Mesotherapy is the injection of active substances into the superficial layer of the skin. This method allows a slower spread, higher levels, and longer lasting effects of drugs in the tissues underlying the site of injection (skin, muscle, and joint) compared with those following intramuscular injection. This technique is useful when a local pharmacological effect is required and relatively high doses of drug in the systemic circulation are not. Mesotherapy should only be undertaken following a complete clinical workup and subsequent diagnosis. Encouraging results have been reported in randomized, controlled clinical trials and in observational studies involving patients with various forms of musculoskeletal pain. Recommendations by experts from the Italian Society of Mesotherapy for appropriate use of mesotherapy in musculoskeletal pain and an algorithm for treating localized painful conditions are provided.

1. Introduction

Mesotherapy is a technique used to inject active substances into the superficial layer of the skin [1–4]. The objective of this type of administration is to modulate the pharmacokinetics of the injected substance and to prolong the pharmacological effects at a local level. One of the main advantages of mesotherapy is that a local pharmacological effect can be obtained without the need for high systemic concentrations [4, 5]. Our group has previously demonstrated that intradermal injections of small amounts of active substance where the injection site corresponds to the area of the pathological condition—for example, in lower back pain—may provide clinical benefits where other therapies are not available/not effective or cannot be used for whatever reason [5]. In addition, intradermal administration of active substances in combination with other systemic therapies can produce synergistic effects, and as a result mesotherapy may have dose-sparing effects [5].

The correct use of mesotherapy requires clinical and pharmacological skills. It is vital that the procedure is carried out using strictly controlled aseptic techniques and that proper hygiene and sterilization procedures are employed. As a result of the use of this procedure by nonmedical personnel, the failure to comply with hygiene standards, incorrect administration techniques and the misuse of drugs (medications mixed together), a number of adverse events have been reported in the medical literature, in particular due to the lack of aseptic conditions [6]. Furthermore, the lack of randomized clinical trials has raised certain doubts on the validity of this technique [7, 8]. In this review we present a critical analysis of the efficacy and tolerability of mesotherapy in patients with painful musculoskeletal conditions.

2. Reasons to Consider Mesotherapy in Pain Management

Pain is an “unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage” [9]. Acute pain is interpreted as an alarm signal related to actual or potential
tissue damage—when pain persists it can become a serious condition in its own right [10]. Usually, pain is caused by stimuli approaching or exceeding harmful intensity, but in the case of prolonged pain the sensitive feedback system is altered, and microglia cells are activated [11, 12]. Even if this hypothesis is not confirmed at clinical level, it could explain the relationships between the lack of inflammatory substances and the chronic pain and the central nervous system pain control failure. Chronic pain is defined as pain that persists for longer than three months [13]. In patients with arthritis or other musculoskeletal conditions, pain is frequently triggered by inflammation of peripheral tissues (nociceptive pain), but it is also associated with a lesion (or dysfunction) of the nerve pathways (neuropathic pain). More often, nociceptive pain and neuropathic pain coexist particularly in patients with chronic back pain [14]. Unfortunately, there is no universally recognised standard of care as there is a number of distinct pathological mechanisms of pain (acute or chronic) as well as a wide range of therapeutic options to manage patients with chronic pain including pharmacological and interventional treatments physical, psychological, complementary and alternative medicine approaches [15]. In Europe nonsteroidal anti-inflammatory drugs (NSAIDs) are the first-line therapy in the majority of patients with musculoskeletal pain in conjunction with nonpharmacological therapies, such as exercise, physiotherapy, acupuncture and herbal-based preparations [16]. The high frequency of adverse events with NSAIDs—gastrointestinal toxicity, renal dysfunction, cardiovascular complications, and the risk of drug–drug interactions, particularly in older patients with comorbidities—in part explains the increasingly widespread use of “alternative” treatments [17]. Local pharmacological therapy, if effective and well tolerated, represents an acceptable alternative to systemic NSAIDs [18, 19].

