ABSTRACT

We investigate the gravitational instability of galactic discs, treating stars and cold interstellar gas as two distinct components, and taking into account the phenomenology of turbulence in the interstellar medium (ISM), i.e. the Larson-type scaling relations observed in the molecular and atomic gas. Besides deriving general properties of such systems, we analyse a large sample of galaxies from The H\textsc{i} Nearby Galaxy Survey (THINGS), and show in detail how interstellar turbulence affects disc instability in star-forming spirals. We find that turbulence has a significant effect on both the inner and the outer regions of the disc. In particular, it drives the inner gas disc to a regime of transition between two instability phases and makes the outer disc more prone to star-dominated instabilities.

Key words: instabilities – turbulence – ISM: kinematics and dynamics – ISM: structure – galaxies: ISM – galaxies: kinematics and dynamics.

1 INTRODUCTION

Today, 30 years after the pioneering work by Larson (1981), observations and simulations of the interstellar medium (ISM) are revealing its turbulent nature with higher and higher fidelity (see, e.g., Elmegreen & Scalo 2004; McKee & Ostriker 2007; Romeo et al. 2010). A fundamental aspect of ISM turbulence is the existence of scaling relations between the mass column density ($\Sigma$), the 1D velocity dispersion ($\sigma$), and the size of the region over which such quantities are measured ($\ell$):

\[ \Sigma \propto \ell^a, \quad \sigma \propto \ell^b. \]  \hspace{1cm} (1)

The values of $a$ and $b$, and the range of scales spanned by $\ell$ depend on which ISM component we consider. In this paper we focus on cold interstellar gas, which is highly supersonic and hence strongly compressible, and which is known to play an important role in the gravitational instability of galactic discs (e.g., Lin & Shu 1966; Jog & Solomon 1984a, b; Bertin & Romeo 1988, and references therein).

In the molecular gas, H\textsc{ii}, the scaling exponents are $a \approx 0$ and $b \approx \frac{1}{2}$, and Eq. (1) holds up to scales of a few 100 pc. In fact, both Galactic and extragalactic giant molecular clouds (GMCs) are fairly well described by Larson’s scaling laws, $\Sigma = \text{constant}$ and $\sigma \propto \ell^{1/2}$, although the uncertainties are still large (e.g., Larson 1981; Solomon et al. 1987; Bolatto et al. 2008; Heyer et al. 2009; Hughes et al. 2010; Kauffmann et al. 2010; Lombardi et al. 2010; Sánchez et al. 2010; Azimlu & Fich 2011; Ballesteros-Paredes et al. 2011; Field et al. 2011; Kritsuk & Norman 2011; Roman-Duval et al. 2011; Beaumont et al. 2012). Besides, Larson-type scaling relations have now been observed, for the first time, in the dense star-forming clumps of a high-redshift galaxy (Swinbank et al. 2011).

In the atomic gas, H\textsc{i}, the scaling exponents are instead $a \sim \frac{1}{3}$ and $b \sim \frac{1}{4}$, and Eq. (1) seems to hold up to scales of a few kpc. A Kolmogorov scaling for both $\sigma$ and $\Sigma$ is suggested by the observed power spectra of H\textsc{i} intensity fluctuations, and is also consistent with other measurements (e.g., Lazarian & Pogosyan 2000; Elmegreen et al. 2001; Begum et al. 2006; Kim et al. 2007; Dutta et al. 2008; Roy et al. 2008; Dutta et al. 2009a, b; Block et al. 2010; Bournaud et al. 2010; Dutta et al. 2010; Dutta 2011; Combes et al. 2012; Zhang et al. 2012). Note, however, that the uncertainties are larger than in the H\textsc{ii} case. For example, high-resolution simulations of supersonic turbulence suggest a Burgers scaling for both $\sigma$ and $\Sigma$, i.e. $a \sim \frac{1}{3}$ and $b \sim \frac{1}{4}$ (e.g., Fleck 1996; Kowal & Lazarian 2007; Kowal et al. 2007; Schmidt et al. 2008; Price & Federrath 2010). Other recent simulation surveys suggest that the scaling exponent $a$ is significantly affected by turbulence forcing (Federrath et al. 2009, 2010) and self-gravity (Collins et al. 2012).

In spite of such a burst of interest in ISM turbulence, and in spite of the dynamical importance of cold interstellar gas, there have been very few theoretical works aimed at evaluating the effect of turbulence on disc instability. In
fact, traditional stability analyses do not take into account the scale-dependence of $\sigma$ (or $\Sigma$), but identify $\sigma$ with the typical 1D velocity dispersion observed at galactic scales. The first theoretical work devoted to the gravitational instability of turbulent gas discs was made by Elmegreen (1996), who assumed Larson-type scaling relations [see Eq. (1)] and investigated the case $a = -1$ and $b = 4$. He found that the disc is always stable at large scales and unstable at small scales. Romeo et al. (2010) also assumed Larson-type scaling relations, but explored the whole range of values for $a$ and $b$. They showed that turbulence has an important effect on the gravitational instability of the disc: it excites a rich variety of stability regimes, several of which have no classical counterpart. See in particular the ‘stability map of turbulence’ (fig. 1 of Romeo et al. 2010), which illustrates such stability regimes and populates them with observations, simulations and models of interstellar turbulence.

In the gravitational instability of galactic discs, there is an important interplay between stars and cold interstellar gas (e.g., Agertz et al. 2009; Elmegreen 2011; Forbes et al. 2011; Cacciato et al. 2012). The gravitational coupling between these two components does not alter the form of the local stability criterion, $Q_{\text{eff}} \geq 1$, but makes the effective $Q$ parameter different from both the stellar and the gaseous Toomre (1964) parameters (Bertin & Romeo 1988; Romeo 1992, 1994; Elmegreen 1995; Jog 1996; Rafikov 2001; Shen & Lou 2003; Elmegreen 2011; Romeo & Wiegert 2011). The gravitational coupling between stars and gas also changes the least stable wavelength (Jog 1996), among other diagnostics.

