Abstract

Despite the success of neural networks (NNs), there is still a concern among many over their “black box” nature. Why do they work? Yes, we have Universal Approximation Theorems, but these concern statistical consistency, a very weak property, not enough to explain the exceptionally strong performance reports of the method. Here we present a simple analytic argument that NNs are in fact essentially polynomial regression models, with the effective degree of the polynomial growing at each hidden layer. This view will have various implications for NNs, e.g. providing an explanation for why convergence problems arise in NNs, and it gives rough guidance on avoiding overfitting. In addition, we use this phenomenon to predict and confirm a multicollinearity property of NNs not previously reported in the literature. Most importantly, given this loose correspondence, one may choose to routinely use polynomial models instead of NNs, thus avoiding some major problems of the latter, such as having to set many tuning parameters and dealing with convergence issues. We present a number of empirical results; in each case, the accuracy of the polynomial approach matches or exceeds that of NN approaches. A many-featured, open-source software package, polyreg, is available.
1 The Mystery of NNs

Neural networks (NNs), especially in the currently popular form of many-layered deep learning networks (DNNs), have become many analysts' go-to method for predictive analytics. Indeed, in the popular press, the term artificial intelligence has become virtually synonymous with NNs.

Yet there is a feeling among many in the community that NNs are “black boxes”; just what is going on inside? Various explanations have been offered for the success of NNs, a prime example being [Schwartz-Ziv and Tishby(2017)]. However, the present paper will present significant new insights.

2 Contributions of This Paper

The contribution of the present work will be as follows:

(a) We will show that, at each layer of an NY, there is a rough correspondence to some fitted ordinary parametric polynomial regression (PR) model; in essence, NNs are a form of PR. We refer to this loose correspondence here as NNAEPR, Neural Nets Are Essentially Polynomial Models.

(b) A very important aspect of NNAEPR is that the degree of the approximating polynomial increases with each hidden layer. In other words, our findings should not be interpreted as merely saying that the end result of an NN can be approximated by some polynomial.

(c) We exploit NNAEPR to learn about general properties of NNs via our knowledge of the properties of PR. This will turn out to provide new insights into aspects such as the numbers of hidden layers and numbers of units per layer, as well as how convergence problems arise. For example, we use NNAEPR to predict and confirm a multicollinearity property of NNs not previously reported in the literature.

(d) Property (a) suggests that in many applications, one might simply fit a polynomial model in the first place, bypassing NNs. This would have the advantage of avoiding the problems of choosing tuning parameters (the polynomial approach has just one, the degree), nonconvergence and so on.

---

1 There are many different variants of NNs, but for the purposes of this paper, we can consider them as a group.

2 Author listing is alphabetical by surname. XC wrote the entire core code for the polyreg package; NM conceived of the main ideas underlying the work, developed the informal mathematical material and wrote support code; BK assembled the brain and kidney cancer data, wrote some of the support code, and provided domain expertise guidance for genetics applications; PM wrote extensive support code, including extending his kerasformula package, and provided specialized expertise on NNs. All authors conducted data experiments.
(e) Acting on point (d), we compare NN and polynomial models on a variety of datasets, finding in all cases that PR gave results at least as good as, and often better than, NNs.

(f) Accordingly we have developed an open source, feature-rich software package in R (a Python version is planned), polyreg, that enables active implementation of the above ideas [Cheng et al. (2018)]. Details are presented in Appendix A.

Point (a) is especially important. Some researchers, e.g. [Choon et al. (2008)], have conducted empirical investigations of the possible use of polynomial regression in lieu of NNs. Some theoretical connections between NNs and polynomials have been noted in the literature, e.g. [Hornik et al. (1989)]. Furthermore, some authors have constructed networks consisting of AND/OR or OR/AND polynomials as alternatives to NNs [Shin and Ghosh (1995)]. [Benitez et al. (1997)] showed an explicit equivalence of NNs to fuzzy rule-based systems, and [Telgarsky (2017)] derived a similar correspondence between NNs and rational functions.

But our contribution is to show that, in essence, conventional NNs actually are PR models. Our focus will be on the activation function. Using an informal mathematical analysis on that function, we show why NNs are essentially a form of PR.

Moreover, we stress the implications of that finding. Indeed, in Section 7, we will use our knowledge of properties of polynomial regression to predict and confirm a corresponding property of NNs that, to our knowledge, has not been reported in previous literature.

3 What This Paper Is NOT

3.1 The Paper Is Not Another Universal Approximation Theorem

Any smooth regression/classification can be approximated by NNs, or by polynomials, so it may at first appear that our work here is to show that NNs are approximately polynomials. But we show a subtle but much stronger connection than that. We are interested in the NN fitting process itself; we show that it mimics PR, with a higher-degree polynomial emerging from each hidden layer.

3.2 The Paper Is Not about Specialized NNs

It must be noted here that our empirical work has not yet involved much on specialized networks such as convolutional NNs (CNNs) for image classification,
recurrent NNs (RNNs) for text processing, and so on. Though we intend to adapt our ideas to these frameworks, we view them as separate, orthogonal issues.

For instance, we view the convolutional “front ends” in CNNs as largely playing the role of preprocessing stages, conducted for dimension reduction, which are easily adaptable to other approaches, including polynomial models. Indeed, convolutional versions of random forests have been developed [Zhou and Feng(2017)]. As [Zhou and Feng(2017)] point out, a key to the success of CNNs has been a general property that is not specific to neural-learning paradigms (emphasis added):

...the mystery behind the success of deep neural networks owes much to three characteristics, i.e., layer-by-layer processing, in-model feature transformation and sufficient model complexity.

Similar points hold for RNNs. For instance, one might use structural equation models [Monecke and Leisch(2012)] with polynomial forms.

