \) is at most \( \left\lceil \frac{r^*}{k} \right\rceil \) more than the lower bound of \( \left\lfloor \frac{n - r}{2k} \right\rfloor \) imposed by Proposition 13 on the smallest set of interventions of size at most \( k \) that fully orients \( D \) starting from \( E(D) \). This completes the proof.

5 Empirical Explorations

In this section, we report the results of two experiments on synthetic data. In Experiment 1, we compare our lower bound with the optimal intervention size for a large number of randomly generated DAGs. Optimal intervention size for a DAG \( D \) is defined as the size of the smallest set of atomic interventions \( I \) such that \( \mathcal{E}_I(D) = D \). Next, in Experiment 2, we compare our universal lower bound with the one in the work of Squires et al. (2020) for randomly generated DAGs with small cliques. These experiments provide empirical evidence that strengthens our result about the tightness of our universal lower bound (Theorem 11) and the constructions presented in Section 3.2. The experiments use the open source causaldag (Squires, 2018) and networkx (Hagberg et al., 2008) packages. Further details about the experimental setup for both experiments are given in Section E.

Experiment 1 For this experiment, we generate 1000 graphs from Erdős-Rényi graph model \( G(n, p) \): for each of these graphs, the number of nodes \( n \) is a random integer in \([5, 25]\) and the connection probability \( p \) is a random value in \([0.1, 0.3]\). These graphs are then converted to DAGs without v-structures by imposing a random topological ordering and adding extra edges if needed. To compute the optimal intervention size,
we check if a subset of nodes, $I$ of a DAG $D$ is such that $E_I(D) = D$, in increasing order of the size of such subsets. Next, we compute the universal lower bound value for each of these DAGs as given in Theorem 9. In Figure 3, we plot the optimal intervention size and our lower bound for each of the generated DAGs. Thickness of the points is proportional to the number of points landing at a coordinate. Notice that, all points lie between lines $y = x$ and $y = 2x$, as implied by our theoretical results. Further, we can see that, a large fraction of points are closer to the line $y = x$ compared to the line $y = 2x$, suggesting that our lower bound is even tighter for many graphs.

**Experiment 2** For this experiment, we generate 1000 random DAGs without v-structures for each size in $\{10, 20, 30, 40, 50, 60\}$ by fixing a perfect-elimination ordering of the nodes and then adding edges (which are oriented according to the perfect-elimination ordering) to the DAG making sure that there are no v-structures, while trying to keep the size of each clique below 5. For each DAG, we compute the ratio of the two lower bounds. In Figure 4, we plot each of these ratios in a scatter plot with the $x$-axis representing the number of nodes of the DAG. Thickness of the points is proportional to the number of DAGs having a particular value of the ratio described above. We also plot the average of the ratios for each different value of the number of nodes. We see that our lower bound can sometimes be $\sim 5$ times of the lower bound of Squires et al. (2020). Moreover, the average ratio has an increasing trend suggesting that our lower bound is much better for this class of randomly generated DAGs.

### 6 Conclusion

We prove a strong universal lower bound on the minimum number of atomic interventions required to fully learn the orientation of a DAG starting from its MEC. For any DAG $D$, by constructing an explicit
Figure 4: Comparison of our Universal Lower Bound with that of Squires et al. (2020)

set of atomic interventions that learns $D$ completely (starting with the MEC of $D$) and has size at most twice of our lower bound for the MEC of $D$, we show that our universal lower bound is tight up to a factor of two. We prove that our lower bound is better than the best previously known universal lower bound (Squires et al., 2020) and also construct explicit graph families where it is significantly better. We then provide empirical evidence that our lower bound may be stronger than what we are able to prove about it: by conducting experiments on randomly generated graphs, we demonstrate that our lower bound is often tighter (than what we have proved), and also that it is often significantly better than the previous universal lower bound (Squires et al., 2020). We then illustrate that the notion of CBSP orderings is also useful in handling the case of multi-node interventions. An interesting direction for future work is to design intervention sets of sizes close to our universal lower bound. We note that in contrast to the earlier work of Squires et al. (2020), whose lower bound proofs were based on new sophisticated constructions, our proof is based on the simpler notion of a CBSP ordering, which in turn is inspired from elementary ideas in the theory of chordal graphs. We expect that the notion of CBSP orderings may also play an important role in future work on designing optimal intervention sets.

A  Properties of Clique-Block Shared-Parents Orderings: Omitted Proofs

In this section, we provide the omitted proofs of the various properties of CBSP orderings.

A.1  Proof of Observation 2

Proof of Observation 2. Let $C$ be a maximal clique of skeleton $(D)$. Since the induced subgraph $D[C]$ is a DAG, there is at least one node $s$ in $D[C]$ with out-degree 0. Thus, for all $v \in C, v \neq s$ we have, $v \rightarrow s$, which implies that $C \setminus \{s\} \subseteq pa_D(s)$. Now, $pa_D(s) \cup \{s\}$ must be a clique as $D$ does not contain v-structures. Thus, we must indeed have $pa_D(s) = C \setminus \{s\}$ since $C$ is maximal. We thus see that there is a unique $s \in C$ such that $C = pa_D(s) \cup \{s\}$.

Now, suppose, if possible that there exist distinct maximal cliques $C_1$ and $C_2$ of skeleton $(D)$ such that $\text{sink}_{D}(C_1) = \text{sink}_{D}(C_2) = s$. Since $C_1$ and $C_2$ are distinct maximal cliques, there must exist $a \in C_1 \setminus C_2, b \in C_2 \setminus C_1$ such that $a$ is not adjacent to $b$. But then, since we have $a \in pa_D(s)$ and $b \in pa_D(s)$, we would have a v-structure $a \rightarrow s \leftarrow b$, which is a contradiction to the hypothesis that $D$ has no v-structures. 

A.2  Proof of Lemma 5

We now provide the proof of Lemma 5. As stated before the statement of the lemma, its proof follows from well-known ideas in the theory of chordal graphs. The following generalization of the definition of the clique block property P1 of Definition 3 will be useful in the proof.

Definition 17 (A-clique block ordering). Let $D$ be a DAG and $A$ a subset of vertices of $D$. Let $\sigma$ be a topological ordering of $D$. Let the elements of $A$ be $a_1, a_2, \ldots, a_k$, arranged so that $\sigma(a_i) < \sigma(a_j)$ whenever $i < j$. Define $L^A_i(\sigma)$ to be the set of nodes $u$ which occur before or at the same position as $a_i$ in $\sigma$ i.e., $\sigma(u) \leq \sigma(a_i)$. Similarly, for $2 \leq i \leq k$, define $L^A_i(\sigma)$ to be the set of nodes which occur in $\sigma$ before or at the same position as $a_i$, but strictly after $a_{i-1}$ (i.e., $\sigma(a_{i-1}) < \sigma(u) \leq \sigma(a_i)$). Then, $\sigma$ is said to be an A-clique block ordering of $D$ if $\bigcup_{i=1}^k L^A_i(\sigma)$ is the set of all vertices of $D$, and for each $1 \leq i \leq k, L^A_i(\sigma)$ is a (not necessarily maximal) clique in skeleton $(D)$.

