ABSTRACT Propionic, sorbic, and benzoic acids are organic weak acids that are widely used as food preservatives, where they play a critical role in preventing microbial growth. In this study, we uncovered new mechanisms of weak-acid resistance in molds. By screening a library of 401 transcription factor deletion strains in Aspergillus fumigatus for sorbic acid hypersensitivity, a previously uncharacterized transcription factor was identified and named weak acid resistance A (WarA). The orthologous gene in the spoilage mold Aspergillus niger was identified and deleted. WarA was required for resistance to a range of weak acids, including sorbic, propionic, and benzoic acids. A transcriptomic analysis was performed to characterize genes regulated by WarA during sorbic acid treatment in A. niger. Several genes were significantly upregulated in the wild type compared with a ΔwarA mutant, including genes encoding putative weak-acid detoxification enzymes and transporter proteins. Among these was An14g03570, a putative ABC-type transporter which we found to be required for weak-acid resistance in A. niger. We also show that An14g03570 is a functional homologue of the Saccharomyces cerevisiae protein Pdr12p and we therefore name it PdrA. Last, resistance to sorbic acid was found to be highly heterogeneous within genetically uniform populations of ungerminated A. niger conidia, and we demonstrate that pdrA is a determinant of this heteroresistance. This study has identified novel mechanisms of weak-acid resistance in A. niger which could help inform and improve future food spoilage prevention strategies.

IMPORTANCE Weak acids are widely used as food preservatives, as they are very effective at preventing the growth of most species of bacteria and fungi. However, some species of molds can survive and grow in the concentrations of weak acid employed in food and drink products, thereby causing spoilage with resultant risks for food security and health. Current knowledge of weak-acid resistance mechanisms in these fungi is limited, especially in comparison to that in yeasts. We characterized gene functions in the spoilage mold species Aspergillus niger which are important for survival and growth in the presence of weak-acid preservatives. Such identification of weak-acid resistance mechanisms in spoilage molds will help in the design of new strategies to reduce food spoilage in the future.

KEYWORDS Aspergillus, food spoilage, fungi, transcription factors, weak-acid resistance
supply and safety. The use of chemical food preservatives to inhibit the growth of bacteria and fungi is a ubiquitous and generally effective strategy in reducing spoilage (2). Some of the most commonly used preservatives are weak organic acids such as propionic, sorbic, and benzoic acids. These are usually included in food and drink products in the form of calcium, potassium, and sodium salts, respectively.

Weak-acid preservatives are broad-spectrum antimicrobials that directly inhibit the growth of yeasts, molds, and bacteria. Although their precise mechanism of action has not yet been fully determined, it is known that weak-acid preservatives cause a reduction in cytoplasmic pH (3, 4) and inhibit nutrient uptake (5, 6). It is also known that weak acids tend to be fungistatic rather than fungicidal, especially at the levels legally permitted in food and drinks. In most cases, microbial growth is completely inhibited by the weak-acid levels used in food and drink products. However, certain species of yeasts and molds demonstrate elevated resistance to weak acids and are therefore capable of causing food spoilage (7, 8).

Weak-acid resistance can be attributed in part to the enzymatic degradation of certain acids (e.g., benzoic, sorbic, and cinnamic acids), which nullifies their antimicrobial effects. Benzoate can be catabolized through a pathway involving an initial hydroxylation step. The enzyme responsible (benzoate para-hydroxylase) has been found to be required for resistance to benzoic acid in Aspergillus niger and Aspergillus nidulans (9, 10). Sorbic and cinnamic acids (and certain other structurally related acids) are degraded by decarboxylation (11). In molds such as A. niger, a cluster of three genes is required for this process, encoding a transcription factor (SdrA), a decarboxylase (CdcA; formerly OhbA1 or FdcA) and a prenyltransferase (PadA) (12–15). The deletion of any of these genes reduces, but does not eliminate, resistance to sorbic acid. Thus, additional and as-yet-uncharacterized mechanisms of weak-acid resistance must operate in this mold species. Enzymatic decarboxylation of weak acids also occurs in numerous yeast species (16). However, contrary to the case in molds, deletion of the phenylacrylic acid decarboxylase gene (PAD1) in the yeast Saccharomyces cerevisiae does not decrease weak-acid resistance (16). Furthermore, certain spoilage yeasts do not appear to decarboxylate weak acids at all, suggesting that alternative mechanisms of resistance also operate in these species.