What is the effect of ISM turbulence in this more realistic context? The first published attempt to answer this question was made by Shadmehri & Khajenabi (2012). They considered two-component discs of stars and turbulent gas, chose $a$ and $b$ so as to sample five of the seven stability regimes found by Romeo et al. (2010), and studied the dispersion relation numerically. Their study suggests that turbulence has a significant effect on disc instability even when stars are taken into account. The goal of our paper is to answer the question above in detail, extending previous work along two directions:

(i) We perform a rigorous stability analysis of two-component turbulent discs, motivated by observations of ISM turbulence in nearby galaxies. In particular, we consider two complementary cases: H$_1$ plus H$_2$, and gas plus stars. In the first case, we examine the dispersion relation analytically, and illustrate how the gravitational coupling between H$_1$ and H$_2$ modifies the main stability regimes of gas turbulence, which were originally derived neglecting such a coupling (Romeo et al. 2010). In the second case, we show that there are four stability regimes of galactic interest, similar to those analysed above, but in only one of them do stars play a non-negligible role. We then focus on such a regime, and illustrate how gas turbulence affects the onset of gravitational instability in the disc, i.e. the local stability threshold and the corresponding characteristic wavelength.

(ii) We apply this analysis to a large sample of star-forming spirals from The H$_1$ Nearby Galaxy Survey (THINGS), previously analysed by Leroy et al. (2008) and Romeo & Wiegert (2011), and illustrate how ISM turbulence affects a full set of stability diagnostics: the condition for star-gas decoupling, the effective $Q$ parameter, and the least stable wavelength.

The rest of the paper is organized as follows. The (in)stability of two-component turbulent discs is analysed in Sect. 2, our application to THINGS spirals is shown in Sect. 3, the relation between our results and those of Shadmehri & Khajenabi (2012) is discussed in Sect. 4, and the conclusions are drawn in Sect. 5.

2 (IN)STABILITY OF TWO-COMPONENT TURBULENT DISCS

2.1 Summary of the one-component case

Here we summarize some of the results found by Romeo et al. (2010), which are fundamental to a proper understanding of Sects 2.2–2.4.

The dispersion relation of a turbulent and realistically thick gas disc is

$$\omega^2 = k^2 - 2\pi G \Sigma(k) + \sigma^2(k) k^2, \quad (2)$$

where $\omega$ and $k$ are the frequency and the wavenumber of the perturbation, and $\kappa$ is the epicyclic frequency. $\Sigma(k)$ and $\sigma(k)$ are the mass column density and the 1D velocity dispersion measured over a region of size $\ell = 1/k$, as inferred from observations (see, e.g., Elmegreen & Scalo 2004; McKee & Ostriker 2007; Romeo et al. 2010):

$$\Sigma(k) = \Sigma_0 \left( \frac{k}{k_0} \right)^{-a}, \quad \sigma(k) = \sigma_0 \left( \frac{k}{k_0} \right)^{-b}. \quad (3)$$

If the disc has volume density $\rho$ and scale height $h$, then $\Sigma \approx 2\rho h$ for $\ell \lesssim h$ and $\Sigma \approx 2\rho \ell$ for $\ell \gtrsim h$. The range $\ell \lesssim h$ corresponds to the case of 3D turbulence (GMCs and H$_1$ at small scales), whereas the range $\ell \gtrsim h$ corresponds to the case of 2D turbulence (H$_1$ at large scales). The quantity $\ell_0 = 1/k_0$ introduced in Eq. (3) is the fiducial scale at which $\Sigma$ and $\sigma$ are observed. This is also the scale at which the Toomre parameter $Q$ and other stability quantities are measured, so that $Q_0 = \sigma_0/\pi G \Sigma_0$.

The scaling exponents $a$ and $b$ have an important effect on the shape of the dispersion relation [Eq. (2)], and hence on the condition for local gravitational instability ($\omega^2 < 0$). As $a$ and $b$ vary, turbulence drives the disc across seven stability regimes, three of which are densely populated by observations, simulations and models of galactic turbulence (see fig. 1 of Romeo et al. 2010):

- For $b < \frac{1}{2} (1 + a)$ and $-2 < a < 1$ (hereafter Regime A), the stability of the disc is controlled by $Q_0$: the disc is stable at all scales if and only if $Q_0 \geq Q_0^d$, where $Q_0^d$ depends on $a$, $b$ and $\ell_0$. This is the domain of H$_1$ turbulence. Both H$_1$ observations and high-resolution simulations of supersonic turbulence are consistent with the scaling $a = b$. In such a case, the local stability criterion degenerates into $Q_0 \geq 1$, as if the disc were non-turbulent and infinitesimally thin.
- For $b > \frac{1}{2} (1 + a)$ and $-2 < a < 1$ (hereafter Regime C), the stability of the disc is no longer controlled by $Q_0$: the disc is always unstable at small scales (i.e. as $k \to \infty$) and stable at large scales (i.e. as $k \to 0$).
- For $b = \frac{1}{2} (1 + a)$ and $-2 < a < 1$ (hereafter Regime B), the disc is in a phase transition between stability à la Toomre (Regime A) and instability at small scales (Regime
C). This is the domain of $H_2$ turbulence. Note, however, that even small deviations from Larson’s scaling laws can drive the disc into Regime A or Regime C, and thus have a strong impact on its gravitational instability.

Since Regimes A–C are fundamental to a proper understanding of Sects 2.2–2.4, we show them in Fig. 1. Note, however, that this simple figure is not meant to be a substitute for fig. 1 of Romeo et al. (2010), which illustrates all seven stability regimes and their relation to the phenomenology of ISM turbulence.

### 2.2 Dispersion relation and general properties

Until now we have considered H1 and $H_2$ separately. How does the stability scenario change when H1 and $H_2$ are considered together? And how does it change when both gas and stars are taken into account? We will answer these questions here and in Sects 2.3 and 2.4.

When H1 and $H_2$ are considered together, their gravitational coupling changes how the disc responds to perturbations. The dispersion relation can be expressed in a form that is particularly useful for discussing the stability properties of the disc:

$$\left(\omega^2 - M_i^2\right)\left(\omega^2 - M_j^2\right) = \left(P_i^2 - M_i^2\right)\left(P_j^2 - M_j^2\right),$$

where

$$M_i^2 \equiv \kappa^2 - 2\pi G \sigma_i^2(k)k^2,$$

$$P_i^2 \equiv \kappa^2 + \sigma_i^2(k)k^2,$$

and $i = 1, 2$.

