**Abstract**

The HERC gene family encodes proteins with two characteristic domains: HECT and RCC1-like. Proteins with HECT domains have been described to function as ubiquitin ligases, and those that contain RCC1-like domains have been reported to function as GTPases regulators. These two activities are essential in a number of important cellular processes such as cell cycle, cell signaling, and membrane trafficking. Mutations affecting these domains have been found associated with retinitis pigmentosa, amyotrophic lateral sclerosis, and cancer. In humans, six HERC genes have been reported which encode two subgroups of HERC proteins: large (HERC1-2) and small (HERC3-6). The giant HERC1 protein was the first to be identified. It has been involved in membrane trafficking and cell proliferation/growth through its interactions with clathrin, M2-pyruvate kinase, and TSC2 proteins. Mutations affecting other members of the HERC family have been found to be associated with fertility and growth retardation. Here, we report the characterization of a recessive mutation named tambaleante, which causes progressive Purkinje cell degeneration leading to severe ataxia with reduced growth and lifespan in homozygous mice aged over two months. We mapped this mutation in mouse chromosome 9 and then performed positional cloning. We found a G⇒A transition at position 1448, causing a Gly to Glu substitution (Gly483Glu) in the highly conserved N-terminal RCC1-like domain of the HERC1 protein. Successful transgenic rescue, with either a mouse BAC containing the normal copy of Herc1 or with the human HERC1 cDNA, validated our findings. Histological and biochemical studies revealed extensive autophagy associated with an increase of the mutant protein level and a decrease of mTOR activity. Our observations concerning this first mutation in the Herc1 gene contribute to the functional annotation of the encoded E3 ubiquitin ligase and underline the crucial and unexpected role of this protein in Purkinje cell physiology.

**Introduction**

The cerebellum plays the role of a coordination centre, integrating peripheral sensory information on movement and position of the body parts to fine-tune gait and balance. Structural or functional alterations of this part of the central nervous system result in a complex syndrome, called ataxia, which is characterized by neurological signs that are clinically obvious in most species including the mouse. Many such mutations, either of spontaneous origin or resulting from strategies of genetic engineering performed in *vivo*, have been studied in detail in this species that, synergistically with human studies, have allowed advancement of our understanding of the developmental mechanisms generating the uniquely complex mature cerebellum.

In this publication, we report the positional cloning of an autosomal recessive mouse mutation, called *tambaleante* (symbol *tbl*, meaning staggering in Spanish), which is precisely characterized by a severe ataxic syndrome [1,2]. Mice homozygous for this mutation (*tbl/*tbl) exhibit an unstable gait, abnormal hindlimb posture and tremor. All these phenotypic characteristics correlate with a progressive degeneration of Purkinje cells (PCs) starting by two months of age. *tbl* mice thus represent a model of recessively inherited ataxia with progressive neurodegeneration of PCs. Using a combination of genetic, histological and biochemical approaches, we have been able to characterize the pathology of this mutation that we could relate to a mutation in the gene encoding the E3 ubiquitin ligase HERC1.

**Results**

Characterization of the *tambaleante* mutation

The *tambaleante* (*tbl*) mutation arose spontaneously in the DW/JPas inbred strain, at the Institut Pasteur, and appeared to be inherited as an autosomal recessive condition with complete
penetrance. The most remarkable phenotypic feature of homozygous (tbl/tbl) mice was an unstable gait with abnormal hind limb-clasping reflex, which became really obvious from two months of age and worsened with time (Figure 1A and Video S1). To quantify these observations, we performed rotarod assays with these animals. Figure 1B shows that tbl animals stayed less time on the rotarod without falling. To visualize the progressive degeneration of PC, we performed an analysis of cerebellum sections stained with haematoxylin and eosin (H&E). In Figure 1C–1F, we can observe the great loss of PC between 1–3 months in tbl animals. Immunostaining using anti-calbindin D28-k antibodies (Figure 1G–1J) of parasagittal sections of mouse cortex of 4 month old shows that tbl mice is almost completely depleted of PCs. Compared to their normal littermates, tbl/tbl homozygotes were smaller in size. Growth curves showed that the weight of the mutant animals was significantly and constantly lower than the weight of controls, varying from 15 to 30% according to age and gender (Figure 2). Mutant animals also showed a lower survival rate since less than 40 percent of the latter survived longer than 40 weeks on the original DW background (Figure 2). Both sexes appeared to be fertile although poor breeders.