We do include one brief, simple image classification example using the MNIST dataset. Though certainly a topic for future work, we view the preprocessing issue as separate from our findings that NNs are essentially PR models, with various important implications, and that PR models perform as well as NNs.

3.3 The Paper Is Not about Other ML Methods

It may well be that PR also has relations to random forests, support vector machines and so on. However, our purpose here is not to seek possible relations of PR to other methods, nor is it our purpose to compare the performance of those other methods to PR and NNs. Similarly, though we find for the datasets investigated here, PR does as well as or better than NNs, there is no implied claim that PR would perform well in comparison to other ML methods.

Instead, we note that NNAEPR implies a very direct relationship between PR and NNs, and explore the consequences.

4 Notation

Consider prediction of $Y$ from a vector $X$ of $p$ features. In regression applications, $Y$ is a continuous scalar, while in the classification case it is an indicator vector,

---

3This is in Section 8.10. It should not be confused with the example in Section 8.4 which involves image classification with the data already preprocessed, or with two examples using MNIST to illustrate other phenomena.
with $Y_i = 1, Y_j = 0$ for $j \neq i$ signifying class $i$. Prediction requires first estimating data the regression function $r(t) = E(Y|X = t)$, which in the classification case is the vector of conditional class probabilities. The function $r(t)$ must be estimated, parametrically or nonparametrically, from sample data consisting of $n$ cases/observations.

5 Polynomial Regression Models

PRs — models that are linear in parameters but polynomial in the predictors/features — are of course as old as the linear model itself. (And they extend naturally to generalized linear models.) Though they might be introduced in coursework for the case $p = 1$, multivariate polynomial models are popular in response surface methods [Myers et al.(2009)].

One issue of concern is multicollinearity, correlations among the predictors/features [Faraway(2016)]. PR models are long known to suffer from multicollinearity at high degrees [Chatterjee and Greenwood(1990)].

Indeed, in the case $p = 1$, fitting a polynomial of degree $n - 1$ will be an ephemeral “perfect fit,” with $R^2 = 1$. Then any variable, predictor or response, will be an exact linear combination of the others, i.e. full multicollinearity.

For this and other reasons, e.g. large fitted values at the edges of the data, many authors recommend not using polynomial models of degree higher than 2 or 3, and in fact in our empirical experiments in this paper, we have seldom found it necessary to use a higher degree.

6 The NNAEPR Principle

Universal Approximation Theorems such as [Hornik et al.(1989)] show that, under various regularity assumptions and sufficient data, NNs can approximate the regression function $r(t)$ to any desired degree of accuracy. But this is essentially just a statistical consistency property; many statistical estimators are consistent but perform poorly.

For example, consider the simple problem of estimating the mean $\mu$ of a Gaussian distribution with known variance. The sample median is a statistically consistent estimator of $\mu$, but it is only $2/\pi$ as efficient as the sample mean [DasGupta(2008)]$^4$ (See also Section 8.8).

Here we illustrate that in an informal way, but with special focus on the activation function.

$^4$The sample mean achieves the same statistical accuracy using only $2/\pi$ as much data.
6.1 The Basic Argument

Take the simple case $p = 2$. Denote the features by $u$ and $v$. The inputs to the first hidden layer, including from the “1” node, will then be of the form $a_{00} + a_{01}u + a_{02}v$ and $a_{03} + a_{05}u + a_{05}v$.

As a toy example, take the activation function to be $a(t) = t^2$. Then outputs of that first layer will be quadratic functions of $u$ and $v$. Similarly, the second layer will produce fourth-degree polynomials and so on. Clearly, this works the same way for any polynomial activation function, for any $p$.

Now let’s turn to more realistic activation functions, we note that they themselves can usually be approximated by polynomials. One could make a Taylor series argument for the smooth activation functions. Moreover, though many implementations of transcendental functions today are rather complex, in some implementations the Taylor series is used directly; this was recommended in [Nyland and Snyder(2004)] for general usage and was used in firmware NN computation in [Temurtas et al.(2004)]. So in such cases, the situation reverts to the above, and NNs exactly become PR.

So one sees that:

If the activation function is any polynomial, or is implemented by one, an NN exactly performs polynomial regression.

Moreover, the degree of the polynomial will increase from layer to layer.

For general activation functions and implementations, we can at least say that the function is at close to a polynomial, by appealing to the famous Stone-Weierstrass Theorem [Katznelson and Rudin(1961)], which states that any continuous function on a compact set can be approximated uniformly by polynomials. In any event, for practical purposes here, we see that most activation functions can be approximated by a polynomial. Then apply the same argument as above, which implies:

(a) NNs can loosely be viewed as a form of polynomial regression, our NNAEPR Principle introduced earlier.

(b) The degree of the approximating polynomial increases from layer to layer.

5Compact sets are bounded, and indeed almost any application has bounded data. No human is 200 years old, for instance.
6.2 Some Elaboration

The informal arguments above could be made mathematically rigorous. In that manner, we can generate polynomials which are dense in the space of regression functions. But let’s take a closer look.

Suppose again for the moment that we use a polynomial activation function. The above analysis shows that, in order to achieve even statistical consistency, the number of hidden layers must go to infinity (at some rate) as \( n \) grows; otherwise the degree of the fitted polynomial can never go higher than a certain level. But for a general activation function, a single layer suffices, providing the number of neurons goes to infinity.

6.3 The Case of Categorical Predictor Variables

The above analysis implicitly involved continuous variables. Things like Taylor series and so on do not apply to the categorical case.