Note that $\omega^2 = M_i^2(k)$ is the one-component dispersion relation for potential-density waves [cf. Eq. (2)], while $P_i^2(k)$ describes sound waves modified by rotation (and turbulence). Since $M_i^2(k) - P_i^2(k)$ represents the self-gravity of component $i$, the right-hand side of Eq. (4) measures the strength of gravitational coupling between the two components.

Eqs (4)–(6) are also applicable to two-component discs of gas and stars, even though the stellar component is collisionless and non-turbulent. This is because stars can be accurately treated as a fluid when analysing the stability of galactic discs (Bertin & Romeo 1988; Rafikov 2001), and because the equations above are valid whether each fluid is turbulent or not. Remember, in fact, that the phenomenology of turbulence is encapsulated in $\Sigma_i(k)$ and $\sigma_i(k)$ without altering the form of those equations. When the disc is made of gas ($g$) and stars ($s$), $\Sigma_g(k)$ and $\sigma_g(k)$ are given by Eq. (3), while the stellar quantities are not. $\Sigma_s(k)$ is the reduced surface density, $\Sigma_s(k) = \Sigma_g/(1 + k h_s)$, where the $k$-dependent factor results from the finite scale height of the stellar layer (Vandervoort 1970; Romeo 1992, 1994; Elmegreen 2011). In contrast, $\sigma_s$ is the radial velocity dispersion and does not depend on $k$, since the pressure term in the dispersion relation is unaffected by disc thickness (see again Vandervoort 1970). The gaseous and stellar Toomre parameters are then defined as $Q_g = \kappa \sigma_g/\pi G \Sigma_g$ and $Q_s = \kappa \sigma_s/\pi G \Sigma_s$.

As Eq. (4) is quadratic in $\omega$, it can be solved with elementary methods. The discriminant is positive, so there are two real roots:

$$\omega_{\pm}^2 = \frac{1}{2} \left[ (M_i^2 + M_j^2) \pm \sqrt{\Delta} \right],$$

$$\Delta = \left(M_i^2 - M_j^2\right)^2 + 4 \left(P_i^2 - M_i^2\right)\left(P_j^2 - M_j^2\right).$$

This means that the dispersion relation has two branches that do not cross, $\omega_k^2 \neq \omega_\pm^2(k)$, except possibly as $k \to 0$ or $k \to \infty$. The functions $\omega_k^2(k)$ satisfy two basic properties, which constrain the gravitational instability of the disc and generalize the stability constraints found in the classical two-component case (Jog & Solomon 1984a; Bertin & Romeo 1988). Such properties are stated and proved below, and can easily be visualized with the help of Fig. 2. The cases illustrated represent a disc made of marginally stable H1 (in Regime A) and unstable $H_2$ (in Regimes A–C).

- **Property I:** $\omega_+^2(k) \leq \omega_-^2(k) \leq \omega_-^2(k)$, i.e. a two-component self-gravitating disc is more unstable (or less stable) than each component, whether this is turbulent or not. This can be proved by noting that $\Delta$ is larger than $\left(M_i^2 - M_j^2\right)^2$, so that $\sqrt{\Delta} > |M_i^2 - M_j^2|$. In turn, this implies that $\omega_{\pm}^2 < \omega_k^2$, where $\omega_k^2$ is the smallest $M_i^2$ for a given $k$.

- **Property II:** $\omega_+^2(k)$ is bounded by $P_i^2(k)$ and $P_j^2(k)$, i.e. this branch is always stable and represents sound waves modified by rotation (and turbulence). To prove this, note that the inequality $\sqrt{\Delta} > |M_i^2 - M_j^2|$ also implies that $\omega_+^2 > \omega_{\max}^2$, where $\omega_{\max}^2$ is the largest $M_i^2$ for a given $k$. Note also that $\omega_+^2$ cannot be smaller than $\omega_{\min}^2$ or larger than $\omega_{\max}^2$, otherwise Eq. (4) would not hold. Therefore it must be $P_{\min}^2 \leq \omega_+^2 \leq P_{\max}^2$.

### 2.3 H1 plus $H_2$

In Sect. 2.1, we have summarized the main stability regimes of one-component turbulent discs. Let us now extend the

---

1 The dispersion relation of an $N$-component turbulent disc is $\sum_{i=1}^{N} (M_i^2 - P_i^2)/\omega^2 = 1$, as can easily be inferred from eq. (22) of Rafikov (2001). This equation cannot be expressed in a form similar to Eq. (4), and will not be used in the rest of the paper.
discussion to two-component discs of H\(_i\) and H\(_2\), analysing three cases of galactic interest (see again Fig. 2).

2.3.1 H\(_2\) in Regime A

The response of each component is driven by pressure at small scales and by rotation at large scales, while self-gravity acts more strongly at intermediate scales (see sect. 2.7 of Romeo et al. 2010). This means that the gravitational coupling between the two components is negligible as \( k \to 0 \) and \( k \to \infty \), and so is the right-hand side of Eq. (4). Therefore the two branches of the dispersion relation behave asymptotically as \( M_i^2(k) \) and \( M_2^2(k) \), i.e. they converge to \( \kappa^2 \) as \( k \to 0 \) and diverge positively as \( k \to \infty \). Since the potentially unstable branch \( \omega^2(k) \) lies below \( M_i^2(k) \) (cf. Property I) and \( M_2^2(k) \) has a minimum for \( k > 0 \), \( \omega^2(k) \) must also have a global minimum below \( \kappa^2 \). Thus the disc is stable à la Toomre, like each component (see left panel of Fig. 2).

2.3.2 H\(_2\) in Regime C

The response of H\(_i\) is similar to the previous case, while H\(_2\) behaves differently (see sect. 2.5 of Romeo et al. 2010). The self-gravity term gets dominant for large \( k \) and makes \( M_{i2}^2(k) \) negative. So \( \omega^2(k) \) is also negative in this limit (cf. Property I). For small \( k \), \( M_{i2}^2(k) \) is positive since it is dominated by the pressure term \( (b > 1) \) and/or the rotation term \( (b \leq 1) \). As neither \( M_{i2}^2(k) \) nor \( M_{i2}^2(k) \) is driven by self-gravity at large scales, the right-hand side of Eq. (4) is negligible as \( k \to 0 \). So \( \omega^2(k) \) is positive in this limit, like \( M_{i2}^2(k) \) and \( M_{i2}^2(k) \). The disc is then unstable at small scales and stable at large scales, like H\(_2\) itself (see right panel of Fig. 2).