Mechanisms of weak-acid resistance have been best characterized in S. cerevisiae. One of the key genes required for resistance is PDR12, encoding an ATP-binding cassette (ABC) transporter (17). PDR12 is required for resistance to carboxylic acids with chain lengths between 1 and 7, presumably by mediating the efflux of weak-acid anions from the cell in an energy-dependent manner (18). PDR12 is itself transcriptionally regulated by War1p, a Zn2Cys6 zinc finger transcription factor that binds to weak-acid response elements (WARE) in the PDR12 promoter (19). Another transcription factor, Haa1p, is also required for resistance to weak acids in S. cerevisiae by regulating the transcription of membrane multidrug transporters (Tpo2p and Tpo3p) among other, less-well-characterized genes (20). High-throughput mutant screens have helped identify many other genes which influence weak-acid resistance in S. cerevisiae. For example, Mollapour et al. (21) reported 237 genes which were required for wild-type resistance to sorbic acid and a further 34 genes which resulted in enhanced sorbic acid resistance when deleted. A similar study, also on S. cerevisiae, revealed 650 determinants of acetic acid resistance (22). Unfortunately, there is a distinct lack of equivalent data in any other fungal species, including molds. Considering the propensity of mold fungi to cause food spoilage, understanding the genetic determinants of weak-acid resistance in these species is very important.

An additional and historically overlooked determinant of antimicrobial resistance is the phenotypic heterogeneity that exists within microbial cell populations. Phenotypic heterogeneity is a phenomenon observed within isogenic cell populations, whereby individual cells can display a markedly different phenotype despite being genetically identical. This has been recognized as an important determinant of microbial cell survival in response to antimicrobial agents and other environmental stressors (23–25). Phenotypic heterogeneity in weak-acid resistance (heteroresistance) has been found in
cell populations of *S. cerevisiae* and the spoilage yeast *Zygosaccharomyces bailii* (8, 26, 27). However, there has been no investigation to date of whether weak-acid resistant subpopulations exist in populations of mold spores, although heterogeneity is known to arise in *A. niger* spore populations as a consequence of asynchronous conidial maturation (28). The presence of weak-acid-resistant spore subpopulations could have significant implications for spoilage control strategies and is therefore worthy of investigation.

In this study, we report the identification and characterization of a novel transcription factor (weak acid resistance A) that is required for resistance to weak-acid preservatives in *A. niger* and *A. fumigatus*. Furthermore, we identify and characterize genes that are putatively regulated by WarA, including a gene encoding a putative membrane transporter protein with similarity to *S. cerevisiae* Pdr12p and which, we show, mediates weak-acid resistance and heteroresistance in *A. niger*. These data significantly enhance our understanding of weak-acid resistance in molds and highlight both similarities and differences in weak-acid resistance strategies between yeast and mold fungi.

(This article was submitted to an online preprint archive [29].)

**RESULTS**

A screen for transcription factor deletion strains sensitive to sorbic acid identifies *warA*. To find genes associated with weak-acid resistance, an *Aspergillus fumigatus* transcription factor deletant collection (30) was screened for sorbic acid sensitivity. *Aspergillus fumigatus* is not commonly associated with food spoilage, and it displays relatively high sensitivity to weak acids such as sorbic acid (14). However, deletant collections are available in *A. fumigatus*, unlike aspergilli associated with food spoilage. It was reasoned that transcription factors associated with weak-acid resistance in *A. fumigatus* may be conserved in related spoilage species such as *A. niger*. This resource comprised a library of 401 deletion strains of nonessential transcription factors. To determine sensitivity of the deletion strains, radial growth was compared on agar medium with and without sorbic acid (Fig. 1). This revealed two deletion strains which were highly sensitive to sorbic acid compared with the wild-type strain (ΔmetR and ΔAFUB_000960 mutants) (Fig. 1 and 2A). A number of other strains exhibited moderate sensitivity to sorbic acid, including the ΔcreA (ΔAFUB_027530), ΔdevA (ΔAFUB_030440) (Fig. 1B and 2A), ΔrfeD (ΔAFUB_022280), ΔAFUB_020350, and ΔAFUB_054360 mutants (Fig. 1B).

MetR is a basic leucine zipper domain (bZIP)-type transcription factor mediating the transcriptional regulation of genes involved in sulfur uptake and utilization (31). Because sorbic acid is known to decrease cellular uptake of some nutrients (6, 32), it was hypothesized that sulfur limitation could be a cause of sorbic acid sensitivity in the ΔmetR mutant strain. To test this, the sorbic acid sensitivity of the ΔmetR mutant strain was determined in medium supplemented with the sulfur-containing amino acid methionine. This showed that the sorbic acid sensitivity of the ΔmetR mutant strain was abolished in the presence of supplementary methionine (see Fig. S1 in the supplemental material).

AFUB_000960 encodes a Zn2Cys6-type transcription factor which contains a fungus-specific transcription factor domain (PF11951). To further investigate the role of AFUB_000960 in weak-acid resistance, sensitivity of the deletion strain to a range of weak acids was evaluated (Fig. 2B). The ΔAFUB_000960 mutant strain was sensitive to propionic, butanoic, pentanoic, hexanoic, sorbic, and benzoic acids but not to acetic acid. Because of these phenotypes, AFUB_000960 was named weak acid resistance A (*warA*).