Either the user or the internal software will convert categorical variables to dummy variables. Powers of dummy variables are the same as the originals and thus need not be computed. But the interaction terms, i.e. cross products, are very important. The product of two dummy variables, for instance, represents a two-way interaction, the effect of both dummies being “on” at the same time. Similarly, we can obtain third-, fourth- and higher-degree interaction terms by forming higher-degree polynomials. Again, one could make this argument mathematically rigorous, and derive a new kind of Universal Approximation Theorem.

7 Lurking Multicollinearity

As noted, PR models of course have a very long history and are well-understood. We can leverage this understanding and the NNAEPR Principle to learn some general properties of NNs. In this section, we will present an example, with intriguing implications.

As mentioned, PR models tend to produce multicollinearity at higher degrees. The material on NNAEPR in the preceding section, viewing NNs as kind of a polynomial regression method, suggests that NNs suffer from multicollinearity problems as well.

Indeed, the conceptual model of the preceding section would suggest that the outputs of each layer in an NN become more collinear as one moves from layer

\[ \text{Specifically the degree of the activation function times the number of layers.} \]
to layer, since multicollinearity tends to grow with the degree of a polynomial. We investigated this, using the \texttt{keras} package to fit NNs and test the multicollinearity\footnote{Our \texttt{polyreg} also facilitates such investigation.}

We used the famous MNIST dataset, included in the package, as a testbed. Our test consisted of sequential models containing linear stacks of layers, with five layers in total. This included two dropout layers. We set the number of units to be equal in each layer.

One then needs a measure of multicollinearity. A very common one is the variance inflation factor (VIF) \cite{Faraway(2016)}\footnote{Various other measures of multicollinearity have been proposed, such as \textit{generalized variance}.}. When running a linear regression analysis (linear in the coefficients, though here polynomial in the predictors/features), a VIF value is computed for each coefficient. Larger values indicate worse degrees of multicollinearity. There are no firm rules for this, but a cutoff value of 10 is often cited as cause for concern.

### 7.1 Experimental Results

For convenience, we used the MNIST data, with the \texttt{keras} package. We calculated two measures of overall multicollinearity in a given NN layer: the proportion of coefficients with VIF larger than 10 and the average VIF.

\textit{First experiment:} The number of units is 10 in each layer, and the model is the following.

\begin{verbatim}
Layer (type)          Output Shape    Param #
============================================================================
dense_1 (Dense)      (None, 10)       7850
____________________________________________________________________
dropout_1 (Dropout)  (None, 10)       0
____________________________________________________________________
dense_2 (Dense)      (None, 10)       110
____________________________________________________________________
dropout_2 (Dropout)  (None, 10)       0
____________________________________________________________________
dense_3 (Dense)      (None, 10)       110
============================================================================
\end{verbatim}

The VIF results are shown in Table\textsuperscript{1}. On average, VIF increases as one moves on to the next layer.

\textit{Second experiment:} We set the number of units to 64 in the first four layers, while the last layer still has 10 outputs. The model is the following.
Table 1: Results of first model

| Layer    | Percentage of VIFs that are larger than 10 | Average VIF  |
|----------|-------------------------------------------|--------------|
| dense_1  | 0                                         | 3.43303      |
| dropout_1| 0                                         | 3.43303      |
| dense_2  | 0.7                                       | 14.96195     |
| dropout_2| 0.7                                       | 14.96195     |
| dense_3  | 1                                         | $1.578449 \times 10^{13}$ |

The results of the VIF values of coefficients are shown in Table 2.

Third experiment: We set the number of units to 128 in the first four layers and the last layer still has 10 outputs. The model is the following.

| Layer (type)      | Output Shape | Param # |
|-------------------|--------------|---------|
| dense_1 (Dense)   | (None, 64)   | 50240   |
| dropout_1 (Dropout)|             | 0       |
| dense_2 (Dense)   | (None, 64)   | 4160    |
| dropout_2 (Dropout)|             | 0       |
| dense_3 (Dense)   | (None, 10)   | 650     |

The results of the VIF values of coefficients are shown in Table 3.

Layer (type)      | Output Shape | Param # |
|-------------------|--------------|---------|
| dense_1 (Dense)   | (None, 128)  | 100480  |
| dropout_1 (Dropout)|             | 0       |
| dense_2 (Dense)   | (None, 128)  | 16512   |
| dropout_2 (Dropout)|             | 0       |
| dense_3 (Dense)   | (None, 10)   | 1290    |

The results of the VIF values of coefficients are shown in Table 3.
Table 2: Results of second model

| Layer       | Percentage of VIFs that are larger than 10 | Average VIF  |
|-------------|------------------------------------------|--------------|
| dense_1     | 0.015625                                 | 4.360191     |
| dropout_1   | 0.015625                                 | 4.360191     |
| dense_2     | 0.96875                                  | 54.39576     |
| dropout_2   | 0.96875                                  | 54.39576     |
| dense_3     | 1                                        | $3.316384 \times 10^{13}$ |

Table 3: Results of third model

| Layer       | Percentage of VIFs that are larger than 10 | Average VIF  |
|-------------|------------------------------------------|--------------|
| dense_1     | 0.0078125                                 | 4.3537       |
| dropout_1   | 0.0078125                                 | 4.3537       |
| dense_2     | 0.9921875                                 | 46.84217     |
| dropout_2   | 0.9921875                                 | 46.84217     |
| dense_3     | 1                                        | $5.196113 \times 10^{13}$ |

7.2 Impact

In the above experiments, the magnitude of multicollinearity increased from layer to layer. This increasing multicollinearity corresponds to the multicollinearity warning in polynomial regression. Thus, NNs and polynomial regression appear to have the same pathology, as expected under NNAEPR.

In other words, **NNs can suffer from a hidden multicollinearity problem.** This in turn is likely to result in NN computation convergence problems.

