Abstract
This systematic review synthesizes research on the influence of human and economic resources for women’s empowerment on their pre- and postnatal mental health, understudied in the Arab world. We include articles using quantitative methods from PubMed and Web of Science. Two researchers reviewed databases and selected articles, double reviewing 5% of articles designated for inclusion. Twenty-four articles met inclusion criteria. All 24 articles measured depression as an outcome, and three included additional mental health outcomes. Nine of 17 studies found an inverse association between education and depression; two of 12 studies found contradictory associations between employment and depression, and four of six studies found a positive association between financial stress and depression. These results suggest that there is a negative association between education and depression and a positive association between financial stress and depression among women in the Arab world. Firm conclusions warrant caution due to limited studies meeting inclusion criteria and large heterogeneity in mental health scales used, assessment measures, and definitions of human and economic resources for women’s empowerment. It is likely that education reduces depression among postpartum women and that financial stress increases their depression. These findings can be used to aid in the design of interventions to improve mother and child outcomes. However, more research in the Arab world is needed on the relationship between human and economic resources for women’s empowerment and perinatal mental health, and more consistency is needed in how resources and mental health are measured.

Keywords Systematic review · Depression · Mental health · Pregnancy · Middle East · Women’s empowerment

Mental health is one of the most neglected public health issues in the Arab world (Haque et al., 2015; Rezaeian, 2010), where there is generally a dearth of rigorous research on mental health conditions among women (Rezaeian, 2010). Medical and public health professionals are concerned about women’s mental health in the perinatal period because common psychiatric disorders, including depression, are more likely to occur then (Satyanarayana et al., 2011). Depression is the most frequently occurring mental health condition among women of childbearing age in low- and middle-income countries (Parsons et al., 2012). Negative consequences have been found for mother and child, including impairments in mother-child interactions and emotional and cognitive disruption of infant development (Haque et al., 2015; Parsons et al., 2012). Poor mental health outcomes among Arab women have been associated with strong patriarchal cultures, which

This review was conducted when Dr. James-Hawkins was a postdoctoral fellow at Emory University, Yara Qutteina and Eman Shaltout were Senior Research Assistants, and Catherine Nasrallah was a Research Assistant at SESRI, Qatar University.

limit opportunities and autonomy for women (Yount and Smith 2012; Yount et al. 2014; Shaikh et al. 2017; Douki et al., 2007).

Women’s empowerment is a critical component of mental health. Thus, women’s empowerment includes the ability or agency to make choices and gain control over available resources to affect better outcomes in their lives (Yount et al. 2015; Campbell and Mannell, 2016; Kabeer, 1999). Resources for empowerment are generally considered to consist of three main categories: (1) financial or economic resources (income, employment, or assets); (2) human resources (education or learned skills); and (3) social resources (social support from family or others; Kabeer, 1999). Gender gaps in mental health may arise from reduced opportunities, status, resources, or power for women in the Arab world (Yount et al. 2014; Hill and Needham, 2013). Thus, human and economic resources for empowerment may influence women’s mental health during and immediately after pregnancy and especially strongly in settings in which women’s access to these resources is constrained (Bener, 2013). Economic resources have been shown to influence women’s empowerment in that they provide the means to exert control over her life by generating income (Kabeer et al., 2013) or increasing her bargaining ability within the home (Kabeer, 2016). Human resources, such as education, are entwined with economic resources in that education and other learned skills can provide the means for women to gain economic resources (Kabeer et al., 2013), often through employment (Hammer and Klugman, 2016; Kabeer, 2016). Education may also provide women with raised awareness of their own rights and entitlements and allow them to have greater influence over how resources are distributed within the household (Kabeer, 2016).

Researchers have identified possible human and economic risk factors for depression during pregnancy and after delivery (Farr et al., 2014; Scheyer and Urizar Jr., 2016). Those risk factors include low levels of education among women (Fall et al., 2013; Miyake et al., 2012), personal income that is too low to meet basic needs or other financial difficulties (Lancaster et al., 2010; Scheyer and Urizar Jr., 2016), and a lack of engagement in the workforce (Fall et al., 2013; Miyake et al., 2012). While other risk factors such as intimate partner violence and life stressors (Lancaster et al., 2010) have been studied, less attention has been paid to the influence of human and economic resources for women’s empowerment on prenatal and postnatal mental health. Therefore, there is a need for a synthesis of existing research to aid in the design of interventions to improve mother and child outcomes.