A WarA orthologue in *A. niger* is important for weak-acid resistance. To determine whether orthologues of WarA are present in other species of fungi, a BLAST search using the WarA of *A. fumigatus* (AfuWarA) protein sequence as a query was conducted. In *A. niger*, this identified An08g08340, a protein with 46.2% identity and 63% similarity to the *A. fumigatus* WarA protein. Orthologues of AfuwarA were also found to be present in *Penicillium* and *Botrytis* spp.
Aspergillus niger is highly resistant to weak acids (especially sorbic and benzoic acids) and can readily cause food and drink spoilage. To determine whether warA is also required for weak-acid resistance in A. niger, An08g08340 was deleted by a targeted gene replacement approach, with successful deletion confirmed by PCR and Southern blotting (Fig. S2). The sensitivity of the ΔAn08g08340 mutant strain to different weak acids was evaluated (Fig. 3). In contrast to the ΔwarA mutant of A. fumigatus, the A. niger ΔAn08g08340 mutant strain demonstrated only slight sensitivity to sorbic acid, which was most apparent when individual conidia of the ΔwarA mutant strain were spread onto medium containing sorbic acid (Fig. S3A). However, the deletant was highly sensitive to propionic, butanoic, and benzoic acids, as evaluated by radial growth on agar (Fig. 3). Determination of MICs in broth also corroborated the radial growth data; the MIC in benzoic acid was 4.5 ± 0.5 mM in the wild type (WT; n = 3) compared with 3.2 ± 0.2 mM in the ΔwarA mutant (n = 3). The MIC in butanoic acid was 8.6 ± 0.0 mM in the WT (n = 2) and 6.9 ± 0.3 mM in the ΔwarA mutant (n = 3). Resistance was restored to WT levels when An08g08340 was reintroduced into the ΔAn08g08340 mutant strain (Fig. S4). Thus, An08g08340 has an important role in weak-acid resistance in A. niger and was named warA also in this species.
Sorbic acid (and structurally related acids) are known to be detoxified by decarboxylation in *A. niger* but not in *A. fumigatus* (14, 15). The decarboxylation process involves three linked genes, *cdcA*, *padA*, and *sdrA* (12, 14). CdcA is the key enzyme involved in the decarboxylation, whereas SdrA is a transcription factor regulating the expression of CdcA, and PadA synthesizes a cofactor for CdcA. It was hypothesized that the mild sorbic acid sensitivity of the *A. niger ΔwarA* mutant may be due to downregulation of

**FIG 2** Growth of *A. fumigatus* transcription factor deletion strains on medium containing weak acids. the cdcA, padA, or sdrA genes in the ΔwarA mutant strain. To investigate the relationship between WarA and weak-acid decarboxylation, a ΔΔcdcA/warA double mutant was constructed. The ΔΔcdcA/warA double mutant strain was more sensitive to sorbic acid than was the ΔcdcA mutant strain (Fig. S3B), suggesting a cdcA-independent role for warA in resistance of A. niger to sorbic acid.

**Determination of WarA-regulated genes by transcriptomic analysis during weak-acid stress of A. niger.** The weak-acid sensitivity of the ΔwarA mutant suggested that WarA regulates genes which are important for weak-acid resistance. Previously, genes upregulated by sorbic acid exposure in A. niger were successfully identified by exposing conidia of the wild type (WT) to sorbic acid during germination (6). In order to identify which genes are differentially regulated in the A. niger ΔwarA mutant, RNA sequencing (RNA-seq) analysis was conducted with WT and ΔwarA mutant conidia germinated in the presence or absence of sorbic acid. Germination of WT conidia for 1 h in the presence of 1 mM sorbic acid resulted in 3,274 differentially expressed genes (false-discovery rate [FDR]-adjusted P < 0.05) (1,885 upregulated and 1,467 downregulated) in comparison with conidia germinated in the absence of sorbic acid. In the ΔwarA mutant conidia, 3,442 genes were differentially expressed during germination in the presence of sorbic acid (1,885 upregulated and 1,557 downregulated), in comparison with germination without sorbic acid. Importantly, a number of genes were identified that were highly upregulated in the WT during sorbic acid exposure but not in the ΔwarA mutant (Tables 1 and S1). This included a gene encoding benzoate para-hydroxylase (bphA), an enzyme known to be required for benzoate detoxification (9), which had a log2 fold change (log2FC) of 6.50 in the WT, compared with a log2FC of −0.51 in the ΔwarA mutant. A number of uncharacterized enzymes also required warA for normal upregulation by sorbic acid, e.g., An12g09130 encoding a putative dienelactone hydrolase, and An12g02790 encoding a putative isoflavone reductase (log2FC 5.95 in the WT and log2FC 0.36 in the ΔwarA mutant), as well as several genes encoding putative transporter proteins. Of particular interest among these transporters was An14g03570, an ABC-type transporter with 56% amino acid sequence similarity to S. cerevisiae Pdr12p.
**cerevisiae** Pdr12p. Pdr12p has a crucial role in weak-acid detoxification in *S. cerevisiae* (17, 18). To support the RNA-seq data, five of the genes showing differential expression between the WT and ΔwarA strains were selected for quantitative reverse transcription-PCR (qRT-PCR) analysis (Fig. 4). The qRT-PCR data supported the trends in gene expression seen in the RNA-seq data set; all of the selected genes had a lower transcript abundance in the ΔwarA mutant than in the WT during sorbic acid treatment. In addition, transcript abundances of the selected genes were compared by qRT-PCR during benzoic acid treatment. As expected, all of the genes upregulated by sorbic acid were also upregulated by benzoic acid and had lower transcript abundances in the ΔwarA mutant than in the WT (Fig. 4).

