Abstract. The flow stress curves of Ti-25Nb alloy were acquired by hot compressive tests on Gleeble-3500 thermo-simulation machine at the strain rate range of 0.001-10 s\(^{-1}\) and temperature range of 470-620°C. The results show that the flow stresses decrease with the decrease in strain rate and the increase in temperature in general and modified constitutive model established by Strain compensation of n and A has a high predicted ability under experimental deformation condition.

1. Introduction
Biomedical titanium alloys play a critical role in biomedical materials [1]. In the past decades, biomedical titanium alloys have been successfully developed in this world. Nowadays, as the new generation biomedical titanium alloys, Ti-25Nb alloys are more outstanding than other material in so many aspects. As a result, it is meaningful and significant to research this alloys for every citizen. Establishing the constitutive models is really critical for processing in factory and simulation in future research.

Some researchers studied the compositions with different Ti/Nb atomic ratios obtained by reactive milling (RM) and mechanical alloying (MA) [2]. They got conclusions that the RM synthesized hydrides acquired better H-absorption/desorption properties at 250-300°C and the hydride nucleation manner changes with increasing the Nb addition. Unfortunately, there are hardly constitutive models of Ti-25Nb alloys in the past studies. In this paper, the true stress-strain curves obtained from experiments were analyzed and the constitutive model was established by combining the Zener-Hollomon parameter and the Arrhenius-type equation.

2. Materials and methods
The chemical compositions of Ti-25Nb alloys used in this research are 85.3 at% Ti and 14.7 at% Nb. The specimens for isothermal compression tests were machined into cylinders 12 mm in height and 8 mm in diameter. The hot compression testing was carried out in the temperatures range of 470-620°C and strain rates range of 0.001-10 s\(^{-1}\) by Gleeble-3500 thermal-mechanical simulator. The samples were extremely compressed 70% in height and the true strain was 1.2 relatively.

3. Results and discussion

3.1. Flow behaviour
The true stress-strain curves obtained at different temperatures and strain rates (Fig. 1) show that the true stress increases rapidly at the initial stage in each curve, which results from work hardening caused
by the rapid augmentation of the dislocation density. Then, stresses quickly reach peak with greatly small strains. After peak stresses, stresses decrease gradually with the increase in strain at the same train rate and temperature.

As Fig. 1(a), the stresses reduce with the decrease in strain rate at the same temperature in general. As Fig. 1(b), the stresses decrease with the increase in temperature in general at the same strain rate. As a result, the temperature and strain rate make a significant difference in the true stress. In this experiment, there are work hardening and dynamic softening caused by DRV and DRX. Generally, the true stress-strain curves mainly show DRX characteristics with obvious peak stresses, which is a matter of balance between working hardening and dynamic softening.

3.2. Constitutive model

The Arrhenius-type equation could be generally used to describe the hot deformation behavior of a material. In addition, the Zener-Hollomon parameter proposed by Zener and Hollomon is a valid way to state the effect of deformation temperature and strain rate on flow stress. Generally, the flow stresses of a material can be modeled by combining the Zener-Hollomon parameter and the Arrhenius-type equation, as shown in Eqs. (1) [4-6].

\[
Z = \dot{\varepsilon} \exp \left( \frac{Q}{RT} \right) = \begin{cases} 
A_1 \sigma^{n_1} & (\sigma \sigma < 0.8) \\
A_2 \exp(\beta \sigma) & (\sigma \sigma > 1.2) \\
A \left[ \sinh(\alpha \sigma) \right]^n & (for all)
\end{cases}
\]

Where \( \dot{\varepsilon} \) is the strain rate (s\(^{-1}\)), \( Q \) is the activation energy of hot deformation (kJ/mol), \( R \) is the gas constant (8.314 J/mol/K), \( T \) is the absolute temperature (K), \( \sigma \) is flow stress (MPa), \( A_1, A_2, A, n_1, n, \alpha, \) and \( \beta \) are the material constants.