Mesotherapy consists of a series of “microinjections” of drug/active substance into the dermis using short needles where the needle is positioned at an appropriate angle depending on the thickness of the skin. We suggest using a single needle, 4 mm (27 gauge) or 13 mm (30 or 32 gauge), positioned at 30–45 degree with respect to the skin surface. In general, 0.10–0.20 mL of product is used and injection points are usually 2 or 3 cm apart. If large areas are to be treated, the drug can be diluted; but this reduces the dosage, and, therefore, additional or more frequent injections are necessary. Following injection, the drug slowly reaches the underlying tissues achieving concentrations higher than those obtained with intramuscular administration [5]. Interestingly, some authors consider mesotherapy as an intra- or subcutaneous technique; however, subcutaneously administered drugs may have different pharmacokinetics (diffusion and distribution) and as a result different onset and duration of activity depending on the site of injection [20, 21]. For example, plasma glucose levels vary depending on the subcutaneous site of injection—abdomen, arm, or leg—due to the level of absorption at the various injection sites [22]. In contrast, injection into the superficial layer of the skin (intradermal) allows slow diffusion of the drug into the tissues underlying the site of injection. Sodium ketoprofen levels in skin, muscles, and joints following local intradermal or intramuscular (IM) have been measured in preclinical studies, and results show higher concentrations of the drug in skin, local muscles, and joints (corresponding the site of injection) following intradermal administration compared with following IM injection and these levels which remain high for longer than following IM administration (Table 1) [5, 23]. These results were confirmed with the intradermal inoculation of procaine and penicillin G [24, 25]. Similar results were demonstrated in human studies following intradermal injection (up to 4 mm), and interestingly results confirmed that when a drug is injected at a depth of more than 10 mm it remains for a short time in the surrounding tissues and reaches the systemic circulation rapidly [6].

To confirm that LIT administration provides prolonged concentration of drugs to local tissues, a study was conducted to compare the immunogenic properties of the tetanus toxoid after intradermal and IM administration [26]. This preclinical study showed that more potent immunological responses (primary and secondary) were elicited after intradermal injection. The authors suggest that the unique capacity of dermis to respond to external stimuli together with the increased distribution of antigen at the area of

| Time (hours) | LIT | IM | LIT | IM | LIT | IM |
|-------------|-----|----|-----|----|-----|----|
| 0           | nd  | nd | nd  | nd | nd  | nd |

| 24          | nd  | nd | 14.9 | nd | 0.8  | nd |

nd = not detectable; t = trace.
inoculation may go some way to explain these findings and have shown the way to a renewed interest in using intradermal administration of human vaccines to reduce antigen concentration (dose sparing) and the possibility of reducing the need for adjuvants (drug sparing) [27].

A recently published study reported that the administration of recombinant human follicle-stimulating hormone (rhFSH) injected into the abdominal skin at a depth of 1–2 mm, instead of using subcutaneous (10–13 mm) administration, extended the absorption of FSH. These data confirm the many potential clinical advantages of using intradermal injection—dose reduction, reduced number of injections needed to maintain elevated FSH levels, and reduced risk of adverse events [28]. The superficial layer of the skin appears to suggest a sort of an innate “slow-release system” (to be demonstrated with other preclinical and clinical studies), and it is interesting to note that the terminology “local intradermal therapy” is used to highlight the fact that it modulates the absorption and diffusion of drugs at a local level [5], even if till today studies were not produced with the technique of microdialysis.

However, the pharmacological effects of intradermal administration do not account entirely for the observed clinical benefits of mesotherapy. It is thought that “micro-doses” of active substances produce a mechanical distention of the surrounding tissues and sensitive fibres. The needle prick activates the cutaneous and subcutaneous receptors (reflex effect), and it is thought that endorphins levels actually increase after the introduction of the needle, but this hypothesis was not confirmed. Furthermore, interactions between the microvascular system and the immune cells in the dermis may play a role in the clinical benefits [29, 30]. Finally, we can argue that the clinical benefits reported by patients treated with analgesic drugs by intradermal injection may be the result of a series of “mesodermic phenomena” that are commonly referred to as mesotherapy.