Mapping and identification of the tambaleante mutation

Genotyping 30 F2 mutant offspring (60 meiotic events) of an inter-subspecific cross between DW-tbl/tbl males and wild type (+/+ ) females of the inbred strain MBT/Pas [3], allowed us to assign the locus for tbl to chromosome 9, within a 1.7 cm interval flanked by markers D9Mit233 and D9Mit165 (Figure 3A and 3B). Although this interval encompassed the locus of the staggerer (Rora<sup>6</sup>) mutation, which occurred in the gene encoding RAR-related orphan receptor alpha and is also characterized by a severe cell-autonomous defect of Purkinje cell [4], we could eliminate this gene as causative of the tambaleante phenotype through the finding and characterization of a recombination event between the loci for tbl and the one of Rora (Figure 3A). In addition, a complementation test performed by mating tbl/tbl mice to +/Rora<sup>6</sup> mice and yielding exclusively normal offspring confirmed non allelism of the two

Author Summary

The cerebellum is a coordination center whose function is to fine-tune vertebrates’ gait and balance; and for this reason, alterations or damage affecting this structure result in a complex syndrome, called ataxia, with neurological signs that are easily recognized. In the mouse, many mutations producing ataxia have been identified and characterized. They have contributed to a better understanding of the genetics of cerebellum development, physiology, and pathology. The present study identifies the recessive allele responsible for the progressive and massive degeneration of the Purkinje cells observed in mutant mice previously named tambaleante. The mutation leads to a single amino acid substitution in a highly conserved domain (RCC1-like) of the giant protein HERC1. This protein belongs to the families HECT (E3 ubiquitin ligases) and RCC1 (GTPases regulators). While a variety of mutations have been reported in several members of these families, leading to sterility, growth retardation, retinitis pigmentosa, amyotrophic lateral sclerosis, or cancer, no mutation had ever been reported so far in the mouse Herc1 gene. This report demonstrates the crucial and unexpected role of HERC1 in Purkinje cell physiology that could be considered helpful in the development of new therapeutic strategies for neurodegenerative disorders.
Figure 2. Growth and lifespan of tambaleante mice and control. Graphs of growth (left) and survival (right) from mice tambaleante (tbl/tbl) and mice control (+/+). Growth was analyzed in mice (n=9) aged 3–12 months of age. Data show mean±s.d.