**Characterization of An02g09970 and An14g03570.** The transcriptomic analysis identified genes that are downregulated in the *A. niger* ΔwarA mutant, relative to the WT strain, during weak-acid stress. These genes may therefore have a role in weak-acid resistance. To investigate this, two genes of interest (An02g09970 and An14g03570) were selected for further characterization. An02g09970 encodes a putative transmembrane transporter of the major facilitator superfamily (MFS) and was selected for further investigation due to its extremely high transcript abundance during sorbic acid treatment and large disparity in transcript abundances between the WT and ΔwarA mutant strains (log₂FC of 8.56 in the WT versus log₂FC of 4.35 in the ΔwarA mutant) (Table 1). The protein also shares significant sequence similarity with Tpo2 and Tpo3, *S. cerevisiae* proteins involved in resistance to acetic, propionic, and benzoic acids (20). An14g03570 encodes an ABC-type transporter with similarity to the weak-acid detoxification protein Pdr12p in *S. cerevisiae*, as stated above. Both genes were deleted in *A. niger* by a targeted gene replacement approach, and mutant genotypes were confirmed by PCR and Southern blotting (Fig. S5). The sensitivity of the constructed deletion strains to weak acids was then evaluated. The ΔAn02g09970 mutant did not exhibit altered sensitivity to any of the weak acids tested (Fig. 5). However, the ΔAn14g03570 mutant was more sensitive to sorbic, pentanoic, and benzoic acids (Fig. 5 and Table 2), and
resistance was restored to WT levels when An14g03570 was reintroduced into the ΔAn14g03570 mutant strain (Fig. S6). Because of the similarity in sequence and function between An14g03570 and Pdr12p, An14g03570 was named PdrA.

**Complementation of the *S. cerevisiae* Δpdr12 mutant strain with PdrA (An14g03570).** The above-mentioned results showed that *pdrA* is required for resistance of *A. niger* to certain weak acids. Because PdrA has significant protein sequence similarity with *S. cerevisiae* Pdr12p (36% sequence identity, 56% similarity), it was hypothesized that these proteins could be functional homologues. To test this hypothesis, functional complementation of the *S. cerevisiae* Δpdr12 mutant strain was attempted. The cDNA sequence of *A. niger* pdrA was cloned between the *S. cerevisiae* PDR12 promoter and terminator to allow for native regulation of *pdrA* in response to weak-acid stress in *S. cerevisiae*. The resulting plasmid (Fig. S7) was transformed into a *S. cerevisiae* Δpdr12 mutant strain. Transformants were tested for sensitivity to a range of weak acids. As hypothesized, pdrA could indeed functionally complement PDR12, as sensitivity of the Δpdr12 mutant strain to weak acids was largely rescued in cells transformed to express pdrA (Fig. 6). The resultant level of resistance was similar to that evident in Δpdr12 mutant cells expressing PDR12 from the same vector backbone.

**TABLE 2** MIC values for *A. niger* WT and the ΔAn14g03570 (ΔpdrA) mutant strain

| Acid     | MIC (mM) for WT | ΔpdrA mutant |
|----------|----------------|--------------|
| Benzoic  | 4.67 ± 0.12    | 3.40 ± 0.20  |
| Pentanoic| 3.70 ± 0.35    | 2.60 ± 0.30  |
| Sorbic   | 5.00 ± 0.35    | 3.80 ± 0.35  |

*Values are averages of 3 biological replicates ± the standard deviation.*
**pdrA** is a determinant of heteroresistance to sorbic acid in *A. niger* conidia.