3. Clinical Trials of Mesotherapy in Musculoskeletal Pain

The first series of open studies conducted in patients with musculoskeletal pain conditions—including arthritis, neck pain, lower back pain, and tendinopathy—showed promising results in terms of pain reduction of at least 50% compared to baseline (Table 2) [31–46]. Positive results in term of reduction of pain and complete recovery were also reported in clinical studies conducted in professional and amateur athletes with posttraumatic pain (Table 3) [47–52]. In randomized and controlled trials, clinical benefits were reported in patients with low back pain, with cervicobrachialgia, and with calcifying tendinitis of the shoulder (Table 4) [53–57]. Confirming those previously reported by other authors showing pain relief and reduction of calcification [39, 43, 58, 59]. Interestingly, better results were reported when mesotherapy was combined with other therapies, for example, transcutaneous electric nerve stimulation (TENS) and laser or dynamic therapy [45, 54, 60–62]. Preliminary positive data have also been obtained in painful orodontal conditions [63–65].

4. Adverse Events and Local Reactions to Mesotherapy

While there is a great deal of data showing that this technique is well tolerated (Tables 2–4), transitory and reversible adverse reactions (allergic reactions, ecchymosis, and urtica) have been described after mesotherapy [4]. Mesotherapy can cause mild discomfort when the needle is introduced, and this is more common in sensitive patients. For this reason it is recommended that the needle should be inserted quickly and gently and that the contents of the syringe are emptied slowly. The different pH of some medications can cause pain during injection, and adjustment of pH with NaHCO₃ has been suggested [66]. However, it is not clear if the painful stimulus caused by microinjections represents an artificial painful impulse (pain scrambler) that participates in the interruption of transmission of “pain” [67–69]. Other local transitory effects (itching, hypersensitivity, discomfort, and irritation), probably due to the type of drug [70] or combination of drugs [38], have been reported. The use of a single drug appears to reduce the risk of drug-drug interactions and local side effects, and the risk of infection is avoided if correct ascetic procedures are employed [5]. Literature reports that the subcutaneous infections [6, 71] seem to be caused by external contamination and malpractice rather than to the technique itself.

5. Role of Skin Cytochromes

The potential role of skin cytochromes is still under discussion both for the pathway of drugs and local interaction [72–77]. The cytochromes expressed in human kerocytes could influence a number of active compounds available for transdermal administration (analgesics, anti-inflammatories, antibiotics, antifungal, and a large number of products recommended by manufacturers for their anti-aging effects), but there are very little data available on possible drug-drug interactions, metabolic pathway activation, photosensitivity reactions, or other bioactivities [78, 79]. For this reason it is preferable to avoid pharmacological mixtures of drugs, drug combined with herbal medicines or other active substances injected by intradermal route.

6. Rationale for Analgesic Drugs Injected at Local Level

A large percentage of patients treated with mesotherapy for musculoskeletal pain disorders had rapid pain relief, generally when the patient responds within the first three sessions of therapy [31–57, 60]. Importantly, in all the studies reviewed in which a wide range of agents (NSAIDs, myorelaxants, EDTA, calcitonin, or vasorelaxants alone or in combination with an anesthetic) were injected at a local level using mesotherapy, no significant adverse events were

The table lists clinical studies or case reports to evaluate the reduction of pain in various clinical conditions. The pain was noted with visual scales. P: prospective, O: open, DB: double blind, RA: randomized, C: controlled, and PC: placebo controlled.
observed. In these studies a low dose of NSAIDs was frequently used.

The World Health Organization (WHO) since 1986 recommends a therapeutic approach for the management of pain based on a three-step process according to the severity of the pain with NSAIDs used in the first step [80]. These drugs exhibit analgesic effects by COX inhibition and the reduction of prostaglandin and other inflammatory mediators [81]. Nitric oxide seems to play a major part and the reduction of prostaglandin and other inflammatory pain based on a three-step process according to the severity recommends a therapeutic approach for the management of frequently used.

In these studies a low dose of NSAIDs was observed. In these studies a low dose of NSAIDs was frequently used.

