Rheumatic heart disease refers to the long-term damage of heart valves and results from an autoimmune response to group A Streptococcus infection. This study aimed to analyze the microbiota composition of patients with rheumatic heart disease and explore potential function of microbiota in this disease. First, we revealed significant alterations of microbiota in feces, subgingival plaques, and saliva of the patients compared to control subjects using 16S rRNA gene sequencing. Significantly different microbial diversity was observed in all three types of samples between the patients and control subjects. In the gut, the patients possessed higher levels of genera including Bifidobacterium and Eubacterium, and lower levels of genera including Lachnospira, Bacteroides, and Faecalibacterium. Coprococcus was identified as a super-generalist in fecal samples of the patients. Significantly alterations were also observed in microbiota of subgingival plaques and saliva of the patients compared to control subjects. Second, we analyzed microbiota in mitral valves of the patients and identified microbes that could potentially transmit from the gut or oral cavity to heart valves, including Streptococcus. Third, we further analyzed the data using random forest model and demonstrated that microbiota in the gut, subgingival plaque or saliva could distinguish the patients from control subjects. Finally, we identified gut/oral microbes that significantly correlated with clinical indices of rheumatic heart disease. In conclusion, patients with rheumatic heart disease manifested important alterations in microbiota that might distinguish the patients from control subjects and correlated with severity of this disease.

Keywords: rheumatic heart disease, microbiota, gut, subgingival plaque, saliva, mitral valves
INTRODUCTION

Rheumatic heart disease (RHD) is a cardiovascular disease characterized by damages to heart valves, triggered by an autoimmune response to group A Streptococcus (GAS) infection (Woldu and Bloomfield, 2016). RHD causes an estimated 300,000 death annually with 30–40 million current cases globally and imposes significant disease burden on low-income countries and some indigenous populations (Watkins et al., 2017). The backbone of RHD therapy is penicillin-based treatment for acute rheumatic fever and replacement of severely damaged heart valves, without an effective vaccine (Tompkins et al., 1972; Nishimura et al., 2014; Woldu and Bloomfield, 2016). There has not been any significant advance in recent history of this field (Watkins et al., 2018). Thus, it is imperative to consider novel strategies for better control of RHD.

Human microbiota has been proven to play essential roles in a wide range of diseases including cardiovascular diseases (Tang et al., 2019). Colon harbors the vast majority of commensal bacteria (Belkaid and Hand, 2014), which can influence immune homeostasis, trigger inflammation, and invade extra-intestinal tissues (Hooper et al., 2012; Anhe et al., 2020). Many studies have focused on revealing the role of gut microbial dysbiosis in the development of cardiovascular diseases such as pulmonary arterial hypertension (Kim et al., 2020), unruptured intracranial aneurysms (Li et al., 2020), chronic heart failure (Kummen et al., 2018), and atherosclerosis (Koren et al., 2010). However, the role of the gut microbiota in RHD has not been studied.

The second most complex population of microbes of human body resides in the oral cavity and influences both oral and systemic health (Zhang et al., 2018; Bui et al., 2019). Periodontal pathogens can alter subgingival microbial composition and host–microorganism interactions, leading to local inflammation and subsequent destruction of periodontal tissues (Hajishengallis et al., 2012). The presence of periodontal bacteria DNA in cardiac tissues and atherosclerotic plaques has suggested connections between oral infections and cardiovascular diseases (Koren et al., 2010; Ziebolz et al., 2018). Periodontitis, a common inflammatory oral disease, increases the risk of adverse pregnancy outcomes, atherosclerosis, stroke, rheumatoid arthritis, diabetes, and other systemic diseases (Pihlstrom et al., 2005). However, there is a paucity of information related the potential role of oral microbiota in RHD.

Here, we aimed to investigate the microbiota composition and structure of RHD patients and explore potential function of microbiota in RHD. We first analyzed microbiota of fecal samples, subgingival plaques and saliva by 16S rRNA gene sequencing to detect alterations between RHD patients and control subjects. We then analyzed microbiota of mitral valves and compared the results with gut and oral microbiota in RHD patients to determine microbial connections between mitral valves and gut/oral cavity. Finally, we explored the possibility using microbiota to discriminate RHD patients from control subjects and analyzed correlations between gut/oral microbiota and severity of RHD.