In the Arab world, the issues affecting women’s mental health are diverse, reflecting the socioeconomic and cultural diversity of the region. National population policies have tended to focus on family planning services and the reduction of total fertility, rather than the scope and quality of antenatal and postnatal care services (Kronfol, 2012). A recent review of barriers to health care in the Arab world found mental health services to be especially limited in scope, accessibility, and affordability within the public sector (Kronfol, 2012). Women’s empowerment as an influence on mental health is especially important in the Arab world because of well-documented constraints on women’s agency (Kandiyoti, 1988), including reproductive agency or freedom, such as deciding if and when to have a child (Eyadat, 2013). Worldwide, reproductive health services have marginalized mental health (World Health et al., 2009). This is especially true of the Arab world, where mental health services are often inadequate and mental illness is stigmatized (Sewilam et al., 2015). Health providers and policy-makers are just beginning to recognize mental health conditions as contributors to the overall disease burden (Rashad, 2014).

Research on the prevalence of perinatal depressive symptoms, specifically, in the Arab world is scarce, although the onset of new cases of depressive symptoms is most common during the prenatal period (Fuggle et al., 2002). Approximately 10% of women worldwide experience some negative mental health condition during pregnancy, including depressive symptoms (World Health Organization, n.d.). Women who are new mothers also are at higher risk of poor mental health outcomes in general, with 10–15% experiencing postpartum depressive symptoms specifically (Haque et al., 2015; World Health Organization, n.d.). Existing studies, however, have shown that Arab women, living in Arab countries, typically experience higher rates of postpartum depressive symptoms compared to women in other world regions (Chaaya et al., 2002; Green et al., 2006). Given the lack of existing literature on maternal mental health and the known adverse health outcomes for mother and child, there is a clear need for further study on the prevalence of prenatal and postnatal depressive symptoms in the Arab world. This article systematically reviews all studies in the Arab world examining the influence of women’s human or economic resources for empowerment on their mental health in the prenatal and postnatal periods.

**Methods**

**Search terms, databases, and search strategies**

We used Cochrane Review guidelines (Higgins and Green, 2008) to conduct our literature search. Search terms were identified, piloted, and revised in PubMed and Web of Science databases. Searches were conducted to capture all articles published up to April 1, 2016, the date of the final search conducted. The full search string used to identify potentially relevant articles in each database (Table 1) covered four domains: (1) human and economic resources for women’s empowerment, (2) geographical region, (3) pregnancy/postpartum, and (4) mental health outcomes. The search
criteria included peer-reviewed articles in English, French, or Arabic. A title and abstract review was conducted against the inclusion criteria, followed by a full-text review of relevant articles. An ancestry search of references sections was conducted for included articles, and each article’s first/ corresponding author was contacted to identify relevant articles in the gray literature.

Selection of studies

Our inclusion and exclusion criteria were established a priori and refined during an extensive pilot phase (Table 2). We excluded studies if neither human nor economic resources were included, if the study population did not consist of Arab pregnant or postpartum women living in an Arab country, or if no mental health outcome was measured.1 We defined the postpartum period as up to 1 year after birth (Canadian Mental Health Association, 2017). We were interested in the relationship between human and economic resources for empowerment and perinatal mental health in women experiencing a “typical”

Table 1 Search terms for identifying studies of the effect of human and economic resources for women’s empowerment on mental health during pregnancy in the Arab Middle East

| Human and economic resources | Pregnancy | Arab Middle East | Mental health outcomes |
|------------------------------|-----------|------------------|-----------------------|
| Resources                    |           |                  |                       |
| Material Resources           |           |                  |                       |
| Access                       |           |                  |                       |
| Ownership                    |           |                  |                       |
| Expenses                     |           |                  |                       |
| Expenditures                 |           |                  |                       |
| Assets                       |           |                  |                       |
| Wealth                       |           |                  |                       |
| Possession                   |           |                  |                       |

| Status                       |           |                  |                       |