The following observation is immediate with this definition.

Observation 18. Let $D$ be a DAG without v-structures, and let $A$ be the set of maximal-clique-sink vertices of $D$. Then, a topological ordering $\sigma$ of $D$ satisfies property P1 of Definition 3 if and only if $\sigma$ is an A-clique block ordering of $D$.

Proof. The “if” direction follows from the definition. For the “only if” direction, we note that since every vertex of $D$ must be contained in some maximal clique $C$ of skeleton $(D)$, and since $C = \{s\} \cup pa_D(s)$ for some maximal-clique-sink vertex $s$, it follows that every vertex of $D$ must lie in some $L_i(\sigma)$ if $\sigma$ satisfies the clique block property P1.

We also note the following simple property of A-clique block orderings.

Observation 19. Let $D$ be a DAG without v-structures, and let $\sigma$ be a topological ordering of $D$. Let $A$ and $B$ be subsets of vertices of $D$ such that $A \subseteq B$. If $\sigma$ is an A-clique block ordering of $D$, then it is also a B-clique block ordering of $D$. 

18
Proof. When $A = B$, there is nothing to prove. Thus, we can assume that there must exist a $b \in B \setminus A$. We consider the case when $B = A \cup \{b\}$. The general case then follows by straightforward induction on the size of $|B \setminus A|$.

For $1 \leq i \leq |A|$, let $L_i^A(\sigma)$ be as in the definition of the $A$-clique block orderings. Let $i$ be the unique index such that $b \in L_i^A(\sigma)$. Now, for $j < i$, define $L_j^B(\sigma) := L_j^A(\sigma)$, and for $j \geq i + 1$, define $L_{j+1}^B(\sigma) := L_j^A(\sigma)$. By construction, for $1 \leq j \leq i - 1$ and $i + 2 \leq j \leq |A| + 1$, the $L_j^B(\sigma)$ are cliques in skeleton $(D)$. Further define

$$L_j^B(\sigma) := \{u \in L_i^A(\sigma) \mid \sigma(u) \leq \sigma(b)\}, \text{and}$$

$$L_{i+1}^B(\sigma) := L_i^A(\sigma) \setminus L_i^B(\sigma).$$

Again, $L_i^B(\sigma)$ and $L_{i+1}^B(\sigma)$ are also cliques in skeleton $(D)$ since they are subsets of the clique $L_i(\sigma)$. Further, by construction, $\bigcup_{j=1}^{B} L_i^B(\sigma) = \bigcup_{j=1}^{A} L_i^A(\sigma)$. This shows that $\sigma$ is also a $B$-clique block ordering.

We can now state the main technical lemma required for the proof of Lemma 5.

**Lemma 20.** Let $D$ be a DAG without $v$-structures. Let $S$ be the set of maximal-clique-sink vertices of $D$. Then, there exists a maximal clique $C$ of skeleton $(D)$ with the following two properties:

1. If $u \in C$ then $\text{pa}_D(u) \subseteq C$. That is, if $u \in C$ and $v \notin C$, then the edge $v \to u$ is not present in $D$.

2. Let $S'$ be the set of maximal-clique-sink nodes of the induced DAG $D[V \setminus C]$, where $V$ is the set of nodes of $D$. Then $S'$ is a subset of $S \setminus \{\text{sink}_D(C)\}$.

**Proof.** As already alluded to before the statement of Lemma 5, the proof of item 1 uses ideas that are very similar to the "maximal cardinality search" algorithm for chordal graphs (Tarjan and Yannakakis (1984), see also Corollary 2 of Wienöbst et al. (2021)). Fix an arbitrary topological ordering $\tau$ of $D$, and let $v_1 = \tau(1)$ be the top vertex in $\tau$. Note that $v_1$ has no parents in $D$, so any vertices adjacent to $v_1$ in $D$ are children of $v_1$. Let $C'$ be the set of these children of $v_1$ in $D$. If $C'$ is empty, then $v_1$ is isolated in $D$ and we are done with the proof of item 1 after taking $C = v_1$. So, assume that $C'$ is not empty, and let its elements be $c_1, c_2, \ldots, c_k$, arranged so that $\tau(c_i) < \tau(c_j)$ whenever $i < j$. Now, define the sets $C'_i$, where $1 \leq i \leq k$ as follows. First, $C'_1 := \{v_1, c_1\}$. For $2 \leq i \leq k$,

$$C'_i := \begin{cases} C'_{i-1} \cup \{c_i\}, & \text{if } C'_{i-1} \subseteq \text{pa}_D(c_i), \\ C'_{i-1}, & \text{otherwise.} \end{cases}$$

Define $C := C_k'$. Note that by construction, $C$ is a clique. Note also the following property of this construction: for any $i, c_i \notin C$ if and only if there exists $1 \leq j < i$ such that $c_j \in C$ and $c_j$ is not adjacent to $c_i$ in $D$.

We now claim that $C$ is also a maximal clique. For, if not, let $u \notin C$ be such that $u$ is adjacent to every vertex in $C$. Then, we must have $u = c_i$ for some $i$ (since $v_1 \in C$, and only the children of $v_1$ are adjacent to $v_1$ in $D$). But then, since $u = c_i \notin C$, there must exist some $c_j, j < i$, such that $c_j \in C$ is not adjacent to $u = c_i$, which is a contradiction to the assumption of $u$ being adjacent to every vertex of $C$.

We now claim that if $v \notin C$, then for all $u \in C$, the edge $v \to u$ is not present in $D$. Suppose, if possible, that there exist $v \notin C$ and $u \in C$ such that $v \to u$ is present in $D$. By the choice of $v_1$ as a top vertex in a topological order, we must have $u \neq v_1$. Thus, $u$ must be a child of $v_1$ in $D$. Suppose $u = c_j$, for some $i \in [k]$. Then, $v$ must also be a child of $v_1$, for otherwise $v \to c_i \leftarrow v_1$ would be a $v$-structure in $D$. Thus, $v = c_j$ for some $j < i$. Since $c_j = v \notin C$, there exists some $\ell < j$ such that $c_\ell \in C$ and $c_\ell$ and $v = c_j$ are not adjacent.
But then \( c_f \rightarrow c_i \leftarrow c_j \) is a \( v \)-structure in \( D \), so we again get a contradiction. This proves item 1 of the lemma for the clique \( C \).