MATERIALS AND METHODS

Study Cohort

A total of 20 RHD patients and 20 age- and sex-matched control subjects were enrolled in this study. RHD patients with symptomatic severe mitral valvular disease and with a history of acute rheumatic fever were enrolled (Reményi et al., 2012; Nishimura et al., 2017). The exclusion criteria were: inflammatory bowel diseases, irritable bowel syndrome, autoimmune diseases, diarrhea, liver diseases, renal diseases, acute infection, smoking, and use of antibiotics or probiotics 3 months before sample collection.

The study protocol was reviewed and approved by the Human Ethics Committee, Shanghai Chest Hospital, Shanghai Jiaotong University and conducted in accordance with the Principles of Good Clinical Practice and the Declaration of Helsinki. Written informed consent was obtained from all the subjects who participated in the study.

Sample Collection and DNA Extraction

Fecal samples, subgingival plaques, and saliva were collected from RHD patients and control subjects. Fecal samples were collected in falcon tubes within 24 h of patients’ admission to the hospital and immediately frozen in –80°C. All subjects were instructed to avoid eating, drinking, and use of a toothbrush or mouth rinse 1 hour before sampling of subgingival plaques and saliva. Subgingival plaques were collected using a dental explorer. Saliva was collected and mixed with 2× lysis buffer at a ratio of 1:1. A total of 16 mitral valves were collected during valve replacement surgeries and were immediately frozen in liquid nitrogen under sterile conditions. Samples were kept in sterile containers and stored at –80°C. Bacterial DNA was extracted using Tiangen kits according to the manufacturer’s recommendations and stored at –80°C until further analyses.

High-Throughput Sequencing and Processing

The V3/V4 regions of 16S rRNA genes were amplified with specific primers of 338F-806R. The PCR products were quantified with PicoGreen dsDNA Assay Kit (Invitrogen, Carlsbad, USA) and sequenced on Illumina Novaseq PE250 platform to generate paired-end reads (2 × 480 bp).

Processing of the sequencing data was performed on QIIME2 platform. Analysis of sequencing data was based on amplicon sequence variants (ASVs) (Bokulich et al., 2018). After chimera detection, high-quality sequences with 97% similarity were clustered into the same ASV. Classification of ASVs was performed based on the Greengenes Database.

Data Analysis

Richness and α-diversity were measured by Chao1 and Shannon index based on the genus profiles. β-diversity was visualized using principal coordinate analysis (PCoA) based on the Bray–Curtis distances. ZP-plot was used to identify of key module members (Deng et al., 2012). Within-module connectivity (Zi) and among-module connectivity (Pi) were calculated as...
previously described (Deng et al., 2012). Microbes were classified into four categories: peripherals (Zi ≤ 2.5, Pi ≤ 0.62), connectors (Zi ≤ 2.5, Pi > 0.62), module hubs (Zi > 2.5, Pi ≤ 0.62), and network hubs (Zi > 2.5, Pi > 0.62) according to the criteria previously set (Deng et al., 2012). Network hubs were considered as super-generalists, which were highly connected within their own modules and among modules (Deng et al., 2012). Raw data of relative abundances of genera were transformed to “log10” and Log100 was shown as “−8” in figures.

Linear discriminant analysis effect size (LEfSe) was used to identify features that differed between groups. The threshold of the logarithmic LDA score for discriminative features was set to 3.0. Identified taxa were plotted in cladograms. A random forest classifier was trained to distinguish the two groups based on the genera abundance profile of RHD patients and control subjects. The important genera of the classifier were ranked by Gini index. The performance of the classifier model was evaluated by 10-fold cross-validations and further applied to construct receiver operating characteristic (ROC) curve. The cross-validation accuracy was measured as the area under the ROC curve (AUC). Heatmaps were hierarchically clustered to represent the microbe-clinical indices associations based on the Spearman correlation coefficients.

**Statistics**

α-diversity was compared using non-parametric Kruskal–Wallis tests and post hoc Dunn’s test with FDR correction. β-diversity was tested by the ANOSIM method. Raw data of relative abundances of genera were compared using non-parametric Mann–Whitney tests. Correlation analysis was performed using Spearman’s correlation. Post hoc power analysis was used to calculate power with significance level set to 0.05 and effect size based on Chao1. The power was 0.88, 0.18 and 0.93 for gut, subgingival plaques and saliva, respectively. Statistical analyses were performed using SPSS 23.0, QIIME2, R package (V3.5.1), or GPower (V3.1.9.4).