1 The majority of the articles rejected during the title and abstract review were excluded for being systematic reviews, having a non-human study population, studying non-pregnant women or non-Arab samples, not measuring a mental health outcome, or the mental health outcome was a severe psychopathology. The remaining articles were then subjected to a full-text review and articles were excluded because economic and human resources for women’s empowerment were not analyzed in relation to mental health.
pregnancy and as such included mental health outcomes that were defined as “normal” by the Diagnostic Statistical Manual of Psychiatric disorders (DSM) such as depression and anxiety. We excluded studies including only women who experienced life-threatening conditions or extreme psychopathology defined as mental health problems or psychological stressors that are classified as “abnormal” by the DSM such as schizophrenia. Systematic reviews and studies

| Criteria                        | Included                                                                 | Excluded                                                                 | Rationale                                                                 |
|---------------------------------|--------------------------------------------------------------------------|--------------------------------------------------------------------------|--------------------------------------------------------------------------|
| Sampling method                  | Population-based, and clinic-based except those admitted for psychopathology or serious pregnancy complications | Convenience-based, clinic-based if sample admitted for psychopathology or serious pregnancy complications | The study aims to understand the effect of empowerment on common pregnancy-related mental health outcomes, rather than mental health complicated by medical concerns or psychiatric disorders (e.g., schizophrenia or mania). |
| Analysis                        | Bivariate analysis; quantitative analysis                                | Anything less than bivariate analysis; qualitative analysis              | Bivariate analysis is included as a minimum in order to understand the complex relationship between dimensions of empowerment and mental health in pregnancy. |
| Date                            | All dates were included                                                  | No elimination based on date                                             | Studies based in any time period would contribute to the objectives of this study. Given the limited research available on mental health among pregnant women within the geographic region of interest, articles were not excluded based on the date of publication. |
| Geographic region               | Arab world (as defined by the Arab League and World Bank)               | Non-Arab countries; Arab populations outside Arab countries (e.g., refugees) | The focus of this review is on perinatal mental health in women from Arab countries, as these countries have seen a dramatic improvement in maternal health and child survival over the past few decades as a result of better living standards and improvements in health care services. |
| Population of interest           | Arab pregnant women and/or women in the perinatal period (22 weeks of gestation to 7 days after birth; WHO, 2016) and postnatal period (up to 1 year after the birth of a child). | More than 1 year after the birth of a child                              | The period of time specified represents the focus of interest for the purposes of the review. |
| Outcome variable                 | Mental and psychological health or well-being; depressive symptoms; anxiety symptoms; perceived psychological stressors | Psychopathology and/or psychiatric disorders                             | This review is concerned with common mental health problems/psychological stressors that are not classified as “abnormal” by the Diagnostic Statistical Manual of Psychiatric disorders (DSM; “abnormal” mental health problems include problems such as schizophrenia or bipolar disorder), and symptoms that have not progressed to mental disorders (e.g., we are looking at anxiety symptoms not generalized anxiety disorder). |
| Exposure variable               | Agency and/or resources for empowerment (or disempowerment; e.g., domestic violence) | Any items that did not fall within the conceptual framework of empowerment outlined by Kabeer (1999) | The definition of empowerment used in this review is based on Kabeer’s (1999) frame work, which includes resources and agency. Different terms were also used to describe these analogous constructs (e.g. decision-making or wealth). |
| Language                        | English, Arabic, and French                                              | All other languages unless translation was provided                     | Majority of the published literature in this field is in English. Some studies conducted in Tunisia and Morocco were published in French journals and were reviewed by French speaking researchers. |
| Peer reviewed                    | Peer reviewed                                                            | Non-peer reviewed                                                        | The use of peer-reviewed articles reflects this review’s focus on using the highest-quality research. |
using qualitative methods also were excluded. All studies published before March 2016 were included.

**Data extraction and analysis**

A total of 2,407 articles were identified and screened for further review based on the titles and abstracts (Fig. 1). We excluded 2,347 articles because they did not address the constructs or population of interest. The remaining 60 articles underwent a full-text review by one of three researchers (ES, AN, CN) resulting in 20 articles that met all inclusion criteria. Articles were excluded if they did not contain a measure of human or economic resources or if those measures were not used in an analysis with mental health as the outcome. Reference and key author searches identified five additional articles. Four met final inclusion criteria after a full-text review, for a total of 24 included articles. The Cochrane Review data extraction form was adapted for use with cross-sectional and observational studies (Norwegian Knowledge Centre for the Health Services, 2013). Five percent of included articles underwent a second review for data extraction to ensure consistency.

