ABSTRACT

The extended TeV gamma-ray source ARGO J2031+4157 (or MGRO J2031+41) is positionally consistent with the Cygnus Cocoon discovered by Fermi-LAT at GeV energies in the Cygnus superbubble. Reanalyzing the ARGO-YBJ data collected from 2007 November to 2013 January, the angular extension and energy spectrum of ARGO J2031+4157 are evaluated. After subtracting the contribution of the overlapping TeV sources, the ARGO-YBJ excess map is fitted with a two-dimensional Gaussian function in a square region of $10^° \times 10^°$, finding a source extension $\sigma_{\text{ext}} = 1.8 \pm 0.5$. The observed differential energy spectrum is $dN/dE = (2.5 \pm 0.4) \times 10^{-11} \text{ photons cm}^{-2} \text{s}^{-1} \text{ TeV}^{-1}$, in the energy range 0.2–10 TeV. The angular extension is consistent with that of the Cygnus Cocoon as measured by Fermi-LAT and the spectrum also shows a good connection with the one measured in the 1–100 GeV energy range. These features suggest to identify ARGO J2031+4157 as the counterpart of the Cygnus Cocoon at TeV energies. The Cygnus Cocoon, located in the star-forming region of Cygnus X, is interpreted as a cocoon of freshly accelerated cosmic rays related to the Cygnus superbubble. The spectral similarity with supernova remnants (SNRs) indicates that the particle acceleration inside a superbubble is similar to that in an SNR. The spectral measurements from 1 GeV to 10 TeV allows for the first time to determine the possible spectral slope of the underlying particle distribution. A hadronic model is adopted to explain the spectral energy distribution.

Key words: acceleration of particles – cosmic rays – gamma rays: general

1. INTRODUCTION

The Cygnus region of the Galactic plane stands out in the northern sky for the complex features observed in radio, infrared, X-rays, and gamma-rays. It contains a high density interstellar medium and is rich in potential cosmic ray acceleration sites, e.g., Wolf–Rayet stars, OB associations, and supernova remnants (SNRs). This region is home of a number of GeV gamma-ray sources as revealed by Fermi-LAT (Nolan et al. 2012). Several noteworthy TeV gamma-ray sources were also detected within the Cygnus region in the past decade. A review of these sources can be found in our previous paper (Bartoli et al. 2012a). Gamma-rays are tracers of non-thermal particle acceleration and propagation. The Cygnus region is therefore
a natural laboratory for studying the origin of cosmic rays, which remains a century-long puzzle.

Cygnus X in the constellation of Cygnus is the largest star-forming region in the solar neighborhood. It contains many distinct H ii regions, a number of Wolf–Rayet stars, and several OB associations, namely OB2, OB1, and OB9. Most objects seen in this region are located at the distance of ∼1.4 kpc (Hanson 2003). In the direction of Cyg OB2, the gamma-ray source TeV J2032+4130 was discovered by the HEGRA collaboration (Aharonian et al. 2002, 2005) and later observed by the Whipple (Konopelko et al. 2007), MAGIC (Albert et al. 2008), and VERITAS (Aliu et al. 2014a) imaging air shower Cherenkov telescopes (IACTs). Its extension is estimated to be about 0.1 and the integral flux above 1 TeV is 3%–6% that of the Crab flux. TeV J2032+4130 is positionally coincident with the GeV pulsar PSR J2032+4127 and could be the corresponding pulsar wind nebula (PWN: Camilo et al. 2009; Aliu et al. 2014a). The sources MGRO J2031+41 and ARGO J2031+4157, detected by Milagro and ARGO-YBJ extensive air shower (EAS) arrays around 20 TeV and 1 TeV, respectively, overlap with TeV J2032+4130, but the fluxes are about 10 times higher (Abdo et al. 2007b; Bartoli et al. 2012a, 2013a).

Using the Fermi-LAT data, Ackermann et al. (2011) found a highly extended gamma-ray source above 1 GeV, overlapping the TeV emission. Assuming a symmetrical two-dimensional Gaussian shape, the source angular extension was estimated to be 2.0 ± 0.2. The emission was interpreted as a cocoon of freshly accelerated cosmic rays in the Cygnus superbubble, which was taken as evidence for the long-advocated hypothesis that OB associations host cosmic ray factories. The extended emission region will be denoted as Cygnus Cocoon here.