We thus believe it would be helpful for NN software to include layer-by-layer checks for multicollinearity. If a layer is found to output a higher degree of multicollinearity, one might consider reducing the number of units in it, or even eliminating it entirely. Applying dropout to such layers is another possible action. One related implication is that later NN layers possibly should have fewer units than the earlier ones.

It also suggests a rationale for using **regularization** in NN contexts, i.e. shrinking estimators toward 0 [Hastie et al.(2015)] [Matloff(2017)]. The first widely-used shrinkage estimator for regression, **ridge regression**, was motivated by amelioration of multicollinearity. The above discovery of multicollinearity in NNs provides at least a partial explanation for the success of regularization in many NN applications. Again due to NNAEPR, this is true for PR models as well. We intend to add a ridge regression option to **polyreg**.

Much more empirical work is needed to explore these issues.
8 PR as Effective, Convenient Alternative to NNs

We compared PR to NNs on a variety of datasets, both in regression and classification contexts (i.e. continuous and categorical response variables, respectively). The results presented here are complete, representing every analysis conducted by the authors, i.e. not just the “good” ones. However, not all tuning parameter combinations that were run are presented; only a few typical settings are shown. Generally the settings that produced extremely poor results for NNs are not displayed.

Each table displays the results of a number of settings, with the latter term meaning a given method with a given set of tuning parameters. For each setting:

- The dataset was split into training and test sets, with the number of cases for the latter being the min(10000, number of rows in full set).
- The reported result is mean absolute prediction error (MAPE) in the regression case and overall proportion of correct classification (PCC) in the classification case.

No attempt was made to clean the data, other than data errors that prevented running the code. Note that this is especially an issue with the NYC taxi dataset.

The reader will recognize a number of famous datasets here, many from the UC Irvine Machine Learning Repository. There are also some “new” datasets, including: a specialized Census dataset on Silicon Valley programmer and engineer wages, curated by one of the authors; data on enrollments in Massive Open Online Courses (MOOCs); data from a Crossfit competition; and data exploring the impact of genetics on brain and kidney cancers, curated by another of the authors.

Abbreviations in the tables:

- PR: Polynomial regression. Degree is given, and if not the same, maximum interaction term degree. A “PCA” designation means that dimension reduction via 90%-total-variance Principal Components Analysis was performed before generating the polynomials.
- KF: NNs through the Keras API, [Chollet et al.(2015)], accessed in turn via the R-language package kerasformula [Mohanty(2018)]. The default configuration is two layers with 256 and 128 units (written as “layers 256,128”), and dropout proportions of 0.4 and 0.3. In our experiments,

---

9We also started an analysis of the Missed Appointments Data on Kaggle, https://www.kaggle.com/joniarroba/noshowappointments. However, we abandoned it because no model improved in simply guessing No (appointment not missed). However, PR and NNs did equally well.
Table 4: Prg/Eng, predict income

| setting          | MAPE   |
|------------------|--------|
| PR, 1            | 25595.63 |
| PR, 2            | 24930.71 |
| PR, 3,2          | 24586.75 |
| PR, 4,2          | 24570.04 |
| KF, default      | 27691.56 |
| KF, layers 5,5   | 26804.68 |
| KF, layers 2,2,2 | 27394.35 |
| KF, layers 12,12 | 27744.56 |

we varied the number of units and dropout rate, and used RELU and either 'softmax' or 'linear' for the prediction layer, for classification and regression, respectively.

- DN: NNs through the R-language package deepnet [Rong(2014)]. The notation is similar to that of KF. We used the defaults, except that we took output to be 'linear' for regression and 'softmax' for classification.

DN can be much faster (if less flexible) than KF, and thus DN was sometimes used in the larger problems, or for comparison to KF. However, their performance was similar.

8.1 Programmers and Engineers Census Data

This is data on programmers and engineers in Silicon Valley in the 2000 Census. There are 20090 rows and 16 columns.

First, we predict wage income, a regression context. The results are shown in Table 4. We then predict occupation (six classes), shown in Table 5. Here PR substantially outperformed NNs.

8.2 Million Song Data

This is a very well-known dataset, listing audio characteristics of songs, along with their year of publication. The latter is the object of prediction. There are 515345 cases, with 90 predictor variables. The results are shown in Table 6. PR was somewhat ahead of NNs in this case.

Concerning speed, KF does have a GPU version available; DN does not.
Table 5: Prg/Eng, predict occ.

| setting                  | PCC  |
|--------------------------|------|
| PR, 1                    | 0.3741 |
| PR, 2                    | 0.3845 |
| KF, default              | 0.3378 |
| KF, layers 5,5           | 0.3398 |
| KF, layers 5,5; dropout 0.1 | 0.3399 |

Table 6: Million Song, predict year

| setting                          | MAPE  |
|----------------------------------|-------|
| PR, 1, PCA                       | 7.7700 |
| PR, 2, PCA                       | 7.5758 |
| KF, default                      | 8.4300 |
| KF, units 5,5; dropout 0.1,0.1   | 7.9883 |
| KF, units 25,25; dropout 0.1,0.1 | 7.9634 |
| KF, units 100,100; dropout 0.1,0.2 | 8.1886 |
| KF, units 50,50,50,50; dropout 0.1,0.1,0.1,0.2 | 8.0129 |
| KF, units 50,50,50,50; dropout 0.1,0.1,0.1,0.1,0.2 | 8.0956 |
| KF, units 10,10,10,10,10,10; dropout 0.1,0.1,0.1,0.1,0.1,0.2 | 8.1102 |
| DN, layers 5,5                   | 8.7043 |
| DN, layers 8,2                   | 9.5418 |
| DN, layers 2,2                   | 7.8809 |
| DN, layers 3,2                   | 7.9458 |
| DN, layers 3,3                   | 7.8060 |
| DN, layers 2,2,2                 | 8.7796 |

Note that the PR experiments used PCA. A current limitation of PR in polyreg is that memory/time can become an issue, which occurred here. Remedies, to be discussed in Section 9.4, include dimension reduction via PCA, which was used here.