**Assessment of study quality and validity**

We used the STrengthening the Reporting of OBservational Studies in Epidemiology (STROBE) checklist to assess study quality (Von Elm et al., 2007). The STROBE checklist uses 22 criteria, so each article was assigned a score between 1 and 22. Articles were rated on quality by one researcher (LJH). Articles with scores of 14 or below were designated as “low quality,” scores between 15 and 17 were “medium quality,” and scores of 18 and above were “high quality” (James-Hawkins et al. 2016; Table 3). A sub-sample of articles were double scored by a second researcher (YQ) for consistency. The lowest quality articles generally did not define outcomes and exposures adequately, explain how variables were handled in the analysis, report sample attrition, discuss potential sources of bias, explain missing data adequately, provide their source of funding, or discuss generalizability of their results. Medium-quality articles generally did not address potential bias, explain missing data, or provide their funding source. High-quality studies generally did not explain how missing data were addressed.

We assessed each study for bias in terms of selection, measurement error, statistical analysis, and confounders using a previously adapted tool (Yount and Smith 2012). One reviewer (LJH) classified each study as low, medium, or high risk for each category. We evaluated selection bias based on sampling design and response rates. Non-probability samples were considered high risk and probability samples were considered low risk. Response rates of 80% or higher were considered low risk, 60–80% were moderate risk, and below 60% or an unreported response rate was considered high risk. If a study was low in one and moderate or high in the other, it was classified as moderate risk. We assessed measurement error based on reporting of measures of internal consistency (e.g., Cronbach’s alpha or similar). Measurement error was rated as low risk if the study
authors addressed the reliability of all key measure(s) (mental health, and human/economic resources), moderate risk if they addressed reliability of mental health or resources, and high risk if reliability of neither was addressed. Statistical analysis bias was assessed based on statistical tests used. Studies with clear descriptions of the analysis plan and statistical tests used were low risk. Studies lacking clear information were considered as moderate risk. High risk studies did not report the statistical tests used. Finally, confounder risk was assessed based on the inclusion of confounders in the analysis. Low risk studies included a comprehensive set of confounders, moderate risk studies included minimal confounders, and high risk studies included no confounders (Table 4).

Results

Characteristics of studies

A total of 24 articles met the inclusion criteria (Table 3). Twenty studies were in English, four in French, and none in Arabic. The studies were published between 1999 and 2016 and conducted in ten different countries. Most studies (N = 19) used convenience sampling, with sample sizes ranging from 79 to 1659 women, and an average of 483 participants across studies. Sixteen studies focused on the postpartum period, five on the prenatal period, and three on both. Ten studies included human or economic resources as control variables, and we used data to calculate population proportions for comparison purposes. All studies collected primary data in clinics.

Measurement of mental health

The majority of studies (N = 21) addressed depression as the sole outcome. Two also included anxiety, and one included anxiety and psychological stress in addition to depression. The Edinburgh Post-Natal Depression Scale (EPDS) was used most commonly (N = 16), The Mini International Neuropsychiatric Interview (MINI; N = 3), Depression Anxiety Stress Scale (DASS-21; N = 2), Beck Depression Inventory (BDI; N = 1), Hospital Anxiety and Depression Scale Questionnaire (HADS; N = 1), and Depression Detailed Inventory (DDI; N = 1) also were used.2 How depression was determined varied with researchers using different cut-points to indicate “major depression,” even when using the same scale.

Measurement of human and economic resources for women’s empowerment

Human resources were represented by measures of education (N = 19), economic resources by measures of employment (N = 18), and financial resources (N = 17). Education was operationalized in multiple ways, including literate versus not (N = 3), ordinal school levels (N = 2), or dummy variables such as completed secondary school or more versus less (N = 9), and greater than secondary versus secondary or less (N = 3). Cut-offs used for education were unclear in three studies. Employment was operationalized as problems at work versus none, among those working (N = 2), or working versus not working (N = 10). Operationalization of financial resources also varied with three studies using perceptions of financial distress, two using a salary cut-off in local currency, one using a continuous income measure, and one using income satisfaction.

Threats to study validity

The majority of studies were rated as high risk on selection bias because they used convenience samples or did not report response rates. Risk of measurement error also was high for most studies. While authors indicated that instruments had been validated in-country, they rarely reported assessments using their sample. Almost all studies presented a description of the statistics and methods used and were rated as low risk for statistical bias. Risk for confounder bias was high overall as there was a general lack of inclusion of confounders.

Prenatal relationships

Education

Four studies assessed the association between education and depressive symptoms (EPDS = 3, MINI = 1). Two studies were medium quality and two were low quality. Two studies using the EPDS found opposite relationships (one positive and one negative), while the third found no relationship. The study using the MINI also found no relationship (Table 5). Thus, the association between education and depression among pregnant women was contradictory and inconclusive.