Resistance to weak-acid preservatives has been found to be heterogeneous between individual cells of genetically uniform cell populations of the yeasts *Zygosaccharomyces bailii* and *S. cerevisiae* (8, 26, 27). We observed a similar phenomenon in populations of *A. niger* conidia, whereby small subpopulations were capable of germinating and forming colonies at high concentrations (>4 mM) of sorbic acid (Fig. 7A). Conidia harvested from colonies that grew on these high concentrations of sorbic acid did not retain increased resistance upon direct reinoculation to sorbic acid-containing medium (data not shown), suggesting that these were transient, nonheritable phenotypes, i.e., not due to genotypic variants within the population. To test whether this heteroresistance had its origin in the ungerminated conidial state, conidia were also pregerminated for 6 h before spread plating onto sorbic acid-containing medium. This showed that germinated conidia were much more susceptible to sorbic acid (Fig. 7A). Moreover, resistance to sorbic acid among pregerminated conidia was much more homogeneous than when the resistance assay commenced with ungerminated conidia, as evidenced by the gradients of the dose inhibition curves; such dose-response curves reflect heterogeneity, with shallower curves indicating greater heterogeneity (23, 33). Thus, at

**FIG 6** Growth of *S. cerevisiae* complemented strains on weak acids. Tenfold dilution series of *S. cerevisiae* strains (isogenic with the BY4743 wild type) were inoculated onto medium containing weak acids. The Δpdr12 mutant strain was transformed with either empty plasmid (+YEp351), YEp351 plasmid containing PDR12 (+PDR12), or YEp351 plasmid containing the pdrA ORF and PDR12 promoter and terminator (+pdrA). Two independent transformants of the +pdrA strain are shown.

**FIG 7** Sorbic acid dose response curves for *A. niger* conidia. (A) Dose-response curves of germinated (blue lines) and ungerminated (black/gray lines) WT conidia, and comparison of slope values. Dose-response curve slope values were compared with 2-way Welch’s t test (*P* = 0.0404) *n* = 2 or 3. (B) Dose-response curves of WT (black/gray lines) and ΔpdrA mutant (pink/red lines) conidia and comparison of dose-response curve slope values, compared using a 2-way Welch’s t test (*P* = 0.0468), *n* = 3. Two representative independent experiments are shown in the dose-response curve. ATAN, arctangent.
least some factors determining heteroresistance to sorbic acid are specific to ungerminated conidia and are lost upon germination. Given the contributions of warA and pdrA to sorbic acid resistance in A. niger, it was tested whether these genes could be determinants of heteroresistance. The dose-response curves of ΔpdrA and ΔwarA mutant conidia demonstrated that pdrA makes a significant contribution to sorbic acid heteroresistance in A. niger conidia, whereas warA does not (Fig. 7B, data for ΔwarA mutant not shown).

**DISCUSSION**

This study reports the discovery of novel factors determining weak-acid resistance in molds. By screening A. fumigatus, we discovered a previously uncharacterized transcription factor that is required for resistance to certain weak organic acids. This transcription factor, here named weak acid resistance A (warA), was also found to be present in the food spoilage mold A. niger, where it also plays an important role in weak-acid resistance. However, WarA appears to mediate resistance to different weak acids in A. fumigatus and A. niger. In A. fumigatus, the ΔwarA mutant strain is particularly sensitive to linear-chain acids 3 to 6 carbons in length, whereas in A. niger, the ΔwarA mutant strain is most sensitive to propionic, butanoic, and benzoic acids but exhibited less sensitivity to 5- and 6-carbon acids. Such differences in acid sensitivity may reflect differences in the WarA regulon between A. niger and A. fumigatus or in the divergence in gene function within the WarA regulon.

We sought to gain insight to the WarA regulon in A. niger by conducting a comparative transcriptomics experiment between germinating WT and ΔwarA conidia treated with sorbic acid. This approach identified several genes that appear to be regulated (either directly or indirectly) by WarA. These include a number of putative enzymes and transporter proteins, offering several candidates for future studies of weak-acid resistance mechanisms in A. niger. Among these candidates, we attempted to characterize two putative transporter protein-encoding genes. The first of these functions, An02g09970, is a transporter of the major facilitator superfamily, with sequence similarity to Tpo2p and Tpo3p in S. cerevisiae. Tpo2p and Tpo3p are transporters of the DHA1 (drug:H+ antiporter-1) family and are known to be required for resistance to acetic, propionic, and benzoic acids (20). However, the deletion of An02g09970 did not sensitize A. niger to any of the acids tested, and so the role of this gene remains unknown. It is possible that this transporter is responsible for detoxification of other xenobiotics not tested here (if indeed it has a role in detoxification at all), or that An02g09970 is functionally redundant with other A. niger genes. We also attempted to characterize pdrA, encoding an ABC-type transporter. The deletion of pdrA resulted in increased sensitivity to pentanoic, hexanoic, sorbic, and benzoic acids, substantiating a role for this protein in weak-acid resistance. Importantly, we were able to demonstrate that pdrA is a functional homologue of PDR12 in S. cerevisiae. Pdr12p is a key protein involved in weak-acid resistance of S. cerevisiae (17), where it is thought to efflux weak-acid anions from the cytoplasm in an energy-dependent manner (18). The identification of PdrA as a functional homologue of Pdr12p in a mold species such as A. niger shows that a similar mechanism of weak-acid detoxification by active efflux may operate in yeasts and molds. Interestingly, the Δpdr12 mutant functional complementation experiment demonstrated that pdrA confers resistance to a broader range of weak acids than was suggested by the weak-acid sensitivity of the ΔpdrA mutant strain. For example, pdrA complemented the propionic acid sensitivity of the S. cerevisiae Δpdr12 mutant, but the A. niger ΔpdrA mutant strain was not more sensitive to propionic acid than was the WT. This may indicate the presence of multiple, redundant mechanisms for resistance to certain weak acids in A. niger which may not operate in S. cerevisiae.