By considering the value of peak stress (\( \sigma_p \)), the average values of \( n_1, \beta \) and \( n \) acquired by Eq. (2)-(4) was found to be 18.089, 0.0562 and 13.472 as shown in Fig. 2a-c.

\[
n_1 = \left[ \frac{\partial \ln \dot{\varepsilon}}{\partial \ln \sigma_p} \right]_T \tag{2}
\]

\[
\beta = \left[ \frac{\partial \ln \dot{\varepsilon}}{\partial \sigma_p} \right]_T \tag{3}
\]
\[ n = \left[ \frac{\partial \ln \dot{\varepsilon}}{\partial \ln \left( \sinh \left( \alpha \sigma_p \right) \right)} \right]_T \]  

(4)

As a result, the value of \( \alpha \) obtained from \( \alpha = \beta / n_1 \) was found to be 0.00311. The activation energy of hot deformation (Q) can be calculated from Eq. (5):

\[ Q = Rn \left[ \frac{\partial \ln \left( \sinh \left( \alpha \sigma_p \right) \right)}{\partial (1/T)} \right] \dot{\varepsilon} \]  

(5)

The average slopes of \( \ln \left[ \sinh (\alpha \sigma) \right] \) against \( 1000/T \) was found to be 5.726 as shown in Fig. 2d. So the value of Q could be calculated to be 641.3kJ/mol. Moreover, the value of \( \ln A \) was acquired by the average intercepts of line \( \ln \left[ \sinh (\alpha \sigma) \right] \)-lnZ as shown in Fig. 3. All in all, the peak stress of Ti-25Nb alloy could be expressed by Eq. (6).

\[ Z = \dot{\varepsilon} \exp \left( \frac{6.413 \times 10^5}{RT} \right) = 6.858 \times 10^{38} \left[ \sinh \left( 0.00311 \sigma \right) \right]^{13.472} \]  

(6)

\[ \text{Figure 2. The relationship between (a) } \sigma-\ln \dot{\varepsilon} \text{, (b) } \ln \sigma-\ln \dot{\varepsilon} \text{, (c) } \ln (\sinh (\alpha \sigma))- \ln \dot{\varepsilon} \text{, (d) } 1000/T- \ln (\sinh (\alpha \sigma)).} \]

In this modified model, based on the peak stress proposed by Mirada [7], the activation energy (Q) and \( \alpha \) are not assumed to be a function of strain. Moreover, the material constants A and n, calculated at different strains by previous mentioned approach, are strain dependents in this modified approach. The
main advantageous of this new model is that the cost of computation and time is reduced mostly as Q and α are constants and just only are calculated at the peak stress.

In the present study, lnA and n were calculated between 0.05 and 1.2 with intervals of 0.05 to establish this modified model. The order polynomial curve of lnA and n was shown in Fig. 4.

Considering strain-independent Q and α and strain-dependent A and n, the modified model equation can present in the following form:

$$\sigma = \frac{1}{\alpha} \left[ \sinh^{-1} \left( \frac{Z}{A(\varepsilon)} \right)^{1/n(\varepsilon)} \right]$$  \hspace{1cm} (7)

Comparisons between the experimental stresses and predicted data calculated by Eqs. (7) at different conditions are plotted in Fig. 5. It can be seen from Fig. 5 that the modified constitutive model can accurately predict the flow stress of Ti-25Nb alloy.

**Figure 4.** The 6th order polynomial of (a) n and (b) lnA with true strain
Figure 5. Comparison between the experimental and predicted flow stresses on the strain rates of 0.01 s\(^{-1}\).

4. Conclusion
The hot deformation behavior of Ti-25Nb alloys was investigated at deformation temperatures 470, 500, 530, 560, 590 and 620°C and at strain rates 0.001, 0.01, 0.1, 1, and 10 s\(^{-1}\). The conclusions are presented below.

1) The flow stresses of Ti-25Nb alloys decrease with the decrease in strain rate and the increase in temperature in general.

2) To predict the flow stresses of Ti-25Nb alloys, modified constitutive model was established by strain compensation of n and A and has a high predicted ability under experimental deformation condition.