Item 2 of the lemma trivially follows if \( V \setminus C \) is empty, therefore, we are interested in the case when \( V \setminus C \) is non-empty. Now consider the induced DAG \( H \coloneqq D[V \setminus C] \). Since \( D \) has no \( v \)-structures, neither does \( H \). Thus, by Observation 2, the maximal-clique-sink nodes of \( H \) and the maximal cliques of skeleton \( (H) \) are in one-to-one correspondence: for each maximal clique \( C' \) of skeleton \( (H) \), there is a unique vertex \( \text{sink}_H(C') \) of \( H \) such that \( C' = \{ \text{sink}_H(C') \} \cup \text{pa}_H(\text{sink}_H(C')) \).

Consider now a maximal-clique-sink vertex \( s' \) of \( H \). There exists then a maximal clique \( C' \) of skeleton \( (H) \) such that \( s' = \text{sink}_H(C') \). Also, since \( H \) is an induced subgraph of \( D \), there must exist a maximal clique \( C'' \) of skeleton \( (D) \) such that \( C'' \supseteq C' \). In fact, we must further have \( C'' \cap (V \setminus C) = C' \), for otherwise \( C' \) would not be a maximal clique of \( H \). Let \( t \coloneqq \text{sink}_D(C'') \). We will show that \( t = s' \). Note first that we cannot have \( t \in C \), for then, by item 1, \( C'' = \{ t \} \cup \text{pa}_D(t) \) would be contained in \( C \), and would not therefore contain \( C' \subseteq V \setminus C \). Thus, \( t \) must be a node in \( V \setminus C \). But then \( C'' \cap (V \setminus C) = C' \) implies that \( t \) must in fact be in \( C' \), and must therefore be equal to \( s' = \text{sink}_H(C') \). We thus see that any maximal-clique-sink vertex \( s' \) of \( H \) is also a maximal-clique-sink vertex of \( D \). Item 2 of the lemma then follows by noting that \( \text{sink}_D(C) \) is the only maximal-clique-sink vertex of \( D \) not contained in \( V \setminus C \).

We are now ready to prove Lemma 5.

**Proof of Lemma 5.** We prove this claim by induction on the number of nodes in \( D \). The claim of the lemma is trivially true when \( D \) has only one node. Now, fix \( n > 1 \), and assume the induction hypothesis that every DAG without \( v \)-structures which has at most \( n - 1 \) nodes admits a topological ordering that satisfies the clique block property \( P1 \) of Definition 3. We will complete the induction by showing that if \( D \) is a DAG without \( v \)-structures which has \( n \) nodes, then \( D \) also admits a topological ordering that satisfies the clique block property \( P1 \) of Definition 3.

Let the maximal clique \( C \) of \( D \) be as guaranteed by Lemma 20 above. If all the nodes of \( D \) are contained in \( C \), then the total ordering on the vertices of the clique \( C \) in \( D \) trivially satisfies the clique block property. Therefore, we assume henceforth that \( V \setminus C \) is non-empty. Thus, the induced DAG \( H \coloneqq D[V \setminus C] \) is a DAG on at most \( n - 1 \) nodes. Let \( S' \) be the set of maximal-clique-sink nodes of \( H \), and let \( S \) be the set of maximal-clique-sink nodes of \( D \). By the induction hypothesis, \( H \) has a topological ordering \( \tau \) which satisfies the clique block property. Equivalently, by Observation 18, \( \tau \) is an \( S' \)-clique block ordering of \( H \).

Consider now the ordering \( \sigma \) of \( D \) obtained by listing first the vertices of the clique \( C \) in the total order imposed on them by the DAG \( D \), followed by the vertices of \( V \setminus C \) in the order specified by \( \tau \). By item 1 of Lemma 20, there is no directed edge in \( D \) from a vertex in \( V \setminus C \) to a vertex in \( C \), so we get that \( \sigma \) is in fact a topological ordering of \( D \).

Define \( T = S' \cup \text{sink}_D(C) \). We now observe that \( \sigma \) is a \( T \)-clique block ordering of \( D \), with \( L^T_1(\sigma) = C \) and \( L^T_{i+1}(\sigma) = L^T_i(\tau) \), for \( 1 \leq i \leq |S'| \). By item 2 of Lemma 20, we have \( T \subseteq S \). Thus, by Observation 19, \( \sigma \) is also an \( S \)-clique block ordering of \( D \), and therefore (by Observation 18) satisfies the clique block property \( P1 \) of Definition 3.

**A.3 Proof of Proposition 6**

**Proof of Proposition 6.** We use the same notation as in the proof of Theorem 4.

1. Since \( y \in Y_\mu \), there exists \( u \in C^a \) such that \( u \) is not adjacent to \( y \) in \( D \). But then, if \( z \in S^a \), we get the \( v \)-structure \( u \rightarrow z \leftarrow y \), which is a contradiction to \( D \) not having any \( v \)-structures. This proves item 1 of the proposition.
We collect here some well known and folklore results concerning without v-structures, in the proof of Theorem 8. Here, we will need to use it in the setting of general graphs. (Theorem 1 in the statement of the theorem can be found on page 6). Recall also that we always assume that (Theorem 1). Recall that in the main paper, this characterization was only used in the setting of DAGs.

Some folklore results

2. Consider the clique $C := \{x\} \cup \text{pa}_D(x)$. There exists a maximal clique $C'$ in skeleton $(D)$ such that $C' \supseteq C$, since $x$ is not a maximal-clique-sink node. Set $y := \text{sink}_D(C')$. Since $x$ is not a maximal-clique-sink node in $D$, we thus have $x \in C \subseteq \text{pa}_D(y)$, so that $y$ is a child of $x$. We also have $y \in S^a$ since $C^a \subseteq \{x\} \cup \text{pa}_D(x) = C \subseteq \text{pa}_D(y)$, where the first inclusion comes from the assumption that $x \in \{a\} \cup S^a$. The fact that $S^a$ is non-empty follows by applying the item with $x = a$, and noticing that, by construction, $a$ is not a maximal-clique-sink vertex in $D$. This follows since $a \in L_i(\sigma)$ has a child (namely, $b$) in $L_i(\sigma)$, while by the definition of the $L_i$, only the last vertex in $L_i(\sigma)$ is a maximal-clique-sink node of $D$. This proves item 2 of the proposition.