Employment

Three studies examined the relationship between women’s employment status and prenatal depressive symptoms. One study used the EPDS and found no relationship. One study used the BDI and found a positive relationship among women who were employed and reported problems at work. The third study used the MINI to compare working versus nonworking women and found no association. Two studies were medium quality, and the other was low quality (Table 5). Overall, two out of three studies found no relationship between employment and depression among pregnant women.

---

2 One study used two different scales for measurement of depression.
### Table 3  Characteristics of included studies (N = 24)

| Author                        | Year | Sample type          | Sample design          | Pregnancy/postpartum period                        | N    | Country     | Study Quality |

All studies used primary data collection and were clinic based.
Financial stress

Three studies examined financial stress and prenatal mental health. Two of the studies used the EPDS with one finding a significant positive association and the other finding no association. The third study used the HADS and found no relationship. All three studies were of medium quality (Table 5). Overall, two out of three studies found no association between financial stress and depression among pregnant women.

Postnatal relationships

Education

Sixteen studies examined the relationship of schooling attainment with depression, anxiety, or psychological stress (EPDS = 10, MINI = 3, DASS-21 = 2, DDI = 1). Among studies using the EPDS, six different cut-offs were used to determine if depression was present, and eight different metrics were used to measure schooling attainment. All studies using the EPDS were of medium quality. Two medium-quality studies used the DASS-21 to assess depressive symptoms, both finding a negative relationship. Two other studies examined the relationship between schooling attainment and postnatal depressive symptoms using the MINI instrument to assess depressive symptoms, with neither finding a relationship. Overall, five of the 16 studies found a negative relationship between schooling attainment and depression, while 11 studies found no association. However, this result appears to be at least somewhat instrument dependent. Overall, one study was high quality, 12 studies were medium quality, and two were low quality (Table 5). All studies that found an association were of medium or high quality, suggesting that there may be a negative association between education and depression for postpartum women.

Employment

Twelve studies examined the association between employment and postnatal depression. Seven of these studies compared women who were working with women who were not working, while one compared trouble at work among women working. Eight studies used the EPDS and found no association between women’s work status and postnatal depression. Three additional studies used the MINI and also found no association. One high-quality study using the DASS-21 found
lower depression among women who were not working. Of the other 11 studies, one was of high quality, seven were medium quality, and three were low quality (Table 5). Overall, no association was found between employment status and postpartum depression.

Financial stress

Four studies examined financial issues and mental health in the postnatal period. Three of these used the EPDS and found an inverse association between actual income or satisfaction with income and levels of depressive symptoms. Of these, one study was high quality and two were medium quality. One low-quality study used the MINI and found no association (Table 5). Overall, an association between financial stress and postpartum depression is plausible.

Discussion

This systematic review examined how women’s human and economic resources for empowerment were associated with their perinatal mental health. Overall, no association is apparent in the prenatal period. However, we cautiously conclude that there is evidence for a negative relationship between schooling and postnatal depression. However, this may be dependent on the instrument used to assess depression, and the low number of studies addressing this relationship makes it difficult to draw strong conclusions. Few studies addressed women’s financial stress and postnatal mental health and they used a variety of instruments and populations; however, the available evidence suggests a positive relationship between financial stress and negative mental health outcomes. Almost none of the studies examining employment and postnatal mental health found an association. While there were substantially more studies examining women’s resources for empowerment and postnatal mental health than for prenatal mental health, multiple factors varied across these studies such as (1) the instrument used to measure depression, (2) how depressive symptoms were assessed, and (3) the metrics used to measure the resource. Thus, conclusions drawn must be tempered by the knowledge that both operationalization and measurement error are likely to have impacted the results we considered.

The tentative negative association between schooling attainment and depression in the postnatal period is important because of the strong emphasis on marriage and family for women living in the Arab world (Barakat, 2005). In many countries in the Arab world, women marry before completing their secondary schooling and do not have the opportunity to continue their education. At the same time, women are considered the “mothers of the nation” and tasked with transmission of culture to younger generations (p. 45, Kandiyoti, 1991). When women marry young, they often do not have strong identities outside their role as wife and mother (Barakat, 2005; Kandiyoti, 1988). The lack of schooling attainment and relative isolation of these women is likely to contribute to depression, as tentatively suggested by the findings of this review.