Figure 3. Molecular genetics of the Herc1tbl locus. (A) Genotyping 30 tbl/tbl–F2 mice (60 meiotic events) of an intersubspecific cross allowed to map the tbl locus to mouse chromosome 9 between D9Mit233 and D9Mit165. White rectangles symbolize homozygosity for the DW genotype, blue rectangles symbolize heterozygosity, and deep blue homozygosity for MBT genotype. A single mouse, with a crossover between D9Mit302 and D9Mit303 and a +/- genotype at the tbl locus, allowed us to eliminate the Rora locus (where the mutation staggerer occurred) as a candidate. (B) The tbl candidate region contains eleven genes. BAC clone RP23-335L9 (shown as a green line) was used for transgenic rescue. (C) Sequence analysis of the cDNA from Herc1tbl/Herc1tbl and +/- DW mice showed a point mutation in exon 5, resulting in a Gly→Glu substitution. This missense mutation is located in the RCC1-like domain (RLD) 1 of the HERC1 protein (arrow in D) and changes a highly preserved glycine in the HERC and RCC1 family of proteins (arrow in E; see also [11]). Mouse HERC family and characteristic domains are also shown (D; see text for details).
doi:10.1371/journal.pgen.1000784.g003
mutations (data not shown). Finally, the tbl candidate region was reduced to a genomic segment of 0.6 cM (~0.98 Mb) between D9Mit233 (65.97 Mb) and D9Mit259 (66.95 Mb), which contains eleven known genes as indicated in the Ensembl sequence database (http://www.ensembl.org/Mus_musculus) (Figure 3A and 3B). Among the eleven genes that were identified in the interval, three candidates (Herc1; Usp3 and Rab11) appeared top ranked considering their expression profile and the known or putative functions of the encoded proteins (Figure 3B). Among these three candidates, Herc1 seemed to be the most likely one considering its large size and its sequence homology with Herc2, a locus where mutations that have phenotypes similar to tambaleante, a locus where mutations that have phenotypes similar to tambaleante, were already reported [5,6]. Sequence analysis of the ~15 kb cDNA corresponding to this gene and comparison with the sequences of the co-isogenic strain DW, allowed to identify a single nucleotide difference (a G1448A transition at ENSMUST00000042824) between the tbl and the normal (+) haplotype that resulted in a Gly483Glu substitution (Figure 3C). Sequence comparison with several other unrelated inbred strains confirmed that this sequence alteration was recent and unique to the mutant haplotype. The G<>A transition in the tambaleante haplotype generated a new restriction site for the MboII enzyme that allowed us to design a PCR assay, helpful for the diagnostic of tbl haplotype by discriminating +/+ from +/- tbl or tbl/tbl (Figure 4).

Rescue of tambaleante phenotype

To ascertain that the Gly483Glu substitution identified in Herc1 was really causative of the abnormal phenotype observed in tbl/tbl mice, we decided to attempt the rescue of the tambaleante phenotype by crossing tbl/tbl mice with transgenic mice expressing a normal copy of the Herc1 gene. We used two strategies to generate such transgenic mice: in the first case we used the mouse BAC clone RP23-355L9 (~160 kb - encompassing the Herc1 locus and a gene encoding a leucine-rich repeat protein 22 (Fbxl22) that is not expressed in the brain [7] (Figure 3B)); then we used the human cDNA of HERC1 (96% amino acid identity with mouse) [8]. BAC transgenic (TgRP23-355L9/+). The complete phenotypic rescue was also achieved with the other transgenic strain generated from the human HERC1 cDNA [6] in pCI-neo (Tg[HERC1DNA]) (Figure S2). The complete phenotypic rescue was also analyzed by weight, rotarod performance, cerebellar staining with H&E and immunohistochemistry with anti-calbindin D28-k antibodies (Figure 5). No differences in the parameters analyzed were observed between wild-type animals and transgenic mice. From these results we considered that the pathology in tambaleante mice is indeed a direct consequence of the molecular defect in Herc1. For this reason, we use Herc1<sup>tbl</sup> as an official symbol for the Herc1 mutant allele.

Expression of the Herc1 gene and functional analysis

Analysis of the Herc1 gene expression by Northern blotting has been previously reported and revealed ubiquitous expression in mammalian tissues although at very low levels in the liver [8]. We have confirmed these data by RT-PCR in mouse tissues using specific primers for Herc1 (Figure 6). In situ hybridization of brain sections also confirmed a pattern similar to that shown in the Allen Brain Atlas [9, and data not shown]. The HERC proteins have a HECT (Homologous to E6-AP COOH-terminus) domain and at least one domain related with RCC1 (Regulator of Chromosome Condensation 1). HECT domains are involved in the transfer of ubiquitin or ubiquitin-like proteins to target substrates. RCC1-like domains (RLD) seem more versatile and may have a role in guanine nucleotide exchange on small GTP-binding proteins, in enzyme inhibition and in interaction with proteins and lipids. Proteins containing