3. Since $x$ is a maximal-clique-sink node in $H = D[S^a]$, $C := \{x\} \cup \text{pa}_H(x)$ is a maximal clique in skeleton $(H)$, and thereby a clique in skeleton $(D)$. However, note that $C' := C \cap C^a$ is also a clique in skeleton $(D)$, since both $C$ and $C^a$ are cliques in skeleton $(D)$, and as $C \subseteq S^a$, every vertex in $C$ is adjacent to every vertex in $C^a$. Thus, there exists a maximal clique $C''$ in skeleton $(D)$ such that $C' \subseteq C''$.

Consider $y := \text{sink}_D(C'')$. Suppose, if possible, that $x \neq y$. Then we must have $x \in \text{pa}_D(y)$ (since $x \in C''$), and also that $C'' \subseteq \text{pa}_D(y)$ (as $C'' \subseteq C''$). Thus, we must have $y \in S^a$. But then, we get that $\{y\} \cup C \subseteq C'' \cap S^a$, which contradicts the assumption that $C$ is a maximal clique in $H$. Thus, we must have $x = y$, so that $x$ is a maximal-clique-sink node in $D$. This proves item 3 of the proposition.

\[ \square \]

**B Some folklore results**

We collect here some well known and folklore results concerning $I$-essential graphs that are used in our proofs. We begin by restating the characterization by Hauser and Bühlmann (2012) of $I$-essential graphs (Theorem 1). Recall that in the main paper, this characterization was only used in the setting of DAGs without v-structures, in the proof of Theorem 8. Here, we will need to use it in the setting of general graphs. (Figure 1 in the statement of the theorem can be found on page 6). Recall also that we always assume that every intervention set contains the empty intervention, but the empty intervention is not counted in the size of an intervention set.

**Theorem 1 (Characterization of $I$-essential graphs, Definition 14 and Theorem 18 of Hauser and Bühlmann (2012)).** Let $D$ be a DAG and $I$ an intervention set containing the empty set. A graph $H$ is an $I$-essential graph of $D$ if and only if $H$ has the same skeleton as $D$, all directed edges of $H$ are directed in the same direction as in $D$, all v-structures of $D$ are directed in $H$, and

1. $H$ is a chain graph with chordal chain components.

2. For any three vertices $a$, $b$, $c$ of $H$, the subgraph of $H$ induced by $a$, $b$ and $c$ is not $a \rightarrow b \rightarrow c$.

3. If $a \rightarrow b$ in $D$ (so that $a$, $b$ are adjacent in $H$) and there is an intervention $J \in I$ such that $|J \cap \{a, b\}| = 1$, then $a \rightarrow b$ is directed in $H$.

4. Every directed edge $a \rightarrow b$ in $H$ is strongly $I$-protected. An edge $a \rightarrow b$ in $H$ is said to be strongly $I$-protected if either (a) there is an intervention $J \in I$ such that $|J \cap \{a, b\}| = 1$, or (b) at least one of the four graphs in Figure 1 appears as an induced subgraph of $H$, and $a \rightarrow b$ appears in that induced subgraph in the configuration indicated in the figure.
Remark 21. Strictly speaking, Theorem 18 of Hauser and Bühlmann (2012) only identifies the class of all $I$-essential graphs. However, it is well known, and follows easily from their results that $H$ satisfies all the four items in the statement of Theorem 1 along with the additional conditions in the theorem (i.e., $H$ has the same skeleton as $D$, all directed edges of $H$ are directed in the same direction as in $D$, and all v-structures of $D$ are directed in $H$), if and only if $H = E_I(D)$.

For completeness, we provide a proof of the above folklore remark in Section F.1. Here, we proceed to state a couple of easy and folklore corollaries of this characterization. The first of these, Corollary 22 below, has a proof similar to the proof of Lemma 1 of Hauser and Bühlmann (2014). For completeness, we provide this proof in Section F.2.

Corollary 22. Let $D$ be an arbitrary DAG, and let $I$ be any intervention set containing the empty set. Let $CC$ be the set of chordal chain components of the essential graph $E(D) = E_{\{\emptyset\}}(D)$ of $D$. For each $S \in CC$, define $I_S := \{I \cap S \mid I \in I\}$ to be the projection of the intervention set $I$ to $S$. Consider vertices $a$ and $b$ that are adjacent in $D$. Then, the edge between $a$ and $b$ is directed in the $I_S$-essential graph $E_{I_S}(D[S])$ of the induced DAG $D[S]$.

In particular, $E_I(D) = D$ if and only if $E_{I_S}(D[S]) = D[S]$ for every $S \in CC$.

The second corollary formalizes the intuitive fact that "breaking up" an intervention $I$ into two smaller interventions provides at least as much "information" as the intervention $I$ itself. Again, for the sake of completeness, we provide the proof in Section F.3.

Corollary 23. Let $D$ be an arbitrary DAG, and let $I$ be any intervention set containing the empty set. Let $I'$ be an intervention set obtained from $I$ by "breaking up" a non-empty intervention in $I$; formally, $I' = (I \setminus \{I\}) \cup \{I^1, I^2\}$ where $I^1, I^2$ are distinct non-empty sets such that $I = I^1 \cup I^2$. Then, any edge that is directed in $E_I(D)$ is also directed in $E_{I'}(D)$.

C Other Omitted Proofs

C.1 Proof of Theorem 9

Proof of Theorem 9. Corollary 22 says that an intervention set $I$ learns $D$ starting with $E(D)$ if and only if $E_{I_S}(D[S]) = D[S]$ for every $S \in CC$. If $I$ is a set of atomic interventions, then for each $I \in I$, $|I \cap S| = 0$ for all but one of the $S \in CC$. This means that if an intervention set $I$ of atomic interventions is such that $E_I(D) = D$, then $|I| = \sum_{S \in CC} |I_S|$, and $E_{I_S}(D[S]) = D[S]$ for every $S \in CC$, where $I_S$ is a set of atomic interventions defined as in Corollary 22. By definition of $E(D)$, $D[S]$ is a DAG without v-structures for every $S \in CC$. Thus, by Theorem 8 we have, $|I_S| \geq \left\lfloor \frac{|S| - r(S)}{2} \right\rfloor$ which implies,

$$|I| \geq \sum_{S \in CC} \left\lfloor \frac{|S| - r(S)}{2} \right\rfloor \geq \sum_{S \in CC} \left\lfloor \frac{|S| - r(S)}{2} \right\rfloor = \left\lfloor \frac{n - r}{2} \right\rfloor.$$

This completes the proof. \qed
C.2 Proof of Theorem 11

Here we restate Theorem 11 and provide its proof.