The extension of MGRO J2031+41, obtained by Milagro with a later analysis, is 1.8, similar to that of the Cygnus Cocoon. For such a complex region, Abdo et al. (2012a) pointed out that the morphology of MGRO J2031+41 may be produced by the superposition of the central source TeV J2032+4130 and a more extended emission, which causes the large discrepancy between the fluxes measured by IACTs and EAS arrays. However, the correlation between the TeV extended emission and the Cygnus Cocoon remained unclear.

VERITAS surveyed the Cygnus region. Due to the narrow field of view (FOV; typically 3.5”), VERITAS could not detect the gamma-ray emission on the angular scale of the Cygnus Cocoon. In Cherenkov telescopes, the background under a point-like source is estimated by the density of events in rings around the source. For an extended source, this method makes the source to be self-subtracted (Aliu et al. 2013). At one corner of the Cygnus Cocoon, VERITAS detected a new TeV gamma-ray source VER J2019+407 (Aliu et al. 2013) in the direction of SNR G78.2+2.1 with an angular extension of 0.23 ± 0.05 and a flux above 320 GeV of 3.7% Crab units. A marginal signal associated with VER J2019+407, denoted as ARGO J2021+4038, was reported by the ARGO-YBJ collaboration when surveying the northern sky (Bartoli et al. 2013a). This source should also partly contribute to the extended source MGRO J2031+41.

The ARGO-YBJ experiment is an EAS array with a wide FOV, able to monitor the sky in the declination band from −10° to 70° (Bartoli et al. 2013a). Due to the full coverage configuration and the location at high altitude (4300 m a.s.l.), the detector energy threshold is ∼300 GeV, much lower than that of Milagro. ARGO-YBJ can extend the measurements of the space-based experiment Fermi-LAT at 0.1–300 GeV to higher energies without any gap. In this paper we reanalyze the ARGO-YBJ data recorded in the region of ARGO J2031+4157 to study the relation of this source with the Cygnus Cocoon detected by Fermi-LAT.

2. THE ARGO-YBJ EXPERIMENT

The ARGO-YBJ experiment, located at the Yangbajing Cosmic Ray Laboratory (Tibet, China, 90° east, 30° north), is designed for very high energy (VHE) gamma-ray astronomy (Aielli et al. 2009b, 2009c, 2010; Bartoli et al. 2011a, 2012a, 2012b, 2012c, 2013b) and cosmic ray (Aielli et al. 2009e; Bartoli et al. 2012d, 2012e, 2013c) observations. The detector, extensively described in (Aielli et al. 2006, 2009d), consists of a ~74 × 78 m² carpet made of a single layer of resistive plate chambers (RPCs) with ~93% of active area, surrounded by a partially instrumented (~20%) “guard ring” area up to ~100 × 110 m². Each RPC (2.8 m × 1.25 m) is equipped with 10 logical pixels (called “pads,” 55.6 cm × 61.8 cm) used for triggering and timing purposes. The arrival times of the particles are measured by 18,360 time-to-digital converters with a resolution of about 1.8 ns (Aielli et al. 2009d), which are calibrated using a software method with precision of 0.4 ns (He et al. 2007; Aielli et al. 2009a).

The ARGO-YBJ experiment in its final configuration started taking data in 2007 November and stopped in 2013 January. The trigger rate is 3.5 kHz with a dead time of 4% and an average duty-cycle higher than 86%. All the ARGO-YBJ data collected in that period are used in this analysis, for a total observation time of 1670 days. Details of the detector performance and data analysis are widely discussed in Bartoli et al. (2013a), where, using the same data sample, a survey of the northern sky is presented, yielding six sources and five candidates, with an integrated sensitivity of 24% Crab units. The detector angular resolution for gamma-rays ranges from 1°7 to 0°2, depending on the number of hit pads $N_{pad}$ (Bartoli et al. 2011b, 2013a). The sky map in celestial coordinates (right ascension and declination) is divided into a grid of 0.1 × 0.1 bins and filled with detected events. The “direct integral method” (Fleysher et al. 2004) is adopted to estimate the number of cosmic ray background events in each bin. A smoothing is applied with an energy-dependent point-spread function (Bartoli et al. 2013a). The Li–Ma method (Li & Ma 1983) is used to estimate the significance of the excess.