pdrA, as well as several other candidate WarA-regulated genes, were all upregulated in response to both sorbic and benzoic acids. This suggests a degree of overlap between transcriptomic responses to different weak acids, as also found in S. cerevisiae.
Thus, although we characterized the WarA regulon by comparative transcriptomics in response only to sorbic acid in the present study, it is likely that many of the differentially expressed genes would be similarly regulated in response to other weak acids. There may be relevant consensus sequences within WarA-regulated genes, although these are not apparent from promoter sequence alignments we have carried out. In *S. cerevisiae*, a cis-acting weak-acid response element (WARE) was discovered in the promoter of *PDR12* which is required for *PDR12* induction by the transcription factor War1p (19).

The regulation of WarA itself is also an outstanding question. Recent evidence in *S. cerevisiae* suggests that weak-acid anions bind directly to the transcription factors War1p and Haa1p, thereby regulating their DNA-binding transcriptional activation (35). However, WarA shares very little sequence homology with either War1p or Haa1p. In fact, a BLAST search of the *S. cerevisiae* protein database with the WarA protein sequence yields no hits at all. Nevertheless, a similar mechanism of transcription factor activation cannot be ruled out for WarA, particularly as direct ligand binding has been established for a number of Zn2Cys6 family transcription factors (of which WarA is a member), including Pdr1p, Pdr3p, Leu3p, and Put3p (36–38).

During the course of this study, experiments with sorbic acid determined that genetically uniform populations of *A. niger* conidia demonstrate heteroresistance to this weak acid. Phenotypic heterogeneity within microbial cell populations has been demonstrated in a number of fungi in response to environmental stresses (reviewed in reference 23); however, this is the first report of weak-acid heteroresistance in fungal conidia. Interestingly, heteroresistance was decreased within 6 h of conidial germination, suggesting that at least some factors underlying this heterogeneity are limited to ungerminated conidia and are lost upon germination. Resistance to sorbic acid was also markedly lower in germinated conidia, which has also recently found to be the case for propionic acid (39). Heteroresistance to weak acids in fungal conidia has significant implications for the food industry, because spoilage of products may occur due to contamination with just a few conidia from a highly resistant subpopulation. Thus, future spoilage control strategies may have to take into account the presence of weak-acid heteroresistance, perhaps by specifically targeting resistant subpopulations.

Conidia of the ΔpdrA mutant strain showed a significantly more homogeneous response to sorbic acid. Heteroresistance typically arises from gene expression heterogeneity (or noise) (40), so the present results suggest that pdrA could be expressed heterogeneously within conidial populations; the conidia expressing more pdrA are potentially able to withstand sorbic acid stress. It is also noted that the deletion of pdrA did not eliminate sorbic acid heteroresistance in *A. niger*, so it is likely that other genes also contribute.

In summary, this study markedly advances our understanding of weak-acid resistance mechanisms in *A. niger*. The identification of WarA as a key transcription factor involved in weak-acid resistance allowed us in turn to identify many more genes which may also be important. Further work is required to determine how all these genes may contribute to weak-acid resistance. Moreover, we demonstrated here that a key weak-acid resistance mechanism operates in both *S. cerevisiae* and *A. niger* in the form of the functionally homologous ABC transporters Pdr12p and PdrA, respectively.