**Theorem 24 (Restatement of Theorem 11).** Let $D$ be an arbitrary DAG and let $\mathcal{E}(D)$ be the chain graph with chordal chain components representing the MEC of $D$. Let $CC$ denote the set of chain components of $\mathcal{E}(D)$, and $r(S)$ the number of maximal cliques in the chain component $S \in CC$. Then, there exists a set $I$ of atomic interventions of size at most $\sum_{S \in CC} (|S| - r(S)) = n - r$, such that $I$ fully orients $\mathcal{E}(D)$ (i.e., $\mathcal{E}_I(D) = D$), where $n$ is the number of nodes in $D$, and $r$ is the total number of maximal cliques in the chordal chain components of $\mathcal{E}(D)$ (including chain components consisting of singleton vertices).

**Proof.** By definition of $\mathcal{E}(D)$, $D[S]$ is a DAG without v-structures for every $S \in CC$. Theorem 10 therefore implies that for each $S \in CC$ there is a set $I_S$ of atomic interventions such that $|I_S| \leq |S| - r(S)$ and $\mathcal{E}_{I_S}(D[S]) = D[S]$. Now, let $I = \cup_{S \in CC} I_S$. $\mathcal{E}_I(D) = D$ by Corollary 22, and $|I| = \sum_{S \in CC} |I_S|$, which means $|I| \leq \sum_{S \in CC} (|S| - r(S)) = n - r$. This shows that there is a set of atomic interventions of size at most $n - r$ which fully orients $\mathcal{E}(D)$. \qed

C.3 Proof of Lemma 12

**Proof of Lemma 12.** Let $C$ be a (necessarily maximal) clique of $G$ of size $\omega$. Since $C$ is a maximal clique of the chordal graph $G$, there exists a perfect elimination ordering $\sigma$ of $G$ that starts with $C$. (This is a consequence, e.g., of the structure of the lexicographic breadth-first-search algorithm used to find perfect elimination orderings of chordal graphs: see, e.g., the paragraph before Proposition 1 of Hauser and Bühlmann (2014) and Algorithm 6 of Hauser and Bühlmann (2012) for a proof. It can also be seen as a consequence of the maximal cardinality search algorithm of Tarjan and Yannakakis (1984): see Theorem 2.5 of Blair and Peyton (1993).)

Now, let $D$ be the DAG obtained by orienting the edges of $G$ according to $\sigma$ (i.e., the edge $u \to v$ in $D$ if and only if $\sigma(u) < \sigma(v)$). Suppose that sink$_D(C) = s$. Note that $C$ cannot contain the node sink$_D(C')$ for any other maximal clique $C'$ since, as $\sigma$ starts with $C$, this would imply $C' \subseteq C$ and would contradict the maximality of $C'$. Thus, there are $|C| - 1$ maximal-clique-sink nodes of $D$ other than $s$ by Observation 2, and, by the above observation, they occur in $\sigma$ after $C$. Thus, $n \geq |C| + |C| - 1$, which gives $n - |C| \geq \omega - 1$ as $|C| = \omega$. \qed

D Various Example Graphs

In Section 3.2, we proved that our universal lower bound is always at least as good as the previous best universal lower bound given by Squires et al. (2020), and also gave examples of graph families where our bound is significantly better. We also pointed out that our lower bound and the lower bound of Squires et al. (2020) are close only in certain special circumstances. We now make give more details of these special cases.

We work with the same notation as that used in Lemma 12: $G$ is an undirected chordal graph, $n$ is the number of nodes in $G$, $\omega$ is the size of its largest clique, and $C$ is the set of its maximal cliques. From Lemma 12, it follows that for our lower bound of $\left\lceil \frac{n-|C|}{2} \right\rceil$ and the lower bound of $\left\lfloor \frac{\omega}{2} \right\rfloor = \left\lfloor \frac{\omega-1}{2} \right\rfloor$ of Squires et al. (2020) to be equal, one of the following conditions must be true: either (i) $n - |C| = \omega - 1$, or (ii) $\omega$ is even and $n - |C| = \omega$.

Now consider the perfect elimination ordering $\sigma$ of $G$ used in the proof of Lemma 12, and let $D$ be the DAG with skeleton $G$ constructed by orienting the edges of $G$ in accordance with $\sigma$. Note that by the
construction of $\sigma$, the $\omega$ vertices of a largest clique $C$ of $G$ are the first $\omega$ vertices in $\sigma$. Note also that $n - |C|$ is the number of vertices in $G$ that are not maximal-clique-sink nodes of $D$ (by Observation 2).

Thus, it follows that condition (i) above for the two lower bounds to be equal can hold only when $D$ is such that all nodes of $G$ outside the largest clique $C$ of $G$ are maximal-clique-sink nodes of $D$. In other words, $\sigma$ is a clique block ordering, in the sense of P1 of Definition 3 of a CBSP orderings, in which the first clique block $L_1(\sigma)$ consists of the largest clique $C$, while all other clique blocks $L_i(\sigma)$, $i \geq 2$ are of size exactly 1. Similarly, condition (ii) above for the two lower bounds to be equal can hold only when $D$ is such that all but one of the nodes of $G$ outside the largest clique $C$ of $G$ are maximal-clique-sink nodes of $G$.

We now give examples of two special families of chordal graphs where the above conditions for the equality of the two lower bounds hold: Split graphs and $k$-trees. Here, $C(G)$ will denote the set of maximal cliques of graph $G$.

**Split graphs.** $G$ is a split graph if its vertices can be partitioned into a clique $C$ and an independent set $Z$. For such a $G$, one of the following possibilities must be true.

1. $\exists x \in Z$ such that $C \cup \{x\}$ is complete. In this case, $C \cup \{x\}$ is a maximum clique and $Z$ is a maximum independent set.

2. $\exists x \in C$ such that $Z \cup \{x\}$ is independent. In this case, $Z \cup \{x\}$ is a maximum independent set and $C$ is a maximum clique.

3. $C$ is a maximal clique and $Z$ is a maximal independent set. In this case, $C$ must also be a maximum clique and $Z$ a maximum independent set.

For each of these cases, we have $n - |C(G)| = \omega - 1$, which implies $\left\lceil \frac{n - |C(G)|}{2} \right\rceil = \left\lceil \frac{\omega}{2} \right\rceil$. 

**$k$-trees.** A $k$-tree is formed by starting with $K_{k+1}$ (complete graph with $k + 1$ vertices) and repeatedly adding vertices in such a way that each added vertex $v$ has exactly $k$ neighbors, and such that these neighbors along with $v$ form a clique. Thus, each added vertex creates exactly one clique of size $k + 1$. In particular, in a $k$-tree, all maximal cliques are of size $k + 1$. So, in a $k$-tree $G$ with $n = k + 1 + r$ nodes, we have, $|C(G)| = 1 + r$ and $\omega = k + 1$, which implies $n - |C(G)| = \omega - 1$. Thus, $\left\lceil \frac{n - |C(G)|}{2} \right\rceil = \left\lceil \frac{\omega - 1}{2} \right\rceil = \left\lceil \frac{\omega}{2} \right\rceil$.