2.3.3 H\(_2\) in Regime B

The behaviour of H\(_2\) is intermediate between the previous two cases (see sect. 2.3 of Romeo et al. 2010). A similar flow of arguments shows that the disc is in a phase of transition between stability à la Toomre and instability at small scales, like H\(_2\) itself. The middle panel of Fig. 2 illustrates the phase of small-scale instability, which occurs for \( k_0 \leq k_{2,0} = 2\pi G \Sigma_{2,0}/\sigma_{2,0}^2 \) (see Hoffmann 2010 for a detailed analysis). Note how the two components contribute to the gravitational instability of the disc, and how their coupling widens the range of unstable scales.

2.4 Gas plus stars

This case involves three components: H\(_i\), H\(_2\) and stars. In nearby spiral galaxies, H\(_i\) and H\(_2\) have distinct domains: H\(_i\) dominates the outer regions of the gas disc, while H\(_2\) dominates the inner regions (e.g., Leroy et al. 2008). We can then consider H\(_i\) and H\(_2\) separately. This makes sense here because we already know how the gravitational coupling between H\(_i\) and H\(_2\) modifies the main stability regimes of gas turbulence (see Sect. 2.3). What we now want to understand is the role that stars play in this stability scenario. Let us then distinguish two cases:

---

**Figure 2.** The two branches of the dispersion relation, \( \omega_i^2(k) \) and \( \omega_2^2(k) \), vs. their one-component counterparts, \( \mathcal{P}_i^2(k) \) and \( \mathcal{M}_i^2(k) \), in stability regimes of galactic interest. These quantities are measured in units of \( \kappa^2 \), the square of the epicyclic frequency, while \( k \) is measured in units of \( k_{T1,0} = \kappa^2/2\pi G \Sigma_{1,0} \), the Toomre wavenumber of component \( i = 1 \) at scale \( \ell = \ell_0 \). The cases illustrated represent a disc made of marginally stable H\(_i\) (in Regime A) and unstable H\(_2\) (in Regimes A–C). The scaling exponents are specified in Fig. 1. The other independent quantities are as follows: \( k_0 = 8 k_{T1,0} \), \( Q_{1,0} = 1 \), \( \Sigma_{2,0}/\Sigma_{1,0} = 1 \) and \( \sigma_{2,0}/\sigma_{1,0} = 1/2 \). These relations imply that \( Q_{2,0} = 1/2 \) and \( k_0 = 1/2 k_{12,0} \), where \( k_{12,0} = 2\pi G \Sigma_{2,0}/\sigma_{2,0}^2 \) is the Jeans wavenumber of component \( i = 2 \) (H\(_2\)) at scale \( \ell = \ell_0 \).
(i) Stars plus H$_2$. Since the stellar component populates Regime A (like H) and H$_2$ populates Regimes A–C, this case is qualitatively similar to the set of cases analysed in Sect. 2.3. So there are three stability regimes: stability à la Toomre, instability at small scales, and a phase of stability transition. Note that such a variety of regimes is driven by H$_2$ turbulence. The stellar component can only modify the shape of the dispersion relation; it cannot change the type of stability regime. Note also that there is a mismatch between two important scales. One is the characteristic scale of stellar instabilities, $L_s = \sigma^2/\pi G\Sigma_*$, which is typically $\sim 1$ kpc (see, e.g., Binney & Tremaine 2008). The other is the largest scale at which H$_2$ turbulence has been observed, $L_{H2} \sim 100$ pc (e.g., Bolatto et al. 2008). Since $L_s$ is one order of magnitude larger than $L_{H2}$, the stellar component cannot play a significant role in such stability regimes. Therefore this is essentially a one-component case, driven and dominated by H$_2$. In Sect. 3, we will show that such stability regimes can indeed be frequent in nearby star-forming spirals.

(ii) Stars plus H1. As both components populate Regime A, this is a case of stability à la Toomre: $\omega^2(k)$ has a global minimum, which determines whether the disc is stable for all wavenumbers or not (cf. Sect. 2.3.1). In contrast to case (i), H1 turbulence reaches scales as large as 1–10 kpc (e.g., Kim et al. 2007; Dutta 2011). This makes it possible for the stellar component to ‘interact’ with H1 turbulence and contribute significantly to two-fluid instabilities, as in the classical case of stars plus non-turbulent gas.

As discussed above, case (ii) represents the only stability regime in which stars play a non-negligible role. We then focus on this case, and analyse how gas turbulence affects the onset of gravitational instability in the disc, i.e. the local stability threshold and the corresponding characteristic wavelength. The effect of disc thickness is well known in this context (Romeo 1992, 1994; Elmegreen 2011; Romeo & Wiegert 2011). So we do not take that effect into account.

2.4.1 The stability threshold

As this is a Toomre-like case, the local stability criterion can be expressed in the usual form $Q_{\text{eff}} \geq 1$, where $Q_{\text{eff}}$ is the effective $Q$ parameter. In the classical case of stars plus non-turbulent gas, $Q_{\text{eff}}$ depends on three parameters: $Q_*$, $Q_\Sigma$ and $s = \sigma_s/\sigma_*$. For analysing $Q_{\text{eff}}$ in detail, it is useful to factor out the dependence on $Q_\Sigma$, $Q_{\text{eff}} = Q_s/Q_*$, and study the stability threshold $\overline{Q}$ as a function of $s$ and $q = Q_s/Q_*$. (Romeo & Wiegert 2011). When gas turbulence is taken into account via Eq. (3), $\overline{Q}$ depends on five parameters:

$$s_0 \equiv \frac{\sigma_0}{\sigma_*}, \quad q_0 \equiv \frac{Q_{0\Sigma}}{Q_*},$$