Figure 4. Genotyping analysis of tbl mutation. The tbl mutation generates a new restriction site (GAAGA) for the MboII enzyme. PCR amplification of genomic DNA samples of wild-type (+) or Herc1<sup>tbl</sup> haphlotypes with specific primers followed by digestion of the amplification products with the MboII enzyme allows identifying a haplotype specific pattern by PAGE. doi:10.1371/journal.pgen.1000784.g004
A Mutation in Mouse Herc1 Causes Neurodegeneration

some of these domains are important regulators of cellular processes such as cell cycle, cell signalling and membrane trafficking. HERC1 protein was the first protein of this family to be identified. It contains one HECT domain, two RLD (RLD1 and RLD2), seven WD40 repeats and one SPRY domain (Figure 3D and 3E) [10–12]. The Gly483Glu substitution found in tambaleante mice is located within the highly conserved N-terminal RCC1-like domain (RLD1) of the HERC1 protein and presumably alters its structure and function (Figure 3D and 3E) [10]. To check whether Herc1<sup>plt</sup> mutation affected the HERC1 protein levels, we performed Western-blot analysis using anti-HERC1 antibodies with samples from brain, cerebellum and kidney of mice older than 3 months. Surprisingly, we observed a significant increase in the amount of HERC1 protein in mutant mice, suggesting a possible increase of its stability (Figure 7A and 7D). No changes were observed with any other protein such as clathrin heavy chain (CHC) that was used as loading control (Figure 7A). Similar results were also found in skeletal muscle (not shown).

HERC1 has been previously reported to interact with TSC2 complex. TSC1 and TSC2 are tumour-suppressor genes that are mutated in the tumour syndrome TSC (tuberous sclerosis complex). Their gene products form the TSC1-TSC2 complex (also named hamartin-tuberin complex) and, through its GAP (GTPase-activating protein) activity towards the small G-protein Rheb (Ras homolog enriched in brain), this complex is a negative regulator of mTORC1 (mammalian target of rapamycin complex 1) [13]. Because processes such as growth, autophagy and neuronal plasticity are known to be regulated, at least in part, through the mTOR pathway [14,15] and because Herc1<sup>plt</sup>/Herc1<sup>plt</sup> mice show features related to these processes (neuronal degeneration and smaller size), we hypothesized that a mutant HERC1 protein might affect some of these events through deregulation of the mTOR pathway. With this guess in mind, we first analyzed whether the levels of the TSC1-TSC2 complex and mTOR protein were modified in the brain of Herc1<sup>plt</sup>/Herc1<sup>plt</sup> mice. We found that the levels of these proteins remained normal in these animals suggesting that the mutant HERC1 protein does not affect their stability (Figure 7B). We then checked whether the mTOR activity was modified, and to achieve this, we analyzed the phosphorylation of a substrate of the mTORC1 activity, the ribosomal protein S6 kinase 1 (S6K1). We observed a decrease of the phosphorylation of S6K1 at threonine 389 (P-T389-S6K1) in cerebellum of Herc1<sup>plt</sup>/Herc1<sup>plt</sup> mutant mice (Figure 7C). These data were also confirmed and quantified in kidney where P-T389-S6K1 levels were found higher compared to +/+ mice (Figure 7C).

Because it had been previously reported that mTOR negatively regulates autophagy [16], we thought that the decrease of the mTORC1 kinase activity could correlate with an increase of autophagy in tbl/tbl mice. The conversion of the microtubule-associated protein light chain 3 (LC3-I) to its phosphatidylethanolamine-modified form (LC3-II) has been used as marker of the accumulation of autophagosomes [17]. We have measured by immunoblot analysis this autophagy marker observing an increase of LC3-II levels in brain and cerebellum of tambaleante mice (Figure 7B and 7C). To check that this increase was due to increases in autophagic activity and not to reduced turnover of autophagosomes [18], we also measured the steady-state levels of the known substrate for autophagy p62/SQSTM1 [19]. We observed a significant decrease in the steady-state levels of p62/SQSTM1 (Figure 7C) indicating that autophagic flux was not blocked. Altogether these data suggest that autophagy is induced in tbl/tbl mice. An attractive hypothesis would be that this activation is the cause of PC death in the tambaleante mice. This however is difficult to ascertain because an increase in autophagy is also a protective mechanism for cells in response to stressing stimuli. To determine whether this was the case or not, we analyzed the occurrence of autophagy at an earlier phase of the PC degeneration; in 2-month-old Herc1<sup>plt</sup>/Herc1<sup>plt</sup> cerebellum. Double labeling with antibodies against anti-calbindin D28-k and
lyssosome-associated membrane protein LAMP-1 allowed us to identify lysosomes with large cytoplasmic accumulations in dendrites and somata being particularly numerous in regions of the cerebellar cortex which had lost the calbindin D28-k expression (Figure 7E). Electron microscopy also performed on 2-month-old mice showed that PC bodies contained numerous autophagosomes (vacuoles with double membrane and filled with cytoplasmic organelles) and autolysosomes (vacuoles with a single membrane and filled with larger inclusions) (Figure 7F–7H). Altogether these data show that activation of autophagy in Herc1 tbl/Herc1 tbl mutant mice is indeed the earliest pathological process that seems to be involved in the degeneration and death of PCs. This high degree of autophagy is unique to the Herc1 tbl mutation and has never been reported before for any other cerebellar mutation [20].