In contrast to the above two families, **block graphs** are an example family of chordal graphs where our lower bound can be significantly better. Construction 1 and 2 presented in Section 3.2 are examples of block graphs, and as discussed there, our lower bound can be $\Theta(k)$ times the previous best universal lower bound for block graphs, where $k$ can be as large as $\Theta(n)$ (where $n$ is the number of nodes in the graph).

### E  Details of Experimental Setup

**Experiment 1** For this experiment, we generate 1000 graphs from Erdős-Rényi graph model $G(n, p)$: for each of these graphs, the number of nodes $n$ is a random integer in $[5, 25]$ and the connection probability $p$ is a random value in $[0.1, 0.3]$. Each of these graphs is then converted to a DAG without v-structures, using the following procedure. First, the edges of $G$ are oriented according to a topological ordering $\sigma$ which is a random permutation of the nodes of $G$: this converts $G$ into a DAG $D$ (possibly with v-structures). Now, the nodes of $D$ are processed in a reverse order according to $\sigma$ (i.e., nodes coming later in $\sigma$ are processed first) and whenever we find two non-adjacent parents, $a$ and $b$ of the current node $u$ being processed, we add an edge $a \rightarrow b$ in $D$ if $\sigma(a) < \sigma(b)$, and $b \rightarrow a$ in $D$ if $\sigma(b) < \sigma(a)$. Since nodes are processed in an order that is a reversal of $\sigma$, this procedure ensures that the resulting DAG $D$ has no v-structures.
In Figure 5, we provide plots from four further runs of Experiment 1. These plots use exactly the same set-up and procedure as the plot given in Figure 3 on 16, and differ only in the initial seed provided to the underlying pseudo-random number generator. These seeds are used for generation of random graphs as well as for generating $n$ and $p$. To avoid any post selection bias, the seeds for these plots were formed using the decimal expansion of $\pi$ after skipping first 1015 digits in the decimal expansion, and then taking the next 10 digits as the first seed, 10 consecutive digits after that as the second seed, and so on. Our interpretation and inferences from these further runs remain the same as that reported in Section 5 for the run underlying Figure 3.

**Experiment 2** For this experiment, we generate 1000 random DAGs without v-structures for each size in $\{10, 20, 30, 40, 50, 60\}$. We now describe the procedure for generating a DAG $D$ (without v-structures) with $n$ nodes, other than $n$, this procedure takes two more inputs, $min\_clique\_size$ and $max\_clique\_size$. If $min\_clique\_size = X$ and $max\_clique\_size = Y$, we try to keep the size of all cliques of $D$ in $[X, Y]$. First, we initialize a DAG $D$ with nodes $0, \ldots, n-1$, and no edges. We take $\sigma = (0, \ldots, n-1)$ to be a perfect elimination ordering of $D$. We then process the nodes of $D$ in reverse order of $\sigma$. When node $u$ is being processed, we
first compute the number of parents that $u$ already has in $D$. Now we compute lower and upper bounds $\ell_1 \geq 0$ and $\ell_2 \geq 0$ on the number of parents that could be added to the set of parents of $u$ while still keeping the total number of parents below $Y - 1$, and at least $X - 1$. (Note that $\ell_1, \ell_2 \leq \left| \{0, \ldots, u - 1\} \setminus \text{pa}_D(u) \right|$, since the latter is the number of currently available vertices that could be added to the parent set of $u$). We now choose an integer $\ell$ uniformly at random from $[\ell_1, \ell_2]$; this will be the number of new parents to be added to the set of parents of $u$. Note that it may happen that $\ell = 0$, for example when $u$ already has $Y - 1$ or more parents, so that $\ell_2 = 0$. Next, we sample a set $Z$ of $\ell$ nodes (without replacement) from $\left( \{0, \ldots, u - 1\} \setminus \text{pa}_D(u) \right)$, and add the edges $z \rightarrow u$ to $D$ for each $z \in Z$. Further, for any two non-adjacent parents of $u$, we add an edge $a \rightarrow b$ to $D$ if $\sigma(a) < \sigma(b)$, and $b \rightarrow a$ if $\sigma(b) < \sigma(a)$. This makes sure that there are no v-structures in $D$. Note that, as described in Section 5, the procedure used here only tries to keep the maximum clique size bounded above by $Y$, but it can overshoot and produce a graph with a clique of size larger than $Y$ as well. In our experiments, we take $\text{min\_clique\_size} = 2, \text{max\_clique\_size} = 4$.

In Figure 6, we provide plots from four further runs of Experiment 2. These plots use exactly the same set-up and procedure as the plot given in Figure 4 in Section 5, and differ only in the initial seed provided to the underlying pseudo-random number generator. Again, to avoid post-selection bias, we use seeds given by the procedure given for Experiment 1 above. Our interpretation and inferences from these further runs remain the same as that reported in Section 5 for the run underlying Figure 4.

F Omitted proofs of folklore results

In this section, we provide the proofs of Remark 21 and Corollaries 22 and 23. As described above, we believe these results to be folklore and well known, and provide the proofs below only for the sake of completeness.

F.1 Proof of Remark 21

Proof of Remark 21. By Theorem 10(iv) of Hauser and Bühlmann (2012), it follows that $\mathcal{E}_{\mathcal{J}}(D)$ must have the same skeleton and the same v-structures as $D$, and must also have all its directed edges directed in the same direction as in $D$. This proves that $\mathcal{E}_{\mathcal{J}}(D)$ satisfies all the conditions of Theorem 1. To complete the proof, we now show that it is the only graph satisfying all the conditions of the theorem.