8.3 Concrete Strength Data

Here one is predicting compressive strength of concrete. This dataset provides some variety in our collection, in that it is much smaller, only 1030 rows. There are eight predictors.

In Table 7 we see that PR significantly outperformed both kerasformula and the neuralnet package. This is probably to be expected in a small dataset.
Table 7: Concrete, predict strength

| method       | correlation (pred. vs. actual) |
|--------------|-------------------------------|
| neuralnet    | 0.608                         |
|.kerasformula | 0.546                         |
| PR, 2        | **0.869**                     |

Table 8: Letter Recognition, predict letter

| setting                      | PCC  |
|-----------------------------|------|
| PR, 1                       | 0.7285  |
| PR, 2                       | **0.9030**  |
| KF, default                 | 0.4484  |
| KF, units 50,50; dropout 0.1,0.1 | 0.5450  |
| DN, units 5,5,5             | 0.5268  |
| DN, units 25,25             | 0.7630  |
| DN, units 50,50             | 0.7825  |
| DN, units 200,200           | 0.7620  |

(Mean absolute error is not reported in this case; the displayed values are correlations between predicted and actual values, the square root of $R^2$.)

8.4 Letter Recognition Data

As noted, we view preprocessing in image classification applications to be orthogonal to the issues we are discussing. But there is another UCI dataset, which is already preprocessed, and thus was easy to include in our experiments here.

The data consist of images of letters, preprocessed to record 16 geometric features. There are 20000 images. In spite of our attempts with various combinations of tuning parameters, the performance of NNs, both KF and DN, here was poor, and PR was a clear winner. See Table 8.

8.5 New York City Taxi Data

This is a Kaggle dataset (https://www.kaggle.com/c/nyc-taxi-trip-duration), in which we predict trip time. Results are shown in Table 9. There was perhaps a slight edge to PR over NNs.
Table 9: NYC Taxi, predict trip time

| setting         | MAPE    |
|-----------------|---------|
| PR, 1           | **580.6935** |
| PR, 2           | 591.1805 |
| DN, layers 5,5  | 592.2224 |
| DN, layers 5,5,5| 623.5437 |
| DN, layers 2,2,2| 592.0192 |

Table 10: Forest Cover, predict grnd. cover type

| setting         | PCC    |
|-----------------|--------|
| PR, 1           | 0.6908 |
| PR, 2           | -      |
| PR, PCA 1       | 0.6525 |
| PR, PCA 2       | 0.6944 |
| PR, PCA 3       | 0.7070 |
| PR, PCA 4,3     | 0.7130 |
| KF, layers 5,5  | **0.7163** |

8.6 Forest Cover Data

In this remote sensing study, the goal is to predict the type of ground cover, among seven classes, from 54 features. There are 581,012 observations and always guessing the mode (Class 2) would yield 49% accuracy. Table 10 shows PRs and NNs both get about 71% right.

We are unable to run the full degree-2 polynomial, illustrating the important limitation of PR in polyreg mentioned earlier; for degree 2, our software could not accommodate the size of the polynomial matrix generated. Section 9.4 outlines future work to remedy this problem.

8.7 MOOCs Data

This dataset on Harvard/MIT MOOCs was obtained from the Harvard Dataverse Network, [http://thedata.harvard.edu](http://thedata.harvard.edu) Here \( n = 641138 \), \( p = 20 \).

We wished to predict whether a student will complete the course and receive certification. A major challenge of this dataset, though, is the large number of missing values. For instance, 58132 of the records have no value for the gender variable. The only fully intact variables were certified, nforum_posts and
Table 11: MOOCs, predict certification

| setting                        | PCC  |
|-------------------------------|------|
| PR, 1                         | 0.9871|
| PR, 2                         | **0.9870** |
| KF, layers 5,5                | 0.9747|
| KF, layers 2,2                | 0.9730|
| KF, layers 8,8; dropout 0.1   | 0.9712|

the course and user ID columns.

For the purpose of this paper, we simply used the intact data, adding four new variables: The first was \texttt{ncert.c}, the total number of certifications for the given course. If student A is taking course B, and the latter has many certifications, we might predict A to complete the course. Similarly, we added \texttt{ncert.u}, the number of certifications by the given user, and variables for mean number of forum posts by user and course. Altogether, we predicted \texttt{certified} from \texttt{nforum_posts} and the four added variables.

The results are shown in Table 11. Note that only about 2.7% of the course enrollments ended up certified, so one hopes for an accuracy level substantially above 0.973. PR did achieve this, but NNs did not do so.

8.8 Crossfit Data

In this section and the next, we present more detailed analyses.

The focus is on publicly available data from recent Crossfit annual opens, amateur athletics competitions consisting of five workouts each year. For each, we fit a neural net and polynomial linear (but not additive) models. To foreshadow, our PR package, \texttt{polyreg}, fit with a first or second degree polynomial and second degree interactions, outperforms the NNs slightly in terms of median MAE. (Though the third degree model did poorly and the fourth degree produced wild estimates symptomatic of severe collinearity.)

Using \texttt{kerasformula}, we built a dense neural network with two five-node layers (other than the outcome) with RELU activation. Kernel, bias, and activity L1-L2 regularization were employed and dropout rate was set to 40% and 30%, respectively. ADAM minimized MSE with batches of 32. Four separate models were fit, corresponding to polynomial degrees 1, 2, 3, and 4, using our PR package. All four models, fit by ordinary least squares, contain two-way interactions.