Discussion

Genes of the Herc/HERC family are absent in prokaryotes and in eukaryotes such as fungi and plants. In mammalian genomes there are several Herc/HERC paralogous copies encoding two subgroups of proteins: large (HERC1–2) and small (HERC3–6 in human; HERC3–5 in mouse). The HERC1 giant protein, which was the first to be identified in a screening looking for human oncogenes, contains several domains (one HECT, two RLDs, seven WD40 repeats and one SPRY) involved in protein ubiquitilation, guanine nucleotide exchange and protein-protein or protein-lipid interactions. This structure probably reflects the multiple interactions of this protein with other cellular proteins. HERC1 interacts with phosphoinositides and with several other proteins such as clathrin, ADP-ribosylation factor (ARF), M2-pyruvate kinase and TSC2 and, through these interactions it has been involved in membrane trafficking, cell growth and proliferation [8,10–12].

The Gly483Glu substitution that we found in tambaleante mice, is sometimes of better value for gene annotation than a knockout allele that, in general, suppresses at once the protein. It does not appear that the Herc1 tbl/b.tbl mutation has a dominant negative effect on the HERC1 function because transgenic mice could rescue the tambaleante phenotype. Our data seem to indicate that the tambaleante protein is not functional or has acquired a different function to the wild-type protein and that the presence of wild-type protein has a dominant effect. For this reason, heterozygous or rescued mice, where the Herc1 tbl mutation has a dominant negative effect on the HERC1 function because transgenic mice could rescue the tambaleante phenotype. Our data seem to indicate that the tambaleante protein is not functional or has acquired a different function to the wild-type protein and that the presence of wild-type protein has a dominant effect. For this reason, heterozygous or rescued mice, where the wild-type HERC1 protein is present, do not exhibit a tambaleante phenotype.

Because ataxia is the most apparent feature in tambaleante mice and because this symptom is commonly associated to a cerebellar defect, we focused more on this part of the CNS than on any other in our morphological survey. However, in all cases, the paraffin embedding and serial sectioning after Nissl staining that were achieved on adult mutant CNS, did not allow detection of any obvious lesion outside the cerebellum (retina was not analyzed). Nevertheless, the possibility that some type of alteration could be disclosed using more specialized methods (immunohistochemistry, electron microscopy) remains open.
In humans, genes encoding proteins with mutations in their RCC1 domains have been found to be involved in several diseases [11]. The best studied is probably the RPGR (Retinitis pigmentosa GTPase regulator) gene, which is responsible for 70–80% of the most severe forms of human the X-linked retinitis pigmentosa [16], and in which more than 200 independent mutations have been identified. Functional studies suggest a role for this protein in microtubule-dependent transport along cilia [21]. Another example is provided by the ALS2 (amyotrophic lateral sclerosis 2-juvenile) locus, which encodes for a protein whose mutations have been associated to an autosomal recessive form of juvenile-onset amyotrophic lateral sclerosis (ALS) [22,23]. All mutations found in this gene lead to the production of truncated proteins. Interestingly, truncations affecting its amino-terminus, where the RCC1-like domain is located, lead to jALS with degeneration of upper and lower spinal cord motoneurons, whereas less severe truncations in the protein Alsin lead only to degeneration of the upper motoneurons [24,25]. Gene expression of HERC1 has also been reported to be increased in human tumour cell lines [8] and decreased in heroin users with a genetic variation of the opioid receptor [26].