**RESULTS**

**Alterations of Gut Microbiota in Rheumatic Heart Disease Patients**

The demographic data for the enrolled RHD patients and control subjects were summarized in Supplemental Table 1. To detect gut microbial alterations, we analyzed the microbiota in fecal samples of control subjects and RHD patients using 16S rRNA gene sequencing. Subgingival plaque microbiota showed no differences of richness and α-diversity between the two groups illustrated by Chao1 and Shannon index (Figures 2A, B). Results of PCoA based on Bray–Curtis distance demonstrated moderate difference in β-diversity between RHD patients and control subjects (Figure 2C). There was no super-generalist based on modular topological roles in subgingival plaque microbiota of RHD patients (Figure 2D). Among the 15 most abundant genera, relative abundance of Corynebacterium and Selenomonas significantly decreased, while that of Streptococcus and Blautia significantly increased in subgingival plaque microbiota of RHD patients compared to control subjects (Figure 2E). LEfSe identified higher levels of taxa including Arthrobacter, Bifidobacterium, Porphyromonas, Melissococcus, Eubacterium, Ruminococcus, Dorea, Gemmiger, etc., as well as lower levels of taxa such as Staphylococcus, Faecalibacterium, Faecalibacterium, and Oxalobacter in fecal samples of RHD patients (Figure 1F). These results demonstrated considerable changes of the gut microbiota in RHD patients compared to control subjects.

**Alterations of Subgingival Plaque Microbiota in Rheumatic Heart Disease Patients**

Next we analyzed the microbiota in subgingival plaque samples of control subjects and RHD patients using 16S rRNA gene sequencing. Subgingival plaque microbiota showed no differences of richness and α-diversity between the two groups illustrated by Chao1 and Shannon index (Figures 2A, B). Results of PCoA based on Bray–Curtis distance demonstrated moderate difference in β-diversity between RHD patients and control subjects (Figure 2C). There was no super-generalist based on modular topological roles in subgingival plaque microbiota of RHD patients (Figure 2D). Among the 15 most abundant genera, relative abundance of Corynebacterium and Selenomonas significantly decreased, while that of Streptococcus and Blautia significantly increased in subgingival plaque microbiota of RHD patients compared to control subjects (Figure 2E). LEfSe identified higher levels of taxa including Streptococcus, Ruminococcus, Blautia, Dorea, Lachnospiraceae, Roseburia, Gemmiger, as well as lower levels of taxa such as Corynebacterium, Staphylococcus, Lactobacillus and Selenomonas in subgingival plaque samples of RHD patients (Figure 2F).

**Alterations of Salivary Microbiota in Rheumatic Heart Disease Patients**

We further analyzed microbiota in saliva of control subjects and RHD patients using 16S rRNA gene sequencing. Salivary microbiota of RHD patients showed significantly higher richness illustrated by Chao1 and similar α-diversity illustrated by Shannon index compared to those of control subjects (Figures 3A, B). Results of PCoA based on Bray–Curtis distance demonstrated significantly different β-diversity between RHD patients and control subjects (Figure 3C). There was no super-generalist based on modular topological roles in salivary microbiota of RHD patients (Figure 3D). Among the 15 most abundant genera, relative abundance of Prevotella, Haemophilus, Veillonella, Campylobacter, and Actinomyces significantly decreased, while that of Streptococcus and Rothia significantly increased in salivary microbiota of RHD...
patients compared to control subjects (Figure 3E). LEfSe identified higher levels of taxa including *Piscicoccus*, *Rothia*, *Abiotrophia*, *Melissococcus*, *Streptococcus*, *Parvimonas*, *Clostridium*, *Lachnoanaerobaculum*, etc., as well as lower levels of taxa such as *Actinomyces*, *Rhodococcus*, *Prevotella*, *Staphylococcus*, *Veillonella*, *Afpia*, *Sphingomonas*, etc. (Figure 3F).