3. RESULTS

The significance map around ARGO J2031+4157 as observed by ARGO-YBJ using the events with $N_{pad} \geq 20$ is shown in Figure 1. The highest statistical significance is 6.1 standard deviations (s.d.s.), corresponding to the position of ARGO J2031+4157. The positions of other known TeV sources and of the Cygnus Cocoon are also marked in the figure. Our excess almost fully fills the extended region of the Cygnus Cocoon, indicating their similar angular size. At the top right corner of the excess, there is a 4.3 s.d. peak corresponding to ARGO J2021+4038, which is associated with VER J2019+407. To derive the possible emission from the Cygnus Cocoon, the contribution from the overlapping sources TeV J2032+4130 and VER J2019+407 and from the nearby sources, VER J2016+371 (Aliu et al. 2014b) and MGRO J2019+37 (Abdo et al. 2007b) must be subtracted. For these sources, the spectra and the angular extensions determined in (Aharonian et al. 2005; Aliu et al. 2013, 2014b) are used. For MGRO J2019+37, the flux measured by Milagro is higher than the upper limits derived...
by ARGO-YBJ, although still within one s.d. error. Recently, MGRO J2019+37 was resolved into two VERITAS sources, namely VER J2016+371 and VER J2019+368. So the spectra determined by VERITAS (Aliu et al. 2014b), which have better precision and are consistent with both Milagro and ARGO-YBJ measurements, are used here. We track the four sources path inside the ARGO-YBJ FOV and simulate the detector response in the gamma-ray energy range from 10 GeV to 100 TeV. The detailed simulation of the ARGO-YBJ detector response to gamma-rays is realized by means of a code based on the GEANT package (Guo et al. 2010). The four sources contributions are removed before estimating the extension and spectrum of the Cygnus Cocoon.

In our previous analysis (Bartoli et al. 2012a), the angular extension of ARGO J2031+4157 was estimated by fitting the angular distribution of the events centered on MGRO J2031+41 within a radius of 2°. The excess events outside this region were considered as due to the Galactic diffuse gamma-ray emission. Now, after the Fermi-LAT result indicating the presence of a large extended source, a larger region is used to evaluate the extension of ARGO J2031+4157. To achieve a better angular resolution, only events with \( N_{\text{pad}} \geq 60 \) are used. Assuming a symmetrical two-dimensional Gaussian function for the source shape, we fit the ARGO-YBJ excess in a square region of \( 10^\circ \times 10^\circ \) around ARGO J2031+4157. The result of the fit gives a source position with R.A. = (307.8 ± 0.8)° and decl. = (24.5 ± 0.6)°; and an extension \( \sigma_{\text{ext}} = (1.8 \pm 0.5)° \), consistent with the angular size of the cocoon as measured by Fermi-LAT (2° ± 0.2)°, within the statistical uncertainties (see Figure 1). The dependence of this result on the source spectral energy distribution is found to be negligible.

To study the spectral behavior of ARGO J2031+4157, the extension \( \sigma_{\text{ext}} = 2° \) and the position of Cygnus Cocoon determined by Fermi-LAT at 1–100 GeV (Ackermann et al. 2011) are used. The fitting method described in Bartoli et al. (2011a) is adopted. In this procedure, the path of the Cygnus Cocoon inside the ARGO-YBJ FOV is tracked during the ARGO-YBJ life time. The expected emission is generated by sampling gamma-rays in the energy range 10 GeV–100 TeV assuming a power-law function. The variable used to determine the event energy is the number of hit pads \( N_{\text{pad}} \). The energy spectrum is estimated by comparing the detected signal and the expected signal in six \( N_{\text{pad}} \) intervals: 20–39, 40–59, 60–99, 100–199, 200–499, and \( \geq 500 \). Before fitting, the contribution of the four nearby sources is removed. According to our simulations, this contribution is dominated by the two sources, TeV J2032+4130 and VER J2019+407, and is equal to 13.2%, 11.1%, 12.1%, 10.4%, and 16.2%, respectively, in the first five \( N_{\text{pad}} \) intervals (in the sixth interval, there is no excess).