HERC2, the other member of the large HERC family, has also been found associated with pathologies. Mutations in the mouse Herc2 gene were found to be responsible for the so-called runty, jerky, sterile-syndrome or, in short, nj-syndrome, also known as jdf-2 (juvenile development and fertility-2) [5,6]. The pathogenic mechanisms of this syndrome are not known at the molecular level, but it has been suggested that at least some of its symptoms could be due to pituitary defects. In humans, the HERC2 genomic locus, including several partially duplicated paralogs (duplicons) of HERC2 [27,28], corresponds to the chromosomal breakpoint region in deletions that cause the Prader-Willi and Angelman syndromes [29,30] although lack of HERC2 protein does not seem to play a role in these syndromes [6]. Recently, it has been reported that a single nucleotide polymorphism in intron 86 of the HERC2 gene determines human blue/brown eye colour by controlling the expression of the neighboring gene OCA2 [31–33].

In summary, the present study unambiguously demonstrates that the gene Herc1 is involved in the mutation tambaleante and shows, for the first time, that this gene has a profound impact on growth and maintenance of the cerebellar structure. To our knowledge, no other mutant allele has ever been reported at the Herc1 locus before Herc1tbl. Considering the relative great size of this gene (78 exons - with a predicted coding region of 14,559 bp) this is rather surprising and probably means that a majority of the mutations likely to occur at this locus either have no deleterious effects or, most probably, that they are lethal in utero and accordingly remained undetected so far. This is an important difference with the Herc2 locus where at least a dozen mutations have been reported that lead to the jdf/jdf2 syndrome [5,6]. This also means that, in spite of ancestral relationships, the two proteins have acquired some specific, non-redundant functions.

Materials and Methods

Animals

The tambaleante mutation is available at the RIKEN BioResource Center, Tsukuba, Japan (<http://www2.brc.riken.jp/> - Ref: RBRC00188). The mouse strain transgenic for the mouse BAC clone RP23-335L9 was generated in Kyoto University by direct in utero injection. The mouse strain transgenic for the full-length human HERC1 cDNA was generated at the Institute Pasteur. The transgene was previously generated in two steps: first, we digested pCIneo vector (The vector carries the cytomegalovirus...
A Mutation in Mouse Herc1 Causes Neurodegeneration

(CMV) immediate-early enhancer/promoter, from Promega) with the GATCCATATGCAATAAG-GCAGCTATGGG-3' and 5'-CCTCAGTGTTCGCCACAC-3', yielding a 476 bp product (PCR settings were: 94°C×5 minutes, 94°C×30 seconds, then annealing at 60°C for 30 seconds, and elongation at 72°C for 30 seconds. Number of cycles: 35). Amplification products were then digested with MboII enzyme and fractionated in a 10% PAGE to distinguish among blb/+ , blb/blb and +/- mice. Transgenic mice were genotyped using the primers: 5'-TGTTGAAATAGTATCCCAC-3' and 5'-CAGCTATGGG-3', yielding a 506 bp product (PCR settings: 94°C×5 minutes, 94°C×30 seconds, then annealing at 53°C for 30 seconds, and elongation at 72°C for 45 seconds. Number of cycles: 35).

RT–PCR
A mouse multiple-tissue and embryo cDNA set (Mouse MTC Panel I, Clontech) was used for expression analysis of Herc1 gene. RT–PCR was performed with following primers: 5'-GTGCAGCAGA-3' and 5'-GGTCTGTCCGGTGAAGGATA-3' for mouse Herc1 cDNA (199 bp), and Gapdh 5' and 3' PCR primers (983 bp) as a control. To assess transgene expression, total RNA was isolated from mouse brains using the Ultraspec RNA Isolation System (Biotech). 2 μg of total RNA were reverse-transcribed using the cDNA Reverse Transcription kit (Applied Biosystems) and random primers. PCR was carried out with primers: 5'-AGTCGACCTGATCGATCCGGATCC-3' and 5'-AGTCTGGTCAAGTGTGTC-3' for the transgene and 5'-ATGGATGAC-3' and 5'-ATGAAGGTAGTCCGTACAGGA-3' for the actin control.