**MATERIALS AND METHODS**

**Strains and media.** The *Aspergillus fumigatus* transcription factor deletant library, derived from wild-type strain MFIG001, was constructed by homologous recombination using gene replacement cassettes and transformation methodologies described previously (30, 41). Studies in *Aspergillus niger* were performed in the *A. niger* N402 background (referred to as the *A. niger* WT throughout) and an *A. niger* ΔcdcA mutant strain (14). *Aspergillus* strains were cultivated on slopes of potato dextrose agar (PDA) (Sigma) for 7 days at 28°C. Conidia were harvested using 0.1% (vol/vol) Tween 80 and filtered through a 40-μm cell strainer (Fisher) before counting on a hemocytometer. Studies in *S. cerevisiae* used the BY4743 background and isogenic Δpdr12 mutant strain cultivated on YEPD agar (2% glucose, 2% Bacto peptone [Oxoid], 1% yeast extract [Oxoid], 1.5% agar) at 30°C. The *S. cerevisiae* strains were obtained from Euroscarf (Frankfurt). Growth assays with weak acids (see below) were performed on YEPD agar (pH 4).
Deletant library screening and growth assays. The first round of A. fumigatus transcription factor deletion library screening was performed in a 96-well array format. Conidial suspensions of the A. fumigatus strains were initially supplied in a 40% glycerol-0.01% phosphate-buffered saline (PBS) solution at a concentration of 4 × 10^6 ml^-1. These were subsequently arrayed in 96-well plates at a concentration of 4 × 10^5 conidia ml^-1 in 0.01% Tween 20, transferred using a 96-pin tool to Nunc OmniTray single-well plates containing YEPD agar (pH 4), and then incubated at 28°C for 2 to 3 days. Radial growth was measured using ImageJ and compared between the control medium and medium containing sorbic acid. The second round of screening was performed on 90-mm petri dishes. Plates were inoculated with 10^5 conidia and incubated at 37°C for 3 days. Radial growth was compared between the control medium (YEPD) and the same medium containing sorbic acid.

Subsequent growth assays with weak acids on solid medium were performed in Aspergillus spp. by inoculating YEPD agar (pH 4) supplemented with weak acids with 5 μl of conidial suspension, containing 10^5 to 10^6 conidia, and subsequent incubation at 28°C for 2 to 3 days. The weak-acid concentrations used for A. fumigatus were 15 mM acetic acid, 4 mM propionic acid, 1.5 mM butanoic acid, 0.75 mM pentanoic acid, 0.2 mM sorbic acid, 0.25 mM hexanoic acid, 0.5 mM benzoic acid, 0.08 mM heptanoic acid, and 0.05 mM octanoic acid. The weak-acid concentrations used for A. niger were 40 mM acetic acid, 10 mM propionic acid, 4 mM butanoic acid, 2 mM pentanoic acid, 1.5 mM sorbic acid, 2 mM hexanoic acid, 2 mM benzoic acid, 1 mM heptanoic acid, and 0.75 mM octanoic acid.

The MICs of weak acids were determined by placing 10 ml of YEPD broth (pH 4) into 30-ml McCartney bottles and inoculating with 10^6 conidia. The bottles were incubated statically at 28°C for 28 days, and the concentration of acids required to completely inhibit visible growth was recorded. The concentrations of acids used were at 0.2 mM increments for benzoic and sorbic acids, 0.3 mM increments for pentanoic and butanoic acids, and 2 mM increments for propionic acid.

Dose-response curves were generated by harvesting conidia as stated above, diluting to 500 spores ml^-1, and spreading 200 μl of this onto YEPD agar (pH 4) containing sorbic acid. Plates were incubated at 28°C for up to 28 days and the colonies counted. For pregerminated conidia, conidia were first inoculated into 10 ml of YEPD-Tween 80 (6.66 ml YEPD and 3.33 ml of 0.1% Tween 80) to a final concentration of 500 spores ml^-1 and incubated statically at 28°C for 6 h before spore plating and incubation as described above. For quantitative comparison of heteroresistance, Hill slopes were fitted to plots (% viability versus log_{10}[sorbic acid]) using the Prism software, and arctangent values for the slopes were calculated with Excel to estimate relative heterogeneity (a shallower slope indicating higher heterogeneity) (33, 42).

RNA-seq and qRT-PCR. For preparation of RNA, conidia of A. niger N402 were inoculated into 1 liter of YEPD broth (pH 4) at a final concentration of 10^6 conidia ml^-1 and incubated at 28°C for 1 h, with shaking at 150 rpm. For sorbic acid or benzoic acid treatments, the medium was supplemented with 1 mM sorbic or 1 mM benzoic acid for the 1-h incubation, as these concentrations inhibit conidial germination over the course of the experiment but are not lethal (~30% of the MIC values for these acids). Conidia were harvested by filtration through a Corning vacuum filtration unit and immediately used for RNA extraction. RNA was extracted using a Norgen Biotek plant/fungi total RNA extraction kit, as per the manufacturer’s instructions.