$$a, b \quad \text{and} \quad \mathcal{L}_0 \equiv \mathcal{L}_0 k_{T\Sigma},$$

where $k_{T\Sigma} = \sqrt{2/\pi G\Sigma_*}$ is the stellar Toomre wavenumber. A general five-parameter study of $\overline{Q}$ is not more useful than a targeted few-parameter analysis. This is because $a, b$ and $\mathcal{L}_0$ are tightly constrained by observations, and because their observed values fall within a single stability regime (remember that this is a region of the parameter space where the disc has similar stability properties). For these reasons, we analyse $\overline{Q}$ as a function of $s_0$ and $q_0$, choosing observationally motivated values of $a, b$ and $\mathcal{L}_0$: $a = b = \frac{1}{3}$, which is the typical scaling of H1 turbulence (see Sect. 1), and $\mathcal{L}_0 = 1.0 \pm 0.5$, which are the median and 1$\sigma$ scatter of $\mathcal{L}_0$ in the outer discs of THINGS spirals (where H1 dominates; see Sect. 3). The range $0.5 \leq \mathcal{L}_0 \leq 1.5$ is also representative of clumpy galaxies at intermediate and high redshifts.

Fig. 3 shows a contour map of the stability threshold $\overline{Q}$ for classical and turbulent discs. Consider the classical case first, and look at the contour levels $\overline{Q} = 1.1$ and $\overline{Q} = 1.4$. Their slope changes abruptly across the line $q_0 = 1$, showing that there are two distinct stability regimes. This fact has a simple explanation in terms of star-gas decoupling (Bertin & Romeo 1988; Romeo & Wiegert 2011). When $s_0 \lesssim 0.2$ and $q_0 \sim 1$, $\omega^2(k)$ has two minima: one at small $k$, where the response of the stellar component peaks; and the other at large $k$, where gas dominates. For $q_0 < 1$, the gaseous minimum is deeper than the stellar one, and therefore it controls the onset of disc instability. Vice versa, for $q_0 > 1$, it is the stellar minimum that determines the stability threshold. The line $q_0 = 1$ separates gas- from star-dominated regimes even when $s_0 \gtrsim 0.2$, but the transition is smooth in this case since $\omega^2(k)$ has a single minimum. In the turbulent case, eac-
tour level is on average shifted down. As $Q$ increases in the same direction, this means that turbulence lowers the stability threshold, i.e. it tends to stabilize the disc. In Sect. 3, we will evaluate the statistical significance of this effect.

2.4.2 The characteristic wavelength

The global minimum of $\omega^2(k)$ provides another useful stability diagnostic: the least stable wavelength $\lambda_{\text{min}} = 2\pi/k_{\text{min}}$ (see Jog 1996 for the classical case). When the disc is marginally stable, the value of $\lambda_{\text{min}}$ is of particular interest. It is the wavelength at which instability first appears as $Q_*$ drops below $Q$. This wavelength can be written as $\lambda = \lambda_{\text{res}} \cdot \lambda_T$, where $\lambda_T = 2\pi/k_T$. The characteristic wavelength $\lambda$ depends on the same parameters as $Q$. So we adopt the same approach as before, and analyse $\lambda$ as a function of $s_0$ and $q_0$ for observationally motivated values of $a$, $b$ and $L_0$.

Fig. 4 shows a contour map of the characteristic wavelength $\lambda$ for classical and turbulent discs. In the classical case, the contour levels $\lambda = 0.1$ and $\lambda = 0.2$ are truncated above $q_0 = 1$. This tells us that such short characteristic wavelengths occur only when stars and gas are decoupled and gas dominates. In fact, star-dominated instabilities appear at longer wavelengths: $\lambda \gtrsim 0.3$ (Bertin & Romeo 1988). Note also that the contour $\lambda = 0.5$ is a separatrix. Levels below 0.5 are on the left of this curve (and connected to the transition line), while levels above 0.5 are on the right. In the turbulent case, each contour level below 0.3 is on average shifted to the right, i.e. in the direction of increasing $\lambda$. This means that turbulence shortens the characteristic wavelength when stars and gas are decoupled and gas dominates. An opposite, although weaker, effect is detectable for $\lambda \gtrsim 1$. Other regimes are also affected, but in a more complex way. This is especially true for $\lambda \sim 0.5$, since the separatrices of the parameter plane shift to larger values. Last but not least, note how turbulence bends the transition line down, favouring star-dominated regimes. In Sect. 3, we will analyse these effects in detail.

3 APPLICATION TO THINGS SPIRALS

We now consider a sample of twelve nearby star-forming spirals from THINGS: NGC 628, 3198, 3184, 4736, 3351, 6946, 3627, 5194, 3521, 2841, 5055, and 7331. For these galaxies, a detailed analysis by Leroy et al. (2008) provides high-quality measurements of kinematics, as well as stellar and gaseous surface densities, at a constant spatial resolution of 800 pc.

Leroy et al. (2008) also analysed the stability of those galaxies, treating the ISM as a single non-turbulent component, gravitationally coupled to stars, with surface density $\Sigma_g = \Sigma_{\text{H}1} + \Sigma_{\text{H}2}$ and velocity dispersion $\sigma_g = 11 \text{ km s}^{-1}$. Such a value of $\sigma_g$ fits the H1 data well, but is twice as large as the typical H2 velocity dispersion observed in nearby spiral galaxies (Wilson et al. 2011). To represent both H1 and H2 well, we choose $\sigma_g = 8 \text{ km s}^{-1}$. This value lies within the 1σ scatter of $\sigma_{\text{H}1}$ (11 ± 3 km s$^{-1}$; Leroy et al. 2008) and $\sigma_{\text{H}2}$ (6.1 ± 2.9 km s$^{-1}$; Wilson et al. 2011), and therefore allows us to carry out an unbiased stability analysis of THINGS spirals.

The constant spatial resolution of 800 pc used by Leroy et al. (2008) makes their data particularly appropriate for analysing the effect of H1 turbulence at galactic scales. H1 dominates the gas surface density in the outer disc, typically for $R > 0.43 R_{25}$, where $R_{25}$ is the optical radius (Leroy et al. 2008). We then treat gas as turbulent for $R > 0.43 R_{25}$, and assume Larson-type scaling relations [see Eq. (3)] with $f_0 = 800 \text{ pc}, \Sigma_{\text{g}0} = \Sigma_{\text{g}0}(R)$ as tabulated by Leroy et al. (2008), and $\sigma_{\text{g}0} = 8 \text{ km s}^{-1}$ (see above). Concerning $a$ and $b$, we analyse the case $a = b = \frac{1}{2}$ in detail, since it represents H1 observations fairly well (see Sect. 1). We have also studied the case $a = b = \frac{3}{4}$, as representative of high-resolution simulations of supersonic turbulence (see Sect. 1), but here we will only mention it when discussing the results of our stability analysis. Hereafter we will refer to the model described above as Model 1.

