Abstract

With worsening obesity epidemic, it has become an international health issue increasing not only morbidity and mortality, but also health care costs while decreasing the quality of life in general. Bariatric surgery has become a significant treatment for morbid obesity and patients with obesity who suffers from multiple medical comorbidities. Among the risks that bariatric surgery carries, intussusception is a rare long-term complication that may occur with gastric bypass, mostly described in case reports and small-scale retrospective study. These reported cases required operative reduction. Reports of spontaneous resolution are rarely reported. We present a patient who had laparoscopic roux-en-y gastric bypass and presented with intussusception that spontaneously resolved within 24 hours. Diagnostic laparoscopy confirmed evidence of resolved intussusception and no further operative intervention was necessary. Bariatric surgeons should be vigilant of intussusception as a long-term complication, and may consider non-operative conservative management under certain presentation.

Introduction

In the United States, over 159 million adults and 37 million children are considered overweight or in obese category. The current obesity epidemic has become an international health issue with 1.46 billion adults falling into overweight or obese categories worldwide in 2008 [1]. In addition to the increasing health care costs and compromised quality of life, increased risks of associated illnesses such as metabolic disorders and hypertension, have caused significant morbidity and mortality. Roux-en-y gastric bypass is a highly successful approach for treating obesity with average loss of 60% to 70% of excess body weight [2]. Intussusception is an invagination of one segment of intestine into another, mostly seen in children. However, intussusception is very rare in adults, accounting for 1-5% of mechanical bowel obstruction [3], causes include malignancy, adhesions, and inflammatory bowel disease. There are rare reports of intussusception in post roux-en-y gastric bypass patients. Due to risk of bowel ischemia, all the diagnosed cases have been treated through immediate operative reduction of intussusception. However, operative intervention carries risks and depending on the presentation, conservative approach maybe considered. We present a patient with history of roux-en-y gastric bypass and now with retrograde intussusception that spontaneously reduced within 24 hours. She was managed mostly by clinical monitoring, supportive care, and repeat imaging. A non-emergent diagnostic laparoscopy was performed on the next day after spontaneous reduction was shown on CT scan. This case demonstrates the potential for conservative management based on clinical picture, and value of repeat imaging such as CT of abdomen for serial evaluation instead of emergent surgery.

Case

A 40 year-old woman with prior laparoscopic roux-en-y gastric bypass 3 years ago, presented with 1 day history of sharp left lateral abdominal pain that started suddenly, accompanied by nausea, vomiting, and obstipation. She denied any current medical conditions. Patient was hemodynamically stable and afebrile. On examination, her abdomen was tender in the left upper quadrant and epigastric area with radiation to back, but overall her abdomen was soft, non-distended, and non-peritoneal. Laboratory values were unremarkable except for a moderately elevated WBC at 12,900/µL. Otherwise; total bilirubin was 0.5 mg/dL, alkaline phosphatase 72 iu/L, AST 18 iu/L, ALT 22 iu/L, lipase 11 iu/L and lactic acid 0.85 mml/L. She received a CT abdomen and pelvis with PO and IV contrast showing a small bowel intussusception jejunal-jejunal anastomosis site (Figure 1). No free air was visualized. Due to overall clinical stability, she was given IV hydration, placed on bowel rest, and monitored with serial abdominal exams. Over the next few hours, abdominal pain significantly improved. Subsequently, a repeat CT abdomen and pelvis was obtained, which showed a complete resolution of the small bowel intussusception with only residual edematous loops of small bowel at the initially involved section, and previous residual oral contrast had now passed through to the colon and rectum (Figure 2).

Despite the resolution and improved clinical exam, her increasing leukocytosis with WBC of 15,500 /µL and persistent obstipation were concerning and a decision was made to proceed with an exploratory laparoscopy on the next day. Laparoscopy showed evidence of a previous intussusception that had spontaneous reduced with mild serosal erythema on the small intestine. There was no internal hernia or abnormal mass found. No intraoperative intervention was performed.
Lesions or irritants disrupt the normal peristaltic activity and lead to another that is adhered structure such as retroperitonium. Intestinal intussusception involves junction between an intestinal segment that is freely moving and another that is adhered structure such as retroperitonium. Intestinal intussusception is usually secondary to a pathologic process with accounting for 5% of all intussusceptions. In adults, 90% of the intussusception is usually secondary to a pathologic process with accounting for 5% of all intussusceptions. Among bariatric patients, current incidence of intussusception is 0.07-0.6%, but it was suggested the actual incidence may be higher due to potential for spontaneous reduction. Common presenting symptoms are abdominal pain, nausea, vomiting, fever, constipation, and weight loss. Diagnosis is most often through CT of abdomen showing distended loop of bowel and characteristic "target sign.") Most of the available literature is based on case reports. Among the cases, most required an operative intervention, including direct reduction, reduction with plication, resection of bowel, and resection of bowel with revision of anastomosis. The largest review consisting of 71 patients, in which intussusception is found to be more common among female patients (98.6%) and most presented with abdominal pain and vomiting. Of these patients, 96% of patients required surgery, 70.6% of whom required anastomotic revision and 23.5% underwent reduction without resection. However, cases of spontaneous reduction in post gastric bypass patients presenting with intussusception is rarely found. The review focused on 23 patients with gastric bypass and presented with intussusception, 9 of the patients were found to have spontaneous reduction, although some were reduced while running the bowel intraoperatively. All of these patients were operated upon and were found to have edema and hyperemia in the bowel segment involved. Instead of immediate operative intervention often involving bowel resection and extended hospital stay along with risk of surgical complications, our case demonstrates the potential role of non-operative management. The patient had spontaneous reduction found on repeat CT scan 24 hours later before diagnostic laparoscopy without involvement of any resection. In selected patients, non-emergent, minimal intervention allows shorter hospital stay without potential risk of surgical complications.

In conclusion, we report the case of spontaneously reduced intussusception that did not require emergent operative intervention. Although a diagnostic laparoscopy was performed on the next day after intussusception was spontaneous reduced, no other operative interventions were required. Our patient did not show any signs of peritonitis and remained hemodynamically stable throughout the hospital course. In such case, potentially non-operative intervention may be applied in such case. Conservative treatment with careful observation, bowel rest, hydration, and repeat imaging 12-24 hours post-presentation maybe preferred in clinical stable patient without signs of peritonitis. Overall, clinicians should be aware of intussusception as a long-term complication of gastric bypass surgery, and instead of immediate surgical reduction, conservative treatment maybe an alternative management in selected patients.