RNA-seq analysis was performed by the University of Liverpool Centre for Genomic Research. Three biological replicates were performed for each time point under each condition. Between 463 and 1,000 ng of total RNA (depending on available material) was poly(A) treated using the NEBNext poly(A) mRNA magnetic isolation module and subsequently purified using AMPure RNA XP beads. Successful depletion of RNA was confirmed using Qubit fluorometric quantification (Thermo Fisher) and an Agilent 2100 Bioanalyzer. All of the depleted RNA was used as input material for the NEBNext Ultra directional RNA library prep kit for Illumina. Following 15 cycles of amplification, the libraries were purified using AMPure XP beads. Each library was quantified using a Qubit fluorometer and the size distribution assessed using the Bioanalyzer. These final libraries were pooled in equimolar amounts using the Qubit and Bioanalyzer data. The quantity was assessed using a Qubit double-stranded DNA (dsDNA) high-sensitivity (HS) assay kit, while the quality and average fragment size were assessed using the high-sensitivity DNA kit on the Agilent Bioanalyzer. The RNA libraries were sequenced on an Illumina HiSeq 4000 platform with version 1 chemistry using sequencing by synthesis (SBS) technology to generate 150-bp paired-end reads.

Initial processing and quality assessment of the sequence data were performed as follows. Briefly, base concentration plots (% viability versus log_{10}[sorbic acid]) using the Prism software, and arctangent values for the ratios were calculated with Excel to estimate relative heterogeneity (a shallower slope indicating higher heterogeneity) (33, 42).

For qRT-PCR analysis of gene expression, RNA was extracted as stated above. Genomic DNA was removed using the Turbo DNase-free kit (Invitrogen). cDNA was synthesized using SuperScript IV reverse transcriptase (Invitrogen) and oligo d(T)20 primer (Invitrogen), according to the manufacturer’s instruc-
Gene deletion studies and complementation in *A. niger*. Gene deletion studies were performed in *A. niger* N402, the open reading frames (ORFs) of the target genes being replaced by a hygromycin resistance cassette (Fig. S2 and S6). Gene deletion cassettes were constructed by gap repair cloning in *S. cerevisiae* (47). Briefly, the hygromycin resistance cassette and the regions approximately 1 kb upstream and downstream of each target gene were amplified from genomic DNA by PCR (the primers used listed in Table S2). The hygromycin resistance cassette had a 20- to 30-bp homology with the 1-kb flanking regions, and each flanking region also had 20- to 30-bp homology with the multiple-cloning site of the Yep351 plasmid. The PCR products and HindIII-linearized Yep351 plasmid were transformed into *S. cerevisiae* BY4743, and transformants were selected by leucine prototrophy. Successful construction of the gene deletion cassettes was confirmed by PCR. The resulting gene deletion cassettes were amplified by PCR and purified using PCR purification columns (Macherey-Nagel) to produce a final linear gene deletion cassette. All PCRs were performed using Phusion high-fidelity DNA polymerase (New England Biolabs). Production of protoplasts and their transformation were performed using standard methods (48). Transformants were selected using 200 μg ml⁻¹ hygromycin (Roche) and confirmed by PCR and Southern blotting (Fig. S2 and S6), using standard methods (49).

For complementation of *A. niger* gene deletion strains, the genes in question (warA and *pdrA* [An14g03570]) were amplified by PCR (primers listed in Table S2) and cloned into the SbfI site of the pAN7.1BAR plasmid (Fig. S8), which contains the BAR gene as a selectable marker (replacing the original hygromycin resistance cassette [50] and imparting resistance to phosphinothricin). PCR amplification included ~1 kb upstream and ~300 bp downstream of the ORF. Transformation of the resulting plasmids was performed as described above, except that transformants were selected using 5 mg ml⁻¹ DL-phosphinothricin (Carbosynth) in YDA agar (yeast nitrogen base without amino acids, including 1.7 g liter⁻¹ ammonium sulfate, 10 g liter⁻¹ glucose, 2.25 g liter⁻¹ ammonium nitrate, and 1 M sucrose; pH was adjusted to 7.0 using Na₂HPO₄, solidified with 1.2% [wt/vol] agar) (51). Transformants were subjected to an additional round of selection by growth on YDA agar containing 5 mg ml⁻¹ DL-phosphinothricin.

Cloning and complementation in *S. cerevisiae*. Cloning studies were performed in the *S. cerevisiae* Δpdr12 mutant strain. The complementation plasmid (Fig. S7) was constructed by yeast gap repair cloning (47). Briefly, the *PDR12* promoter and terminator and *PdrA* ORF were amplified by PCR (primers listed in Table S2). Each amplified fragment included a 20- to 30-bp region of homology either with the Yep351 plasmid or with a neighboring fragment. The PCR products and HindIII-linearized Yep351 plasmid were transformed into the *S. cerevisiae* Δpdr12 mutant, and transformants were selected by leucine prototrophy (47). Complementation was also performed with the *PDR12* ORF as a positive control for successful complementation. The *S. cerevisiae* Δpdr12 mutant strain was also transformed with the empty Yep351 plasmid as a negative control.

Data availability. RNA-seq data have been deposited in GenBank under BioProject no. PRJNA594492.