3.1 The condition for star-gas decoupling

In Sect. 2.4, we have seen that there is a region in the parameter plane where $\omega^2(k)$ has two minima. This is the ‘two-phase region’ introduced by Bertin & Romeo (1988) and further investigated by Romeo & Wiegert (2011).

Fig. 5 shows the two-phase region for classical and turbulent discs. Within this region, stars and gas are dynamically decoupled and the disc is susceptible to instabilities at two different wavelengths, where the responses of the two components peak. In the stellar phase the disc is more susceptible to long-wavelength instabilities, whereas in the gaseous phase it is dominated by short-wavelength instabilities. Along the transition line between the phases, neither component dominates and instabilities occur both at short and at long wavelengths. Outside the two-phase region, the
The parameter plane populated by THINGS spirals (Model 1), and the ‘two-phase region’ where stars and gas contribute separately to the gravitational instability of the disc: neglecting gas turbulence (left), and taking into account H\textsc{i} turbulence for $R > 0.43 R_{25}$ (right). In the turbulent case, the solid lines and the shaded regions correspond to the median and the 1σ scatter of $\mathcal{L}_0$ in that radial range. Data from THINGS are coloured according to the dominant component: H\textsubscript{2} for $R \leq 0.43 R_{25}$, and H\textsc{i} for $R > 0.43 R_{25}$.

![Parameter Plane](image)

**Figure 5.**

Two components are strongly coupled and instabilities occur at intermediate wavelengths. We populate the parameter plane with measurements taken from the sample of spiral galaxies, and colour-code them by radius. We draw the turbulent two-phase region corresponding to the median and 1σ scatter of $\mathcal{L}_0$ for $R > 0.43 R_{25}$. Note the following points:

(i) The two-phase region of a classical disc is symmetric about $q = 1$. This symmetry is broken for a turbulent disc because gas (dominant for $q < 1$) follows turbulent scaling, but stars (dominant for $q > 1$) do not.

(ii) The turbulent two-phase region is larger than the classical one. This follows from the fact that turbulence pushes the minima of $\omega^2(k)$ further apart, and the maximum between them further up, so as to favour star-gas decoupling.

(iii) The transition line appears unaffected by the scatter of $\mathcal{L}_0$. This is because the shape of the two-phase region depends on $s$ and $q$, and $q$ is not affected by turbulence ($q = q_0$) if $a = b$.

(iv) Turbulence increases the size of the stellar phase more than that of the gaseous phase. Recall that the boundary of the two-phase region is marked by the disappearance of the non-dominant peak, i.e. the gas peak in the stellar phase and vice versa. Since turbulence affects the gaseous peak more than the stellar peak, the size of the stellar phase is affected more than that of the gaseous phase. For $R > 0.43 R_{25}$, this causes a significant number of measurements to populate the stellar phase.

(v) For $R \leq 0.43 R_{25}$, we find that $f_2 = 61\%$ of all points populate the two-phase region, two-thirds of them in the gaseous phase. In such cases, the onset of gravitational instability is controlled by H\textsubscript{2}. Turbulence is expected to play an important role in this process at scales smaller than about 100 pc (see Sect. 2.4). For $R > 0.43 R_{25}$, only 4% of all points populate this region for a classical disc. This fraction increases to 22% for a turbulent disc with $a = b = \frac{1}{2}$, and to 52% for $a = b = \frac{1}{4}$.

### 3.2 The effective $Q$ parameter

Fig. 6 shows radial profiles of the effective $Q$ parameter, $Q_{\text{eff}} = Q_{\text{eff}}(R)$, for our sample of galaxies. In the left panel, we neglect gas turbulence. On the right, we consider turbulent H\textsc{i} ($a = b = \frac{1}{2}$) for $R > 0.43 R_{25}$. Values of $Q_{\text{eff}}$ smaller than unity mean gravitational instability. We indicate the median and 1σ scatter of $Q_{\text{eff}}$ for radii smaller and larger than $R = 0.43 R_{25}$. We also colour-code the component that contributes more to disc instability according to the classical condition: gas for $Q_{g0} < Q_*$, and stars for $Q_* < Q_{g0}$ (Romeo & Wiegert 2011).

For $R \leq 0.43 R_{25}$, $Q_{\text{eff}}$ spans a wide range of values, with 13% of points in the unstable regime. Here 56% of points are gas-dominated and tend to be less stable than the star-dominated points (the median value of $Q_{\text{eff}}$ is $Q_{\text{eff},g} \approx 1.3$ and $Q_{\text{eff},*} \approx 2.3$ in the two cases). For $R > 0.43 R_{25}$, the range spanned by $Q_{\text{eff}}$ is tighter and only 4% of measurements are in the unstable regime. Here the majority (61%) of points are star-dominated, and there is no clear difference in $Q_{\text{eff}}$ between star- and gas-dominated points ($Q_{\text{eff},g} \approx 1.3$ and $Q_{\text{eff},*} \approx 1.7$).

Introducing turbulent scaling for $R > 0.43 R_{25}$ only has a small effect on the measurements. For $a = b = \frac{1}{4}$, the median of $Q_{\text{eff}}$ increases by 3% and the 1σ scatter by 15%. For $a = b = \frac{1}{2}$, the median increases by 6% and the 1σ scatter...
by 26%. This suggests that turbulence tends to stabilize the
disc (the median increases), although the magnitude of this
effect is small and depends on the non-turbulent value of
$Q_{\text{eff}}$ (the scatter increases).