For each of four datasets (Men’s 2017, Men’s 2018, Women’s 2017, Women’s 2018) we fit 10 models, representing all distinct pairs of opens that could be used
Table 12: Crossfit Open, predict Rx rank

| model | MAPE | range among 5 runs |
|-------|------|--------------------|
| KF    | 0.081| 0.164              |
| PR, 1 | 0.070| 0.027              |
| PR, 2 | 0.071| 0.069              |
| PR, 3 | 0.299| 7.08               |
| PR, 4 | 87.253| 3994.5             |

as features to predict each competitor’s final rank. “Rx”, as in “prescription”, denotes the heaviest weights and most complex movements. In this analysis, we restrict the population to those who competed in at least one round at the “Rx” level and who reported their age, height, and weight. The final sample sizes were 118,064 (Men’s 2018), 41,103 (Men’s 2017), 53,958 (Women’s 2018), and 13,815 (Women’s 2017). The outcome is rank in the overall competition; like all other variables, it is scaled 0 to 1.

The results (Table 12) suggest that a first or second degree polynomial (with two-way interactions) is best in this case in terms of median mean absolute error (low bias). The first degree model is preferable because it has lower variance. The third and fourth degree models are not admissible.

Figure 1: Predictive Accuracy by Sample Size
Next, to assess sample size requirements we compare KF to the best fitting PR. For each competition, we take subsamples of 1000, 2000, ..., \(N_{\text{open}}\) (using only the first two competitions as features). Figure 1 reports median out-of-sample measures of fit. PR is uniformly lower though KF nearly converges at fairly modest sample sizes. Notably, PR’s performance is all but invariant—PR performs as well \(N_{\text{subsample}} = 1,000\) as it does on the full sample for all four competitions.

8.9 Big Data and Small Data: New Case-Studies in Cancer Genomics

We construct two cancer datasets from the NCI Genomic Data Commons (GDC) \cite{Grossmanetal2016}. The first is a compendium of all known cases for the aggressive brain cancer glioblastoma multiforme (GBM), as well as lower grade glioma (LGG), with \(n = 129,119\). The second is of kidney cancer cases, specifically of papillary renal cell carcinoma \((n = 32,457)\). We build models that classify patients as ‘alive’ or ‘dead’ based on genetic mutation type and three variables that assess the impact of the cancer (as well as patient gender). The larger sample size notwithstanding, the brain cancer dataset is considerably more challenging since it does not contain any quantitative variables. By contrast, in addition to the impact variables, the kidney dataset contains patient age at time of diagnosis. The kidney data also includes patient ethnicity. The brain cancer data are also higher entropy (49.94% of patients are alive compared with 83.68% in the kidney cancer data). As added challenge, the working memory limitations discussed in the Section 9.4 affected this analysis.

For each data set, we fit six polynomial models, which differed as to whether second-order interactions were included (in addition to first order). Models which took advantage of principal components included quadratic terms; models fit on the mostly qualitative raw data did not. We fit an NN with \texttt{deepnet} with as many hidden nodes as columns in the model matrix (64 for the brain data and 40 for the kidney). We also fit an NN with \texttt{nnet} of size 10. For each design, we cross-validated, holding 20% out for testing (and we report the median of trials).

The results are encouraging for PR (Table 13). On the brain cancer data, where polynomial regression might be expected to struggle, \texttt{polyreg} performs as well out of sample as the NNs. On the kidney cancer data, \texttt{polyreg} performs noticeably better than either \texttt{deepnet} or \texttt{nnet}.

8.10 MNIST Data

As explained in Section 3.2 we have not yet done much regarding NN applications in image processing, one of the most celebrated successes of the NN method. We will present an example here, but must stress that it is just preliminary. In particular, for our preprocessing stage we simply used PCA, rather than
Table 13: Cancer, predict vital status

| model          | PCC, brain cancer | PCC, kidney cancer |
|----------------|------------------|-------------------|
| deepnet        | 0.6587           | 0.5387            |
| nnet           | **0.6592**       | 0.7170            |
| PR (1, 1)      | 0.6525           | **0.8288**        |
| PR (1, 2)      | 0.6558           | 0.8265            |
| PR (PCA, 1, 1) | 0.6553           | 0.8271            |
| PR (PCA, 2, 1) | 0.5336           | 0.7589            |
| PR (PCA, 1, 2) | 0.6558           | 0.8270            |
| PR (PCA, 2, 2) | 0.5391           | 0.7840            |

Table 14: MNIST classification accuracy

| model          | PCC          |
|----------------|--------------|
| PR 1           | 0.8692       |
| PR 2           | 0.9708       |
| PR 3,2         | -            |
| best reported NN | **0.9860**  |

sophisticated methods such as blocked image smoothing. It is also a relatively simple image set, just black-and-white, with only 10 classes.

Some results, in this case using 26 principal components (representing 30% of total variance) are shown in Table 14. Again there seemed to be a memory issue with degree 3, which must be addressed (Section 9.4). Nevertheless, even without use of advanced preprocessing techniques and without degree 3, PR held its own against NNs.

9 Discussion

The NNAEPR Principle, combined with our experimental results, gives rise to a number of issues, to be discussed in this section.

9.1 Effects of Regularization

Many practitioners tend to initialize their networks to large numbers of units, and possibly large numbers of layers, reflecting a recommendation that large networks are better able to capture non-linearities [Friedman et al.(2001)]. However, that
Table 15: Zeros among MNIST weights

| layer | neurons | prop. 0s |
|-------|---------|----------|
| 1     | 256     | 0.8072   |
| 2     | 128     | 0.6724   |
| 3     | 64      | 0.5105   |

implies a need for regularization, which kerasformula does for kernel, bias, and activity terms by default.