**Comparisons of Microbiota Composition Between Mitral Valves and Other Body Sites in Rheumatic Heart Disease Patients**

Subsequently, we analyzed the microbiota in mitral valves of RHD patients (*n* = 16) using 16S rRNA gene sequencing. The 15 most abundant genera in mitral valves of RHD patients were *Ralstonia*, *Pelomonas*, *Acinetobacter*, *Neisseria*, *Sphingomonas*, *Streptococcus*, *Agrobacterium*, *Thermus*, *Shigella*, *Rothia*, *Fusobacterium*, *Prevotella*, *Afpia*, *Caulobacter*, and *Burkholderia* (Supplemental Figure 1A). There was no super-generalist based on modular topological roles in microbiota of mitral valves of RHD patients (Supplemental Figure 2). We next compared microbiota in mitral valves with gut and oral microbiota in these 16 RHD patients. PCoA based on Bray–Curtis distance demonstrated distinct β-diversity among microbiota of mitral valves, gut, and oral cavity, although microbiota of mitral valves in some RHD patients had similar β-diversity with oral microbiota (Figure 4A). As expected, β-diversity of subgingival plaque microbiota and salivary microbiota are similar (Figure 4A). Taxonomic composition plots at phylum level showed that mitral valves contained significantly more Proteobacteria and less Firmicutes compared to gut,

![Figure 1](image-url)
subgingival plaques, and saliva (Figure 4B), similar to the results of a previous study in atherosclerotic plaques (Koren et al., 2010). We further searched for microbes shared by mitral valves and other body sites using three criteria: (1) detected in mitral valve and at least another body site of an individual RHD patient; (2) detected in mitral valves and another body site of more than eight RHD patients (50%) simultaneously; (3) relative abundance ranked among top 35 (Supplemental Figure 1). Mitral valves and fecal samples shared Streptococcus, Shigella, Lactobacillus, and Bacteroides in all 16 patients, Oscillospira in 15 patients, Blautia in 11 patients, and Prevotella in nine patients (Figure 4C). Mitral valves and subgingival plaques shared Streptococcus and Fusobacterium in all 16 patients, Neisseria in 15 patients, Prevotella in 13 patients, Campylobacter in 10 patients, as well as Rothia and Veillonella in nine patients (Figure 4D). Mitral valves and saliva shared Streptococcus and Fusobacterium in all 16 patients, Neisseria in 15 patients, Prevotella in 13 patients, Campylobacter in 10 patients, as well as Rothia and Veillonella in nine patients (Figure 4E).

Microbiota Discriminates Rheumatic Heart Disease Patients From Control Subjects

To explore the diagnostic value of microbiota in discriminating RHD patients from healthy controls, we constructed random forest classifiers. According to random forest classifier based on gut microbiota, the top 15 important gut genera were Ruminococcus, Dorea, Arthrobacter, Lachnospira, Shigella, Gemmiger, Bifidobacterium, Ralstonia, Faecalibacterium, Subdoligranulum, Burkholderia, Blautia, Turicibacter, Streptococcus, and Selenomonas (Supplemental Figure 3A).
Area under the curve (AUC) of the gut microbiota was 0.74 (Figure 5A). As for subgingival plaque microbiota, the top 15 important subgingival plaque genera were Roseburia, Acinetobacter, Turicibacter, Bifidobacterium, Lactobacillus, Leptotrichia, Faecalibacterium, Lachnoanaerobaculum, Clostridium, Streptococcus, Atoxoplasma, Blautia, Gemmiger, Filifactor, and Granulicatella (Supplemental Figure 3B). AUC of subgingival plaque microbiota was 0.89 (Figure 5B). In saliva, the top 15 important salivary genera were Streptococcus, Shigella, Rothia, Pelomonas, Lachnoanaerobaculum, Parvimonas, Arthrobacter, Clostridium, Abiotrophia, Afipia, Streptobacillus, Ralstonia, Turicibacter, Cardiobacterium, and Haemophilus (Supplemental Figure 3C). AUC of salivary microbiota was 1.00 (Figure 5C).

**Microbial Taxa Correlate With Clinical Indices in Rheumatic Heart Disease Patients**

Mitral valves are the most common heart valves affected by RHD (Russell et al., 2017). Mitral stenosis and regurgitation cause depressed left atrial compliance and elevated left atrial pressure, leading to atrial remodelling and increased left atrial diameter (LAD). Furthermore, pulmonary hypertension is one of the most frequent medical complications in RHD (Watkins et al., 2018). We explored the relationship between these clinical indices and microbial taxa differentially enriched or important to discriminate RHD patients from healthy controls. The results showed that Bacteroides and Eubacterium in the gut negatively correlated with LAD; Roseburia and Lachnoanaerobaculum in subgingival
plaques, on the other hand, positively correlated with LAD (Figure 6A). *Blautia* in the gut negatively correlated with pulmonary artery systolic pressure (PASP); *Corynebacterium* and *Roseburia* in subgingival plaques, on the other hand, positively correlated with PASP (Figure 6B).