The stabilizing effect of turbulence seems at odds with
results from Romeo et al. (2010), who found that the sta-
bility of gaseous discs is unaffected by turbulence if $a = b$.
The difference lies, of course, in the gravitational couplin-
g of stars and gas. Consider the approximation for the effective
$Q$ parameter introduced by Romeo & Wiegert (2011):

$$
\frac{1}{Q_{\text{eff}}} = \begin{cases} 
\frac{W}{Q} + \frac{1}{Q_g} & \text{if } Q_\star \geq Q_g, \\
\frac{1}{Q} + \frac{W}{Q_g} & \text{if } Q_g \geq Q_\star,
\end{cases}
$$

(11)

$$
W = \frac{2\sigma^2 \sigma^2_g}{\sigma^2_\star + \sigma^2_g}.
$$

(12)

We see that, even if $Q_g = Q_{\text{eff}}$, the scaling $\sigma_g = \sigma_{\text{eff}} (\ell/\ell_0)^b$ affects the weight factor $W (\sigma_\star, \sigma_g)$. The strength of this ef-
fect is determined by the power-law slope $b$. Therefore the
effective $Q$ parameter of turbulent discs always differs from
the classical case.

### 3.3 The least stable wavelength

Fig. 7 shows radial profiles of the least stable wavelength,
$\lambda_{\text{min}} = \lambda_{\text{min}} (R)$, for our sample. On the left we neglect gas
turbulence, whereas on the right we consider turbulent $H_1$
for $R > 0.43 R_{25}$. Colour-coding indicates the component
that dominates gravitational instability. As before, the me-
dian and 1σ scatter are indicated separately for small and
large radii.

For $R \leq 0.43 R_{25}$, there is a clear gap between gas-
and star-dominated points (the median value of $\lambda_{\text{min}}$
is $\lambda_{\text{min},g} \approx 0.7$ kpc and $\lambda_{\text{min},\star} \approx 8.2$ kpc in the two cases).
So the gas-dominated points are characterized by much
smaller values of $\lambda_{\text{min}}$. The discrepancy is less significant
for $R > 0.43 R_{25}$, apart from a few measurements close to
$R = 0.43 R_{25}$ ($\lambda_{\text{min},g} \approx 3.9$ kpc and $\lambda_{\text{min},\star} \approx 6.3$ kpc).

Introducing a turbulent gas component for $R >
0.43 R_{25}$ causes a significant increase in $\lambda_{\text{min}}$. For $a = b = \frac{1}{3}$,
the median of $\lambda_{\text{min}}$ increases by 28% and the 1σ scatter by
34%. For $a = b = \frac{1}{2}$, the median increases by 41% and the
increase in 1σ scatter is again 34%. This suggests a ten-
dency of turbulence to boost the least stable wavelength. As
for $Q_{\text{eff}}$, the magnitude of this effect depends on the non-
turbulent value of $\lambda_{\text{min}}$. There is a small number of gas-
dominated measurements for which the least stable wave-
length decreases, but these have large uncertainties.

Why does turbulence affect $\lambda_{\text{min}}$ more than $Q_{\text{eff}}$? The
answer is twofold. First, for a purely gaseous disc $\lambda_{\text{min}}$
increases markedly with $Q_{\text{eff}}$ (Romeo et al. 2010), so that any
change in $Q_{\text{eff}}$ will be amplified in $\lambda_{\text{min}}$. Second, as stars
are taken into account, gas-dominated points can enter the
star-dominated regime, where $\lambda_{\text{min}}$ is much larger (see Sect.
2.4). Both effects depend on the power-law slopes $a$ and $b$.
They sum up and drive $\lambda_{\text{min}}$ to significantly larger values.

### 3.4 Robustness of the results

Modelling the gas disc as a single component with an inter-
mediate value of $\sigma_g$ is not the best that can be done. Here
The effect of ISM turbulence on the gravitational instability of galactic discs

we will no longer follow this traditional approach. We will model the gas disc as made of two components, each with the more representative value of $\sigma_8$. A simple way to do it is to treat the inner part of the disc as H$_2$ dominated and the outer part as H I dominated. We then set $\sigma_8 \approx 6$ km s$^{-1}$ for $R \leq 0.43$ $R_{25}$ and $\sigma_8 \approx 11$ km s$^{-1}$ for $R > 0.43$ $R_{25}$ (cf. introductory part of Sect. 3).

Besides $\sigma_8$, there is another quantity that deserves particular attention: the stellar radial velocity dispersion, which we now denote with $\sigma_R$. Leroy et al. (2008) inferred $\sigma_R$ from the vertical velocity dispersion, $\sigma_z$, assuming that $(\sigma_z/\sigma_R)_* = 0.6$. In turn, $\sigma_z$ was inferred from the stellar exponential scale height, $H_*$, using the relation $H_* = \sigma_z^2/2\pi G \Sigma_*$. Gerssen & Shapiro Griffin (2012) showed that $(\sigma_z/\sigma_R)_*$ decreases markedly from early- to late-type spirals. The average Hubble stage of THINGS spirals is $(T) = 4$, which corresponds to galaxy type Sbc (the mean and the median of $T$ are equal). The best-fitting model of Gerssen & Shapiro Griffin (2012) then yields $(\sigma_z/\sigma_R)_* = 0.5$ (see their fig. 4). Concerning $H_*$, the relation used by Leroy et al. (2008) is not correct. It is the total surface density in the disc that determines the stellar exponential scale height: $H_* = \sigma_z^2/2\pi G \Sigma_{\text{tot}}$, where $\Sigma_{\text{tot}} = \Sigma_\text{gas} + \Sigma_\text{H}_2$ (Bahcall & Casertano 1984; Romeo 1992). In view of these facts, we set $(\sigma_z/\sigma_R)_* = 0.5$ and use the correct relation for $H_*$. Finally, we implement gas turbulence as in Model 1, i.e. only for $R > 0.43$ $R_{25}$, where the disc is H I dominated. This is simply because the constant spatial resolution of 800 pc used by Leroy et al. (2008) is too coarse to probe the range of scales affected by H$_2$ turbulence [see Sect. 2.4, case (i)]. Hereafter we will refer to the model described above as Model 2.

Table 1 summarizes the dynamical differences between Models 2 and Model 1. On the whole, the stability diagnostics are moderately affected by the model. The most sensitive diagnostic is $\lambda_{\text{min}}$, which differs by a factor of 2–3. $Q_{\text{eff}}$ is more robust, with a difference well below a factor of 2. In Model 2, both $\lambda_{\text{min}}$ and $Q_{\text{eff}}$ are smaller for $R \leq 0.43$ $R_{25}$ and larger for $R > 0.43$ $R_{25}$.