The best fit to the spectrum (\( \chi^2/\text{dof} = 2.4/4 \)) is

\[
\frac{dN}{dE} = (2.5 \pm 0.4) \times 10^{-11} (E/1 \text{ TeV})^{-2.6 \pm 0.3} \text{ photons cm}^{-2} \text{ s}^{-1} \text{ TeV}^{-1}.
\]

The integral flux above 1 TeV is \((1.52 \pm 0.37) \times 10^{-11} \text{ photons cm}^{-2} \text{ s}^{-1}\), corresponding to 0.8 ± 0.2 Crab units. The median energies of the six \( N_{\text{pad}} \) intervals are 0.40, 0.64, 0.92, 1.4, 2.7, and 6.5 TeV, respectively. The found spectrum and the corresponding 1σ errors are shown in Figure 2.

The highest energy point is a 95% confidence level (c.l.) flux upper limit. The flux is higher than in our previous report (Bartoli et al. 2012a), since a larger source region is considered here. This also gives us a hint that the extension of the source is really larger than our previous estimation. The given errors on the flux are statistical. The systematic errors are estimated to be less than 30% (Bartoli et al. 2011a).

Note that to subtract the contributions of TeV J2032+4130 and VER J2019+407, the gamma-ray fluxes determined by IACTs are used. Some unclear systematic discrepancy between EAS arrays and IACTs has been found when determining the flux of extended sources. It is worth noting that these two techniques have achieved a good agreement for the point source Crab Nebula (Abdo et al. 2012b; Bartoli et al. 2013a). The fluxes of MGRO J1908+06 and HESS J1841−055 measured by the EAS arrays Milagro and ARGO-YBJ are about two to three
and nearby sources. In (Ackermann et al. 2011), the flux of which should contain the contributions from the overlapping at 12 and 20 TeV was determined in a region of 3° shown in Figure 3. We should also remind that the Milagro flux of TeV J2032+4130 at 12 TeV. This "corrected" value is also MGRO J2031+41 is corrected by subtracting the extrapolation if we use the Milagro result instead of the VERITAS one, the VER J2019+407 are smaller than those of MGRO J1908+06 and LAT, ARGO-YBJ, and Milagro. The Milagro data refer to the Cocoon determined here would be overestimated by about presence of a slope change or cutoff below ~1 GeV and above ~10 TeV, respectively.

4. DISCUSSION

The angular size of about 2° places the Cygnus Cocoon among the most extended VHE gamma-ray sources. At a distance of 1.4 kpc, the observed angular extension corresponds to more than 50 pc, making the Cygnus Cocoon the largest identified Galactic TeV source. Such a large region can be related to different scenarios. PWNs and SNRs contribute to most of the extended Galactic TeV sources identified up to now. Toward the Cygnus Cocoon, two pulsars (PSR J2021+4026 and PSR J2032+4127) and one SNR (SNR G78.2+2.1) have been detected. As remarked on by Ackermann et al. (2011), the PWNs powered by these two pulsars are unlikely to explain the cocoon emission and SNR G78.2+2.1 could be too young to be the unique accelerator in the cocoon able to diffuse over the whole region. However, PSR J2032+4127 and the Cygnus Cocoon are well-coincident apparently, and we cannot rule out the possibility that the cocoon emission is from the yet undiscovered remnant of a supernova that originated the pulsar. The favored scenario of Ackermann et al. (2011) is the injection of cosmic rays via acceleration from the collective action of multiple shocks from supernovae and winds of massive stars, which form the Cygnus superbubble. Such superbubbles have been long advocated as cosmic ray factories (Bykov & Toptygin 2001; Parizot et al. 2004; Ferrand & Marcowith 2010). Possibly, the Cygnus Cocoon is the first evidence supporting such a hypothesis.

For such a large extended region, no significant morphology and spectral variation have been found by Ackermann et al. (2011) in the range from 1 to 100 GeV. The energy spectrum from 1 GeV to 10 TeV shows a simple power-law shape, which is very similar to those of SNRs, such as Cassiopeia A, Tycho, W51C, IC 443, and so on (Yuan et al. 2012). This indicates that the Cygnus Cocoon may be an unknown SNR, or that the particle acceleration inside a superbubble is similar to that in an SNR. No matter which accelerator is responsible for the Cygnus Cocoon emission, the whole spectral shape of the gamma-ray emission from 1 GeV to 10 TeV allows us to determine a possible spectral slope of the underlying particle distribution for the first time. Different scenarios have been proposed to explain the emission mechanism of gamma-rays, which can be produced via inverse Compton (IC) scattering of background photon fields by high-energy electrons or, in hadronic models, by π0 decay from inelastic proton–proton or proton–photon interactions. The electron bremsstrahlung can be ignored if the electron-to-proton ratio is about 1% as measured around Earth. The close relation between the emission morphology and the interstellar structure revealed by Ackermann et al. (2011) favors a cosmic ray origin. The Fermi-LAT measurement below 3 GeV is also a hint of the π0 decay feature Ackermann et al. (2013). Moreover, the gamma-ray spectrum predicted by IC process is always curved, and it is difficult for the pure leptonic model to produce such a simple power-law shape from 1 GeV to 10 TeV.