One of the reasons for the popularity of $L_1$ regularization is that it tends to set most weights to 0, a form of dimension reduction. But it has a particularly interesting effect in NNs:

If most weights are 0, this means most of the units/neurons in the initial model are eliminated. In fact, entire layers might be eliminated. So, a network that the user specifies as consisting of, say, 5 layers with 100 units per layer may in the end have many fewer than 100 units in some layers, and may have fewer than 5 layers.

Some preliminary investigations conducted by the authors showed that many weights are indeed set to 0. See Table 15. Note in particular that the larger the initial number of units set by the user, the higher the proportion of 0 weights. This is consistent with our belief that many users overfit. And note carefully that this is not fully solved by the use of regularization, as the initial overfitting is placing one additional burden on the estimative ability of the NN (or other) system.

9.2 Extrapolation Issues

One comment we have received in response to our work here is that polynomials can take on very large values at the edges of a dataset, and thus there is concern that use of PR may be problematic for predicting new cases near or beyond the edges.

This of course is always an issue, no matter what learning method one uses. But once again, we must appeal to the NNAEPR Principle: Any problem with PR has a counterpart in NNs. In this case, this means that, since the NN fit at each layer will be close to a polynomial, NNs will exhibit the same troublesome extrapolation behavior as PR. Indeed, since the degree of the polynomial increases rapidly with each layer, extrapolation problems may increase from layer to layer.

On the other hand, note too that, regardless of method used, extrapolation tends to be less of an issue in classification applications. Consider a two-class setting,
for example. In typical applications, the conditional probability of class 1 will be close to 0 or 1 near the edges of the predictor space, so large values of the estimated $r(t)$ won’t be a problem; those large values will likely become even closer to 0 or 1, so that the actual predicted value will not change.

A similar way to view this would be to consider support vector machines. The kernel function is either an exact or approximate polynomial, yet SVMs work well.

9.3 NNs and Overfitting

It is well-known that NNs are prone to overfitting [Chollet and Allaire(2018)], which has been the subject of much study, e.g. [Caruana et al.(2000)]. In this section, we explore the causes of this problem, especially in the context of the NNAEPPr Principle. These considerations may explain why in some of the experiments reported here, PR actually outperformed NNs, rather than just matching them.

In part, overfitting stems from the multitude of tuning parameters in typical implementations. As one tries to minimize the objective function, the larger the number of tuning parameters, the more likely that the minimizing configuration will seize upon anomalies in the training set, hence overfitting.

One popular technique to counter overfitting in neural networks is dropout [Srivastava et al.(2014)]. This “thins out” the network by randomly culling a certain proportion of the neurons. Note, though, that if the dropout rate is to be determined from the data, this is yet another tuning parameter, compounding the problem.

9.4 Limitations and Remedies

As mentioned, the PR method, while effective, has potential limitations in terms of memory, run time and multicollinearity. In this section, we discuss existing and future remedies.

To set the stage, let’s take a closer look at the problems. As before, let $n$ and $p$ denote the number of cases and the number of predictors/features, respectively. Denote the degree of the polynomial by $d$.

First, how large will the polynomial matrix be? It will have $n$ rows; how many columns, $l_d$, will there be? This can be calculated exactly, but a rough upper bound will be handler. With $d = 1$, the number of possible terms $l_d$ is about $p$. What happens when we go to degree $d + 1$ from degree $d$? Consider one of the $p$ variables $x_i$. We can form $l_d$ new terms by multiplying each of the existing ones by $x_i$. So, we have $l_{d+1} \approx (p + 1)l_d$. That implies that $l_d$ is $O(p^d)$. So the
polynomial matrix can be large indeed.

The computation for the linear and generalized linear model (e.g. logistic) involves inversion (or equivalent) of an $l_d \times l_d$ matrix. Using QR decomposition, this takes $O(n, l_d^3)$ time. In the classification case, this becomes $O(n, ql_d^3)$, where $q$ is the number of classes.

Beyond that, there is the statistical issue. The results of Portnoy (1984) would suggest that we should have $l_d < \sqrt{n}$. Though modern research results on the LASSO and the like are more optimistic, it is clear that we need to keep $d$ small unless $n$ is extremely large. This is consistent with our empirical findings here, in which we found that $d = 2$ is sufficient in most cases.

Dimension reduction via PCA remedies time, space, and multicollinearity problems and was found to work well in the case of Million Song dataset. Another possible form of dimension reduction would be to mimic the dropout “lever” in NNs. Another possibility would be to apply PCA to the matrix of polynomial terms, rather than to the original data as is presently the case; this may help with nonmonotonic data. Other approaches to nonmonotonicity may be nonlinear PCA [Zhang and Jordan (2009)] and nonnegative matrix factorization [Lee and Seung (1999)].

One can also delete randomly-selected columns of the polynomial features matrix. Our polyreg package does have such an option.

Multicollinearity itself might be handled by ridge regression or the LASSO. It should be kept in mind, though, that our results indicate the multicollinearity is manifested in NNs as well, and is a possible sign of overfitting in both. See related work in Shin and Ghosh (1995).

Parallel computation is definitely a possibility. The software currently provides the option of parallelizing PR in the classification case. Both time and space issues might be resolved by using the Software Alchemy technique of Matloff (2016). Physical memory limitations could be resolved using the backing store feature of the bigmemory package.

10 Conclusions and Future Work

We have presented a new way to look at NNs, as essentially a form of PR. Though some previous work had noted some other kinds of connection of NNs to polynomials, we presented a simple analytic argument involving the activation function showing the connection explicitly and in a very strong manner.