High financial stress has been associated with pre- and postpartum depression among women in many regions of the world (Eastwood et al., 2011; Ehrlich et al., 2010; Yelland et al., 2010). The tentative association found here suggests that this relationship may be true for women in the Arab world, as well. Women experiencing financial stress may be overwhelmed by trying to care for their child and attend to household duties. In addition, women in the Arab world may be restricted from working by their husbands and thus may be unable to contribute financially to their family or may not have control over any financial resources (James-Hawkins et al., 2016). The inability to either contribute to the household financially or to control resources may leave women feeling overwhelmed and helpless. However, employment status may not be as relevant as type of job or the conditions of employment, which were not detailed in the studies reviewed.

Also, the work-related options available to women may not be desirable enough for women to pursue work, and so the alternative of staying home is preferred.

A limitation of the articles reviewed is the lack of theory about how women’s resources for empowerment may influence their perinatal mental health. This concept has been shown to be relevant to mental health, with researchers finding significant associations between women’s empowerment and levels of anxiety in women of reproductive age in the Arab world (Yount and Smith, 2012; Yount et al., 2014). The small number of studies identified also presents a problem. Given the demonstrated importance of mental health in the pre- and postnatal periods for positive mother and child outcomes (Glover, 2014; Leis et al., 2014), and the impact of reduced human and economic resources on women’s health and well-being in the Arab world (Haghighat, 2013, 2014; Price, 2016), more studies should be conducted on this topic to allow for more robust conclusions. Focus on a wider scope of mental health outcomes is also needed. While other mental health issues in pregnancy such as anxiety, mood, and psychological stress have been well-studied in Western countries (Hall et al., 2014, 2015; Redshaw and Henderson, 2016; Rubertsson et al., 2014), they have been virtually ignored in the Arab world. A critical limitation of these studies was the inconsistency in how scales were used and how outcomes were operationalized. We encourage researchers interested in perinatal mental health outcomes to spend time creating standards for the use of different scales and suggest they validate those standards in relevant, culturally appropriate contexts as a part of the research process.

(continued)
Future research should expand the number of psychological conditions assessed in this region, as the current literature focuses almost exclusively on depression, ignoring other mental health issues that may influence the health of the mother and child such as stress, anxiety, or negative mood states (Hall et al., 2014, 2015; Redshaw and Henderson, 2016; Rubertsson et al., 2014). Overall, the pattern of associations found appeared to be attributable to the variety of instruments used, how depression was assessed, and how women’s human and economic resources for empowerment were measured, which speaks more to the consistency and quality of measurement in the literature than to any substantive conclusions about the actual association between domains. This lack of uniformity in the use of consistent cut-off scores was especially true for the EPDS, the most frequently used instrument. Differences in how depression was determined may be complicated by the wide variety of ways in which human and economic resources for empowerment were measured. Finally, the research conducted spanned ten different countries in the MENA region. Overall, there was limited research in the Arab world that addressed mental health.

Limitations and strengths

First, this systematic review is limited to the examination of common and usually less severe mental health outcomes and does not address severe pathologies such as schizophrenia or bipolar disorder. Thus, it may be that there are associations between the human and economic resources for empowerment assessed and other psychological morbidities. However, we intentionally focused on less severe mental pathology in order to assess symptoms of mental distress that are more likely to be experienced by women in the region. Second, there may be older articles that were not included in the electronic databases we searched. However, it is likely that older research has been included in the databases at least in citation form and thus would have been identified. Third, it is possible that our selection of databases missed relevant literature for this review. However, extensive piloting of other databases suggested that we would not gain from including them. A major strength of this review is that it is the first systematic review of mental health issues experienced during pregnancy and in the postpartum periods in the Arab world.

Implications for policy and practice

We identified possible associations between schooling attainment and depression and between financial stress and depression. These findings suggest that closer attention should be paid to women’s access to enabling resources when evaluating them for mental health issues during or after pregnancy. Overall, further research is needed on mental health and the perinatal period both to supplement the existing limited research and to clarify relationships tentatively identified here. Also, we suggest that the international community of researchers attempt to determine specific ways in which human and economic resources for women’s empowerment can be measured in more standardized ways.

Funding This study was funded by The Qatar National Research Foundation (NPRP-7-666-5-081) to Dr. Kathryn M Yount, LPI, and Dr. Hanan Abdul Rahim, co-PI.