In this work, we adopt a purely hadronic emission model (Drury et al. 1994) to produce the gamma-ray emission from the cocoon. In our model, the observed gamma-rays are attributed to the decay of π0 mesons produced in inelastic collisions between accelerated protons and target gas. The predicted spectrum is shown as the thick solid line in Figure 3. It is assumed that the primary proton spectrum follows a power law with index α and with an exponential cutoff energy $E_{\pi^0}$, i.e., $dN/dE \propto E^{-\alpha} e^{-E/E_{\pi^0}}$. The value
of $\alpha$ is the same as the spectral index of gamma-rays and $E_c$ is set to 150 TeV. This $E_c$ value is the maximum allowed by the ARGO-YBJ upper limit. It is worth recalling that as explained in the last section, the data points obtained by Milagro are not taken into account for this model. Taking them into account, the $E_c$ would be around 40 TeV, giving the dotted line shown in Figure 3. The total energy of the high-energy protons is $\sim 10^{50}$ (Ackermann et al. 2012). The interstellar gas density should be higher than 10 cm$^{-3}$. Hence, the derived proton power should be less than $1.5 \times 10^{50}$ erg, which can be reasonably provided by one supernova, which usually releases $\sim 10^{51}$ erg, about 10% of which can be transferred to the accelerated particles. This result plausibly supports one SNR or several SNRs, i.e., a supperbubble, as the accelerator responsible for the Cygnus Cocoon emission. The main feature of the gamma-ray emission from the hadronic model is that it predicts a clear cutoff at energy below 1 GeV (Ackermann et al. 2013), which is significantly different from that of the leptonic model and can be checked by future long-term observation from Fermi-LAT.

In a cosmic-ray source, both electrons and nuclei can be accelerated at the same time. The gamma-ray spectrum of Cygnus Cocoon can also be reproduced by a hybrid model. Recently, Yuan et al. (2012) proposed a unified model for the gamma-ray emission of SNRs. In this model, they assumed a constant ratio (1%) and identical spectral shape for cosmic-ray protons and electrons, which were derived from the locally observed spectra by taking into account the transport effects from sources to the observers. The diversity of gamma-ray spectra can be caused only by the differences of the medium gas density. According to this model, when the differential spectral index of gamma-rays is 2.16, the gamma-ray emission below 100 GeV is dominated by pion decay and the emission above 100 GeV is dominated by the electron inverse Compton scattering on low-energy background photons.

5. CONCLUSIONS

Using the whole ARGO-YBJ data collected from 2007 November to 2013 January, we reanalyzed the TeV gamma-ray emission from ARGO J2031+4157. The source extension is found consistent with that of the Cygnus Cocoon determined by Fermi-LAT at 1–100 GeV. The measured spectrum is consistent with a simple power-law extrapolation of the spectrum measured by Fermi-LAT, suggesting the same origin for both GeV and TeV gamma-ray emissions. These features support the identification of ARGO J2031+4157 as the TeV counterpart of the Cygnus Cocoon.

Even if a yet undiscovered nebula cannot be ruled out, such a large extended emission is likely due to the collective action of multiple shocks in a superbubble. The broad spectrum and the similarity with other SNRs indicate that the particle acceleration inside a superbubble is similar to that in an SNR. The GeV–TeV spectrum allows for the first time to determine the possible spectral slope of the underlying particle distribution. To further investigate into the Cygnus Cocoon and its relation with TeV J2032+4130, more sensitive observations by detectors with large collection area, high angular resolution, and wide FOV are needed. The new EAS experiments, such as HAWC, Tibet+MD, and LHAASO (more details about these detectors can be found in Chen 2013) are expected to play an important role for such an issue.