**DISCUSSION**

To our knowledge, this work is the first one to present comprehensive characterization of the microbiota in RHD patients. Our study demonstrated that RHD patients had altered gut and oral microbiota, which was likely to translocate to mitral valves and correlate with severity of the disease. These results provided new insights on etiology, diagnosis, prevention, and treatment of RHD.

We identified significant alterations in the microbial profile of gut in RHD patients. We observed that relative abundances of *Bifidobacterium* and *Eubacterium* increased and those of *Faecalibacterium* and *Bacteroides* decreased in RHD patients. Moreover, *Coprococcus* served as a super-generalist in gut microbiota of RHD patients. *Bifidobacterium* has been
considered a probiotic that can alter host microbiota in favor of a “healthier” composition (Toscano et al., 2017). *Eubacterium*, *Faecalibacterium*, *Bacteroides*, *Coprococcus*, and *Blautia* are important propionate- or butyrate-producing bacteria (Hoyles and Swann, 2019; Blak et al., 2020). Propionate can enhance generation of macrophage and dendritic cell precursors in the bone marrow (Trompette et al., 2014) and butyrate can facilitate extrathymic generation of T-reg cells (Arpaia et al., 2013). Butyrate also helps to maintain the integrity of the intestinal epithelium and reduce injury in distant organs such as lungs (Haak et al., 2018; Hoyles and Swann, 2019). Therefore, it seemed counterintuitive that *Bifidobacterium* and *Eubacterium* increased in the gut microbiota of RHD patients. We postulated that during the progression of RHD the decrease of some beneficial genera such as *Faecalibacterium* and *Bacteroides* contributed to disruption of immune homeostasis, resulting in passive increase of some other beneficial genera such as *Bifidobacterium* and *Eubacterium* in response to lasting immune dysbiosis. Similarly, previous studies have demonstrated an increase of *Bifidobacterium* or *Eubacterium* in patients with inflammatory bowel disease (Wang et al., 2013) or systemic lupus erythematosus (He et al., 2016). We also observed that *Bacteroides*, *Eubacterium*, and *Blautia* in the gut negatively correlated with severity of RHD, suggesting beneficial roles of these three genera in RHD. However, neither *Bifidobacterium* nor *Faecalibacterium* significantly correlated with any clinical indices of RHD (Data not shown). The detailed functions and mechanisms of these individual microbes in RHD remain to be further delineated.

The gut microbiota of RHD patients manifested some similarities but more differences comparing to that of patients with other diseases. We observed increases in most of the abundant genera in the gut microbiota of RHD patients. The reason may be that RHD patients were subjected to high levels of stress and gut inflammation that reduced gastrointestinal motility and clearance capacity, leading to bacterial overgrowth in turn. This phenomenon has been previously observed in patients with type 1 diabetes, chronic heart failure, or other critical illness (Btaiche et al., 2010; Pasini et al., 2016; Malik et al., 2018). The gut microbial profile of RHD patients differed significantly from other cardiovascular diseases such as chronic heart failure and pulmonary arterial hypertension (Kummen et al., 2018; Kim et al., 2020). For example, gut microbiota of patients with chronic heart failure had relatively low abundance in *Bifidobacterium* and high in *Prevotella* (Kummen et al., 2018), whereas our results demonstrated that the gut microbiota of RHD patients had relatively high abundance in *Bifidobacterium* and no difference in *Prevotella*. Some genera in RHD patients had similar alterations as in patients with pulmonary arterial hypertension, including decreased *Bacteroides* and increased *Bifidobacterium* (Kim et al., 2020). However, alterations of some other genera were completely different between RHD patients and patients with pulmonary arterial hypertension. For example, the abundance of *Eubacterium* increased in RHD patients, while it decreased in patients with pulmonary arterial hypertension (Kim et al., 2020). Thus, we propose that the same bacteria may respond to different stimuli specifically and play different roles in various disease conditions. Further animal experiments should be implemented to confirm their specific functions. It is the unique microbial profile that makes it possible to discriminate RHD patients from healthy controls or even other diseases.