We have shown that viewing NNs as PR models reveals properties of NNs

\footnote{This notation is a bit nonstandard. We do not use a product notation, as the timing is not multiplicative. The time depends on $n$ and $l_d \times l_d$, but separately.}
that are, to our knowledge, new to the field, and which should be useful to practitioners. For instance, our NNAEPR Principle predicted that NNs should have multicollinearity problems in later layers, which in turn suggests ways to avoid convergence problems. Among other things, this suggests some useful improvements in diagnostic features in NN software.

Most importantly, we have shown that PR should be an effective alternative to NNs. We performed experiments with a variety of data of various types, and in all cases, PR performed either similarly to, or substantially better than, NNs — without the NN troubles of trying to find good combinations of tuning parameters.

The fact that in some cases PR actually outperformed NNs reflects the fact that NNs are often overparameterized, in essence fitting a higher-degree polynomial than they should.

Much remains to be done. The problems and remedies outlined in the preceding section need to be tested and implemented; the phenomenon of multicollinearity in NNs needs thorough investigation; more experimentation with large-p datasets should be conducted; and the approach here needs to be integrated with preprocessing of images, text and so on as with, e.g., CNNs.

It is conceivable that PR may be competitive with other machine learning techniques, such as random forests, SVM and so on. We have focused on NNs here because of the direct connection to PR described in Section 6, but similar connections to other methods could be explored.

A The polyreg Package

Though we have presented the polyreg package [Cheng et al.(2018)] as an alternative to using NNs, it is useful in its own right.

The package provides an easier interface to perform polynomial regression for both prediction and classification, using linear regression and logistic regression respectively. It features solutions to potential problems arising with polynomial regression, such as repetition of dummy predictor variables, overfitting and multicollinearity.

A.1 Model Description

The polynomial terms in a model are generated by the getPoly() function. Suppose that we use a dataset containing two predictor variables. The basic linear regression model can be fitted as:

\[ r(t) = \beta_0 + \beta_1 x_1 + \beta_2 x_2 \]
Then the polynomial regression model of degree 2 for this dataset is:

\[ r(t) = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \beta_3 x_1^2 + \beta_4 x_2^2 + \beta_5 x_1 x_2 \]

And for degree 3:

\[ r(t) = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \beta_3 x_1^2 + \beta_4 x_2^2 + \beta_5 x_1 x_2 + \beta_6 x_1^3 + \beta_7 x_2^3 + \beta_8 x_1^2 x_2 + \beta_9 x_1 x_2^2 \]

A.2 Polynomial Term Generation

The \texttt{getPoly()} function generates these terms for any degree and any number of predictors \( p \). However, if one of the predictor variables is a categorical variable, we often encode it into dummy variables. Suppose that \( x_1 \) is a categorical variable and only has two classes, which could be presented as either 0 or 1. Then we know that:

- \( x_1, x_1^2, x_1^3 \), and all powers of \( x_1 \) have the same values.
- \( x_1 x_2, x_1^2 x_2 \) and so on will all have the same values.

The \texttt{getPoly()} function generates the polynomial terms of the predictor variables in a dataset without repetition. In the small example above, the terms that are generated by \texttt{getPoly()} are:

\[ x_1, x_2, x_1^2, x_1 x_2, x_2^2, x_1 x_2^2 \]

The model fitting is handled by the \texttt{polyFit()} function, which calls \texttt{getPoly()}.  

A.3 Dimension Reduction

Clearly there is a combinatorial explosion of polynomial terms. To keep the number of terms to a manageable level, the package offers several options:

the function also provides a parameter, \texttt{maxInteractDeg}, to specify the maximum degree of dummy and nondummy predictor variable interaction terms.

Another way to reduce the number of terms is the principal components analysis (PCA) approach, specified by the argument \texttt{pcaMethod}. By default, the number of components is set so that 90% of the total variance is attained; in general, this is specified via \texttt{pcaPortion}.

Still another approach is the \texttt{dropout} parameter. Inspired by the notion of the same name in NNs, this one deletes random terms in the polynomial model.
A.4 Other Parameters

The parameter `use` specifies the model to be fitted (currently linear or logistic). In the latter case, there are further choices. If the number of classes in response variables is two, then we directly use the `glm()` function with `family = binomial(link = "logit")`.

If there are more than two classes, the original `glm()` can’t generate the predicted results for these classes. We provide the parameter, `glmMethod`, to use the all-vs-all or the one-vs-all method for multiclass classification [Matloff(2017)]. The multinomial logistic model may also be used.

A.5 Prediction

Using the generated model from the `polyFit()` function, we obtain a `polyFit` object, and pass in this object and new data to the generic function `predict.polyFit()` for prediction. Also, we have the `xvalPoly()` function to perform cross validation.

A.6 Parallel Computation

Computation for the `glm()` option is time-consuming, as a logit model must be fit multiple times (Section 9.4). Accordingly, there is an option for parallel computation of this part of the algorithm.

Specifically, the `polyFit()` function has an optional argument `cls`, specifying an R virtual cluster, which can consist either of several cores on a multicore machine, or several machines in a physical cluster. The latter is recommended, in order to alleviate strains on physical memory.

A.7 Comparisons to NNs

To easily compare PR with the performance of neural networks, we provide functions for cross validation of a given dataset using neural networks functions from different packages.

- `xvalNnet`: This function uses the `nnet` function from `nnet` package, and provides the option to scale the data matrix.
- `xvalKf`: This function uses the `kms` function from `kerasformula` package.
- `xvalDnet`: This function uses the `nn.train` function from `deepnet` package.