Histology and immunohistochemistry
Mice were perfused transcardially with a fixative containing 4% formaldehyde in 0.1 M phosphate buffer after being deeply anesthetized by diethyl ether inhalation. The cerebellum was removed and postfixed in the same fixative for two hours, then embedded in gelatin 8% and subsequently processed for respective histochemical analyses. Tissue samples were stored at −80°C and cut on a cryostat. Cryosections were stained with H&E or immunostained with rabbit polyclonal anti-calbindin D28k or anti-LAMP-1 (N-19) antibodies (Santa Cruz Biotechnology, Inc.); anti-CHC antibody (BD Transduction laboratories); anti-HERC1 antibodies [8]; anti-LC3 antibody (MBL); anti-calbindin D28k antibody (Swant, Bellinzona, Switzerland); and anti-p62/SQSTM1 antibody (Abnova).

Lysates and immunoblotting
Mice (3–7 months old) were euthanized by cervical dislocation. Organs were collected and frozen in liquid nitrogen and stored at −80°C until analysis. Tissues were prepared in lysis buffer (consisting of 10 mM Tris-HCl, pH 7.5, 100 mM NaCl, 1.5 mM MgCl2, 50 mM NaF, 1 mM sodium vanadate, 1 mM phenylmethylsulfonyl fluoride, 5 mg/ml leupeptin, 5 mg/ml aprotinin, 1 mg/ml pepstatin A, 50 mM β-glycerophosphate, 100 mg/ml benzamidine), homogenized in a motor-driven Polytron PT3000 (Kinematica AG) incubated in a precooled tube with CHAPS 0.3% for 20 minutes, and centrifuged at 13,500g for 15 min at 4°C. Total protein levels were measured by BCA (Pierce). Equal amounts of supernatant proteins (200μg/lane) were separated by electrophoresis. To analyze simultaneously in the same SDS/PAGE gel giant proteins such as HERC1 or mTOR and small proteins such as LC3, lysates were loaded in a combination of SDS/PAGE gels named LAG gel [36]. After running the gel overnight, the proteins were transferred to PVDF membranes and visualized by immunoblotting using specific antibodies as previously described [36]. Band intensities were analyzed with a gel documentation system (LAS-3000 Fujifilm). The protein levels were normalized with respect to CHC, mTOR or S6K1 levels and expressed as percentage of controls.

Figure S2 Expression of the transgene TgHERC1DNA. Total RNA was isolated from mouse brains (blb/blb, TgHERC1DNA/++; tbl/tbl, TgHERC1DNA/++). 2 μg of total RNA were reverse-transcribed using random primers. PCR was carried with specific primers for transgene and actin. Actin was used as control. Transgene cassette (pJLR189) was used as positive control and pDEST-HA vector as trained a constant speed (16 rpm) for 60 s. The animals were put on the rotarod until the latency to fall off reached the total time of 60 s. Each mouse was placed on the rotarod with its head in the direction of rotation and so had to turn to the opposite direction. We performed three trials per day with 2–6 min intervals, on three consecutive days. During the pauses between the turns, mice were allowed to rest in their home cages. After training, mice were evaluated once at 6, 8 and 12 weeks of age at a constant speed of 12 rpm until the latency of fall reached 1 min. The percentage (%) of animals that stayed for 60s is shown in Figure 5. For Figure 1, each mouse had three trials per test with an intertrial interval of 5 minutes. Mice (n = 4 to 9) were placed on the rotating drum at 20 rpm and the time the animal stayed on the rotarod without falling off was measured. The hind limb clasping reflex was assessed by holding the mouse by its tail for 30 seconds.
negative control. Amplified DNA was run in agarose gels stained with ethidium bromide.