For if not, then let $G$ and $H$ be two different graphs satisfying all the conditions of Theorem 1. Thus, $G$ and $H$ have the same skeleton as $D$, all their directed edges are in the same direction as in $D$, and further, all v-structures of $D$ are directed in both $G$ and $H$. If $G \neq H$, the set $E'$ of edges that are directed in $G$ but not in $H$ is therefore non-empty (possibly after interchanging the labels $G$ and $H$). Fix a topological ordering $\sigma$ of $D$, and let $a \rightarrow b \in E'$ be such that $\sigma(b) \leq \sigma(b')$ for all $a' \rightarrow b' \in E'$. Since $a \rightarrow b$ in $G$, $a \rightarrow b$ must be strongly $\mathcal{J}$-protected in $G$. Now, there cannot exist $J \in \mathcal{J}$ such that $|J \cap \{a, b\}| = 1$, since in that case $a \rightarrow b$ would be directed in $H$ as well (by item 3 of Theorem 1). Thus, at least one of the four graphs in Figure 1 must appear as an induced subgraph of $G$, with $a \rightarrow b$ appearing in that induced subgraph in the configuration indicated in the figure. If subgraph (i) appears as an induced subgraph of $G$, then we must have $c \rightarrow a$ in $H$ since $\sigma(a) < \sigma(b)$, but this means that $c \rightarrow a \rightarrow b$ would be an induced subgraph of $H$, contradicting item 2 of Theorem 1. Similarly, $a \rightarrow b$ cannot be in the configuration indicated in subgraph (ii), since any v-structure in $G$ is directed in $H$, so that $a \rightarrow b$ would be directed in $H$ as well. If subgraph (iii) appears as an induced subgraph of $G$, $a \rightarrow c$ must be directed in $H$, as $\sigma(c) < \sigma(b)$, but this would mean that $H$ contains a directed cycle $a, c, b, a$ (since $a \rightarrow b$ is undirected in $H$), and this contradicts that $H$
Figure 6: Experiment 2 Runs with Varying Seeds

is a chain graph.\textsuperscript{3} If subgraph (iv) appears as an induced subgraph of $G$, then $c_1 \rightarrow b \leftarrow c_2$ appears in $H$ as well since any $v$-structure of $G$ must also be directed in $H$. Further, at least one of the following four configurations must appear in $H$: (a) $a \rightarrow c_1$ (b) $a \rightarrow c_2$ (c) $a - c_1$ (d) $a - c_2$ (for if not, then $c_1 \rightarrow a \leftarrow c_2$ would be a $v$-structure in $H$ that is not directed in $G$, contradicting that all $v$-structures of $D$ are directed in both $G$ and $H$). However, if any of the four configuration appears in $H$, we get a directed cycle in $H$ (since $a - b$ is undirected in $H$), which contradicts the fact that $H$ is a chain graph.

We conclude therefore that $E'$ must in fact be empty and hence $G = H$. Thus, given a DAG $D$, the unique graph satisfying all conditions of Theorem 1 is the $I$-essential graph $E_I(D)$ of $D$. \hfill $\square$

F.2 Proof of Corollary 22

Proof of Corollary 22. Let $H$ be the graph with the same skeleton as $D$ in which exactly the edges satisfying one of the two conditions of the corollary are directed. We prove that $H$ satisfies all the conditions of

\textsuperscript{3}Recall that a directed cycle in a general graph is a cycle in which all directed edges point in the same direction, and in which at least one edge is directed. The formal definition is given in Section 2.
Theorem 1, and must therefore be the same as $E_I(D)$ (see also Remark 21). This will complete the proof of the corollary.

Recall that by construction, any edge of $H$ is directed if and only if

1. the endpoints of the edge are in different chain components of $E(D)$, so that it is already directed in $E(D)$, or

2. the endpoints of the edge lie in the same chain component $S$ of $E(D)$, and the edge is directed in $E_{I_S}(D_S)$.

In particular, item 1 implies that any edge that is directed in $E(D)$ is also directed in $H$ (since all directed edges of a chain graph have their endpoints in different chain components).

We now verify that $H$ satisfies all the conditions of Theorem 1. By construction, $H$ has the same skeleton as $D$, and all its directed edges are directed in the same direction as $D$. Further, all the v-structures of $D$ are directed in $H$, since these are directed in $E(D)$.

Any directed cycle $C$ in $H$ would be a directed cycle either in $E(D)$ (in case $C$ includes vertices from at least two different chain components of $E(D)$), or in $E_{I_S}(D_S)$ for some chain component $S$ of $E(D)$ (in case $C$ is contained within a single chain component $S$ of $E(D)$). Since both $E(D)$ and $E_{I_S}(D_S)$ are chain graphs (from Theorem 1), they do not have any directed cycles. It therefore follows that $H$ cannot have a directed cycle either, and hence is a graph. Further, the chain components of $H$ are induced subgraphs of the chain components of $E(D)$. Since the chain components of $E(D)$ are chordal (again from Theorem 1), it follows that the chain components of $H$ are also chordal. Thus, $H$ satisfies item 1 of Theorem 1.

Suppose now that, if possible, $H$ has an induced subgraph of the form $a \to b \to c$. Thus, the edge $b \to c$ must be undirected in $E(D)$ as well, so that $b$ and $c$ are in the same chain component $S$ of $E(D)$. If $a$ is also in $S$, then $a \to b \to c$ would be an induced sub-graph of the interventional essential graph $E_{I_S}(D_S)$, which would contradict item 2 of Theorem 1. Similarly, if $a$ is not in $S$, then $a \to b$ would be directed in $E(D)$, so that $a \to b \to c$ would be an induced sub-graph of the essential graph $E(D) = E_{\{a\}}(D)$, again contradicting item 2 of Theorem 1. We conclude that an induced subgraph of the form $a \to b \to c$ cannot occur in $H$. Thus, $H$ satisfies item 2 of Theorem 1.

To verify item 3, consider any two adjacent vertices $a$ and $b$ in $H$ such that $|I \cap \{a, b\}| = 1$ for some $I \in \mathcal{I}$. If $a$ and $b$ are in different chain components of $E(D)$, then the edge between them is directed in $E(D)$ and hence also in $H$. On the other hand, if $a$ and $b$ are in the same chain component $S$ of $E(D)$, then we have $|(I \cap S) \cap \{a, b\}| = |I \cap \{a, b\}| = 1$ for $I \cap S \in I_S$, so that the edge between $a$ and $b$ is directed in $E_{I_S}(D_S)$ (by item 3 of Theorem 1) and hence also in $H$. It thus follows that $H$ satisfies item 3 of Theorem 1.

Finally, we show that any directed edge in $H$ is $I$-strongly protected. Consider first a directed edge $a \to b$ in $H$ where $a$ and $b$ belong to the same chain component $S$ of $E(D)$. Then, since $a \to b$ is directed also in $E_{I_S}(D_S)$, it must be $I_S$-strongly protected in $E_{I_S}(D_S)$. It follows directly from the definition of interventional strong protection and the construction of $H$ that $a \to b$ is $I$-strongly protected in $H$ (since any of the configurations of Figure 1, if present as an induced subgraph of $E_{I_S}(D_S)$, is also present as an induced subgraph in $H$).