Despite these differences, the effect of turbulence is comparable in the two models. For $R \leq 0.43$ $R_{25}$, $f_2$ and $f_{3,8}$ are slightly larger in Model 2. So H$_2$ is more decoupled from stars and slightly more dominant. For $R > 0.43$ $R_{25}$, $f_2$ is almost identical in the two models, irrespective of the value of $\alpha = b$. Turbulence increases the median value of $Q_{\text{eff}}$ by less than 10% in both models. In contrast, the median value of $\lambda_{\text{min}}$ increases by 20–30% in Model 2, i.e. less than in Model 1. Summarizing, the effect of H turbulence in Model 2 is only slightly weaker than in Model 1. This points to the robustness of our results.

4 DISCUSSION

Our results cannot be directly compared with those of Shadmehri & Khajenabi (2012), hereafter SK12. This is partly because of the wider scope of our paper, which embraces a brand-new application to THINGS spirals, and because most of the analysis carried out by SK12 cannot be easily interpreted.

SK12 analysed five stability regimes of gas turbulence: $\alpha > 1$ and $b < \frac{1}{2} (1 + \alpha); \alpha = 1$ and $b \neq 1$; and Regimes A–C. The first regime corresponds to a fractal dimension $D = a + 2$ higher than 3, and is therefore beyond the natural range of $a$ (see fig. 1 and sect. 3 of Romeo et al. 2010). In the second regime, the volume density is scale-independent ($D = 3$),

Figure 7. Radial profile of the least stable wavelength, $\lambda_{\text{min}}(R)$, for THINGS spirals (Model 1): neglecting gas turbulence (left), and taking into account H I turbulence for $R > 0.43$ $R_{25}$ (right). For each measurement, colour-coding indicates whether gas ($Q_{\text{eff}} < Q_0$) or stars ($Q_0 < Q_{\text{eff}}$) dominate the stability level. Thick black lines and dark grey shading indicate the median and 1$\sigma$ scatter of $\lambda_{\text{min}}$ in the two radial ranges.
so the medium is incompressible and hence subsonic. Cold interstellar gas is instead dominated by compressible structures and supersonic motions. Therefore even this regime is of marginal interest (see again fig. 1 and sect. 3 of Romeo et al. 2010). Regimes B and C are populated by H$_2$ turbulence, which manifests itself at scales less than $L_{\text{H}_2} \sim 100$ pc. In turn, $L_{\text{H}_2}$ is one order of magnitude smaller than the characteristic scale of stellar instabilities. Therefore stars play a negligible role in these stability regimes [see Sect. 2.4, case (i)]. SK12 reached the opposite conclusion. But this is because they assumed Larson-type scaling relations even at kpc scales, disregarding the type of turbulence associated with such regimes. Regime A is populated by both H$_2$ and H$^1$ turbulence. While the H$_2$ case raises the same issue as Regimes B and C, the H$^1$ case is conceptually simpler. H$^1$ turbulence manifests itself at all scales of galactic interest, so stars can play a significant role in this stability regime [see Sect. 2.4, case (ii)]. SK12 reached a similar conclusion. However, even in this case, their approach is different from ours. They chose a, b and $L_0$ so as to sample Regime A, and studied the dispersion relation numerically. We have instead examined the whole regime analytically (see Sect. 2.3.1). We have then chosen observationally motivated values of a, b and $L_0$, and analysed the onset of gravitational instability in the disc (see in particular Sects 2.4.1 and 2.4.2).

In conclusion, there is a fundamental difference between our analysis and that of SK12. Our analysis takes into account the astrophysical relevance of the various stability regimes, as well as the tight constraints imposed by observations of ISM turbulence in the Milky Way and nearby galaxies. These are important aspects of the problem, which are missing from their analysis.

5 CONCLUSIONS

Our analysis of THINGS spirals shows that H$^1$ turbulence has a triple effect on the outer regions of galactic discs: (i) it weakens the coupling between gas and stars in the development of disc instabilities, (ii) it makes the disc more prone to star-dominated than gas-dominated instabilities, and (iii) it typically increases the least stable wavelength by 20–40% (the steeper the H$^1$ scaling relations, the larger the effect). This is in contrast to the typical 3–8% increase predicted for the effective $Q$ parameter. The effect of H$^1$ turbulence is in a sense complementary to the effect of disc thickness. In fact, disc thickness increases the effective $Q$ parameter by 20–50% (Romeo & Wiegert 2011) but hardly changes the least stable wavelength (Romeo 1992, 1994) or the condition for star-gas decoupling (Romeo & Wiegert 2011).

Our analysis of THINGS spirals also suggests that H$_2$ turbulence has a significant effect on the inner regions of galactic discs. For $R \lesssim 0.4 R_{25}$, i.e. where H$_2$ dominates over H$^1$, 60–70% of the data fulfil the condition for star-gas decoupling and 70–80% of these points represent gas-dominated stability regimes. In such cases, the onset of gravitational instability is controlled by H$_2$. Turbulence is expected to play an important role in this process at scales smaller than about 100 pc (see Sect. 2.4). If $a = 0$ and $b = \frac{1}{2}$, then H$_2$ turbulence drives the disc to a regime of transition between instability at small scales and stability à la Toomre, as was first pointed out by Romeo et al. (2010) in the case of one-component turbulent discs. Since this is a regime of transition, even small deviations from the standard H$_2$ scaling laws ($a = 0$ and $b = \frac{1}{2}$) can have a strong impact on the gravitational instability of the disc. This is true even when the mass densities of H$^1$ and H$_2$ are comparable, since small-scale instabilities are more actively controlled by H$_2$ (see Sect. 2.3).

ACKNOWLEDGMENTS

We are very grateful to Oscar Agertz, Christoph Federrath, Mathieu Puech and Joachim Wiegert for useful discussions. We are also grateful to an anonymous referee for constructive comments and suggestions, and for encouraging future work on the topic. ABR thanks the warm hospitality of both the Department of Physics at the University of Gothenburg and the Department of Fundamental Physics at Chalmers.