We also identified significant microbial alterations in oral cavity of RHD patients. A large variety of microbiota resides in different locations of the oral cavity (Avila et al., 2009). We analyzed the microbiota of saliva and subgingival plaques in this study. Salivary microbiota of RHD patients showed higher richness than that of control subjects, likely because of poor oral hygiene (Maharaj and Vayej, 2012; Belstrom et al., 2018). The difference in β-diversity of salivary microbiota between RHD and control subjects was more dramatic in comparison with that of gut and subgingival plaque microbiota. In line with this, the diagnostic value of salivary microbiota was the greatest according to random forest analysis. The results underpinned the theory that saliva represented a significant source of
discriminatory biomarkers for oral and systemic diseases (Yoshizawa et al., 2013). For example, salivary microbes were able to correlate with clinical indices and stratify active and moderately active patients of rheumatoid arthritis (Zhang et al., 2015). Similar results were obtained in Crohn’s disease, another autoimmune disease (Zhang et al., 2020). Although microbes in saliva had large potential to differentiate RHD from control subjects, there was no correlation between any single salivary microbe and RHD severity. The reason may be that salivary microbes closely interacted with each other and functioned as a whole (Jenkinson and Lamont, 2005). Our data showed that genus such as Roseburia, Lachnoanaerobaculum, and Cornyebacterium in subgingival plaques correlated with RHD severity, although the functions of these genera in periodontal lesions of RHD remain to be further explored.

Our results also showed that Streptococcus significantly increased in saliva of RHD patients. There are 74 species under the genus of Streptococcus (Wong and Yuen, 2012). GAS is responsible for pharyngitis and the post-infection sequela, including RHD (Soderholm et al., 2018). GAS can survive the oral immune defense system and remain viable for long periods (Gray et al., 2017). Similar results were obtained in Crohn disease, another autoimmune disease (Yoshizawa et al., 2013). GAS is a gut commensal and can translocate to the oral cavity and can act as a probiotic (Segre, 2012). As the gut-to-valve translocation of this microbe, Streptococcus was abundantly distributed in mitral valves of every RHD patient. This is consistent with the theory that GAS or its components can enter the circulation and gain access to the subendothelial collagen matrix (Avila et al., 2009). Neisseria, Lactobacillus, Campylobacter and Prevotella were detected in the mitral valves of most RHD patients. It would be reasonable to speculate that these microbes, together with Streptococcus, could translocate from the gut and/or oral cavity to the mitral valves, creating antigens that provoke autoimmune response against host cardiac tissues over the progression of RHD.

Our data suggested potential transmission of microbes from the gut or oral cavity to heart valves of RHD patients. Some genera were shared by mitral valves and gut or oral cavity in RHD patients, indicating that microbes in the gut and/or oral cavity might translocate to the mitral valves. In the context of immunological cascade caused by GAS infection, gut microbial dysbiosis may increase endotoxin production and weaken gut barrier function, leading to increase of intestinal permeability and subsequent bacterial translocation (Camilleri, 2019). Oral cavity is another potential origin of the microbiota in mitral valves. Transmission of oral microbes to other body sites can be caused by invasive dental procedure or even normal daily activities such as tooth brushing and food intake (Smith and Nehring, 2020). Our results demonstrated that the microbiota in mitral valves partially overlapped with that in oral cavity. Intriguingly, Campylobacter was distributed in most mitral valves and oral cavity but only presented in one fecal sample of RHD patients, pointing to the possibility of oral-to-valve but not gut-to-valve translocation of this microbe. Streptococcus was abundantly distributed in mitral valves of most RHD patients. It would be reasonable to speculate that these microbes, together with Streptococcus, could translocate from the gut and/or oral cavity to the mitral valves, creating antigens that provoke autoimmune response against host cardiac tissues over the progression of RHD.
It is feasible to treat diseases through manipulation of the microbiota. For example, fecal microbiota transplantation has been safely performed in the treatment of diarrhea and sepsis in critical care (Li et al., 2015). Moreover, microbiota affects drug pharmacokinetics. The rate of absorption and bioavailability of many oral drugs depends on their exposure to bacterial enzymes before entering the circulation (Li and Jia, 2013). For RHD patients with prosthetic valves, the gut microbiota has been implicated to affect anticoagulant therapy that is mandatory after surgery (Wang et al., 2020). Our study is a start point for potential microbiota-targeting therapies, although more studies are required to establish causative links between the microbiota and RHD.

In conclusion, we described important alterations in the microbiota of RHD patients, provided evidence that microbiota in gut and oral cavity might translocate to mitral valves, demonstrated the possibility of distinguishing patients from control subjects using microbiota, and identified gut/oral microbes that correlated with severity of RHD. Our study paved a promising path for using microbiota as a potential diagnostic, prophylactic, and therapeutic tool for RHD.