Consider now a directed edge $a \to b$ in $H$ when $a$ and $b$ are in different chain components of $E(D)$. Then $a \to b$ must be directed, and hence also $\{\emptyset\}$-strongly protected, in $E(D)$. Now, if $a \to b$ appears as part of an induced subgraph of $E(D)$ of the forms (i), (ii) or (iii) of Figure 1, then the same configuration also appears as an induced subgraph of $H$ (since all directed edges of $E(D)$ are directed in $H$), so that $a \to b$ is also $I$-strongly protected in $H$. Suppose then that $a \to b$ appears as part of an induced subgraph of the form (iv) of Figure 1. Then, the vertices $a, c_1$ and $c_2$ appearing in the configuration must be in the same chain component $S$ of $E(D)$ (since they are in a connected component of undirected edges). It follows
that the configurations $c_1 \rightarrow a - c_2$ and $c_2 \rightarrow a - c_1$ cannot appear in $H$. For, if they did, then they would also appear in the $I_S$ essential graph $E_{I_S}(D_S)$, thereby contradicting item 2 of Theorem 1 (when applied to the interventional essential graph $E_{I_S}(D_S)$). The configuration $c_1 \rightarrow a \leftarrow c_2$ also cannot occur in $H$, since otherwise, the v-structure $c_1 \rightarrow a \leftarrow c_2$ of $D$ could not have remained undirected in $E(D)$. It follows that at least one of the following three configurations must appear in $H$: $a \rightarrow c_1$, $a \rightarrow c_2$ or $c_1 - a - c_2$. In the last case, $a \rightarrow b$ is $I$-strongly protected in $H$ as configuration (iv) of Figure 1 appears as an induced subgraph of $H$ (exactly as it does in $E(D)$). In the first two cases, $a \rightarrow b$ is $I$-strongly protected in $H$ as configurations (iii) of Figure 1 appears as an induced subgraph of $H$ (with the role of the vertex $c$ in that configuration played by either $c_1$ or $c_2$, as the edges $c_1 \rightarrow b$ and $c_2 \rightarrow b$ are both directed in $H$, since they are directed in $E(D)$). Thus, we see that every directed edge in $H$ is $I$-strongly protected in $H$, and hence $H$ satisfies item 4 of Theorem 1 as well.

It follows from Theorem 1 therefore that $H = E_I(D)$. As discussed at the beginning of the proof, this completes the proof of the corollary. □

F.3 Proof of Corollary 23

Proof of Corollary 23. Suppose that there exists an edge $a \rightarrow b$ which is directed in $E_I(D)$ but undirected in $E_{I'}(D)$. Fix a topological ordering $\sigma$ of $D$, and among all such edges, choose any one with the smallest possible value of $\sigma(b)$. Thus, we have $a \rightarrow b \in E_I(D)$ and $a \not\rightarrow b \in E_{I'}(D)$. Also, by the choice of $b$, if $c \rightarrow d$ is directed in $E_I(D)$, and $\sigma(d) < \sigma(b)$, then $c \rightarrow d$ is also directed in $E_{I'}(D)$.

Now, we will derive a contradiction to the requirement in item 4 of Theorem 1, which says that $a \rightarrow b$ must be strongly $I$-protected in $E_I(D)$. We consider all the five possible ways in which $a \rightarrow b$ may be strongly $I$-protected in $E_I(D)$, and derive a contradiction in each case.

Case 1 There exists $J \in I$ such that $|J \cap \{a, b\}| = 1$. In this case there exists $J' \in I'$ such that $|J' \cap \{a, b\}| = 1$: in case $J \neq I$ we can take $J' = J$, while if $J = I$, we can take $J'$ to be one of $I^1$ and $I^2$, since $I = I^1 \cup I^2$. But then, by item 3 of Theorem 1, $a \rightarrow b$ must be directed in $E_I(D)$ as well, which is a contradiction.

Case 2 The subgraph (i) of the form $c \rightarrow a \rightarrow b$ in Figure 1 appears as an induced subgraph of $E_I(D)$. In this case, $c \rightarrow a$ must be directed in $E_I(D)$, since $\sigma(a) < \sigma(b)$. But then, the induced subgraph $c \rightarrow a \rightarrow b$ of $E_{I'}(D)$ contradicts item 2 of Theorem 1.

Case 3 The subgraph (ii) of the form $c \rightarrow b \leftarrow a$ appears as an induced subgraph of $E_I(D)$. In this case, $c \rightarrow b$ must be directed in $E_I(D)$, and hence also (by Theorem 1) in $D$. Thus, again by Theorem 1, it must also be directed in $E_{I'}(D)$. This contradicts the assumption that $a \not\rightarrow b$ is undirected in $E_I(D)$.

Case 4 The subgraph (iii) in Figure 1 appears as an induced subgraph of $E_I(D)$. In this case, $a \rightarrow c$ is directed in $E_I(D)$, since $\sigma(c) < \sigma(b)$ (because of the presence of the edge $c \rightarrow b$ in $E_I(D)$, and hence also in $D$). Now, irrespective of whether the edge between $c$ and $b$ is directed or not in $E_I(D)$, we have a directed cycle in $E_I(D)$: this directed cycle is $a \rightarrow c - b - a$ in case $c \rightarrow b$ is undirected in $E_I(D)$, and $a \rightarrow c \rightarrow b - a$ in case $c \rightarrow b$ is directed in $E_I(D)$ (note that Theorem 1 implies that since $c \rightarrow b \in E_I(D)$, it must also be present in $D$, so that $b \rightarrow c$ cannot be present in $E_I(D)$). However, this is a contradiction, since, by Theorem 1, $E_I(D)$ must be a chain graph, and hence cannot contain any directed cycles.

Case 5 The subgraph (iv) in Figure 1 appears as an induced subgraph of $E_I(D)$. In this case, $c_1 \rightarrow b \leftarrow c_2$ is a v-structure in $E_I(D)$, and hence, by Theorem 1, must be directed in $E_I(D)$ as well. Now, if any
one of the edges $a - c_1$ or $a \rightarrow c_1$ or $a - c_2$ or $a \rightarrow c_2$ are present in $\mathcal{E}_{\mathcal{I}}(D)$, we get a contradiction to the fact that $\mathcal{E}_{\mathcal{I}}(D)$ must be a chain graph (exactly as in Case 4 above). The only remaining possibility is that $c_1 \rightarrow a$ and $c_2 \rightarrow a$ are both present in $\mathcal{E}_{\mathcal{I}}(D)$. But this is a contradiction to the fact that the edges $c_1 - a$ and $c_2 - a$ are undirected in $\mathcal{E}_{\mathcal{I}}(D)$. To see this, note that since $c_1 \rightarrow a \leftarrow c_2$ is a v-structure in $\mathcal{E}_{\mathcal{I}}(D)$, it must (by Theorem 1) also be directed in $\mathcal{E}_{\mathcal{I}}(D)$.

Thus, we conclude that every edge that is directed in $\mathcal{E}_{\mathcal{I}}(D)$ must also be directed in $\mathcal{E}_{\mathcal{I}}(D)$.