7. Recommendations

In 2010, a panel of experts from a range of specialties reviewed and validated the scientific rationale, advantages, indications and contraindications of the use of mesotherapy, with the aim of formulating a series of recommendations on the appropriate use of local intradermal therapy [5]. There was overwhelming consensus among the group members that local intradermal administration is a valuable therapeutic option in the treatment of painful and locoregional conditions, and if used correctly it represents an important addition to the physicians’ armamentarium [5]. The experts agreed that mesotherapy should be performed only after a medical diagnosis, and patients should receive information on risk/benefits ratio in particular when off-label drugs are used. They also recommended strongly that the patient’s written informed consent should always be obtained before the procedure is carried out to ensure that all possible therapeutic options have been explored and considered. A complete patient clinical report form to include a detailed report of the characteristics of the patient’s condition and pharmacological (drugs, doses, and route of administration) and nonpharmacologic techniques previously/currently used together with outcome reports and details of any adverse events observed/reported is mandatory. In this way systematic data can be collected and analyzed retrospectively to determine the efficacy of a given therapeutic approach, and clinical data can be shared among the multidisciplinary team. This procedure has been adopted in Italy since March 2010 where physicians and other healthcare personnel involved have an obligation to record all information in the patient’s clinical record. The use of previously untested compounds should be avoided (the exception being clinical trials that conform to good clinical practice, with ethical committee agreement). The physician should supply patients with information in a clear way so that he/she can make an informed decision. All adverse events should be reported to the pharmacovigilance health authorities.

The use of a mixture of drugs did not receive full consensus among experts due to the increased risk of pharmacological interactions, even if in some circumstances two active ingredients have been reported to be safe (there are no data on possible drug interactions, although changes in pH, color, and precipitation/flocculation have been observed in mixtures of drugs. Moreover, using drug mixtures, it is not possible to identify the effects of individual drugs both in terms of efficacy and tolerability). Particular attention should be paid to conforming to international hygiene standards and to avoid contamination of the sterile syringes and needles. Before using intradermal therapy, or other therapies, an internationally validated scale should be used to classify pain based on the type and intensity. Mesotherapy
is recommended in the management of musculoskeletal pain alone or in combination with other therapies where there are no contraindications to the pharmacologically active agents. Mesotherapy is not recommended in patients with a history of allergic reactions, disorders of coagulation (haemophiliacs, undergoing therapy with anticoagulants or antiplatelet agents), pregnant or lactating women, or cancer patients undergoing chemotherapy. Due to the broad range of pain mechanisms and the lack of a recognized standard of care, when mesotherapy is used the patient’s response drives subsequent clinical decisions, and the number of sessions depends on the severity of the pain. Mesotherapy protocols allow for one or more cycles of treatment depending on the symptoms and severity of the underlying condition and the individual patient’s response to therapy (Figure 1). When treating a chronic painful condition there are normally three distinct phases. The first period (attack) to reduce pain, a second (control) period to confirm the results and to improve efficacy/tolerability ratio, and a subsequent (maintenance) period to prevent recurrences [4]. In real-life clinical practice, we propose an example of algorithm to manage patients who can benefit from a local treatment instead of a systemic more aggressive pharmacologic approach or who can benefit from a synergistic combination of local and systemic therapy. Obviously, every physician who applies mesotherapy for analgesic purposes should assess pain before and during the treatment. For this reason we strongly suggest the use of validated scales to assess pain and to consider extending the mesotherapy treatment only if the patient declares a relief of at least 50% from baseline.

8. Conclusions

For many years, mesotherapy has been considered by physicians (and nonmedical personnel) as a “personal” pharmacological approach, treatment practices were based on personal observations and experience, but in the era of evidence-based medicine this approach is no longer adequate, and standard treatment algorithms are required. We have reviewed and analyzed the data available in the treatment of various forms of musculoskeletal pain, and although the number of randomized, controlled trials is still low, overall results suggest that this technique provides clinical benefits and importantly is well tolerated. Mesotherapy allows the drug to diffuse slowly into the tissues at the site of injection and to have a prolonged period of action at low dosages. Microinjections facilitate the rebalancing of the nociceptive system through a series of complex and as yet not well-understood local actions involving nociceptive receptors, nociceptive central feedback mechanisms, and the immune system. The pain relief reported by patients occurs as a result of all these phenomena.

The Italian Society of Mesotherapy considers that the intradermal injection of drugs is effective and well tolerated
if administered according to approved techniques and when administered after a complete clinical workup from which there is a clear rationale for local treatment. We believe that this method provides potential benefits in terms of clinical effectiveness and cost savings in the management of musculoskeletal pain. Many studies have been conducted in the open, and few randomized controlled trials have a limited number of subjects, it should be pointed out however that more large-scale and randomized clinical trials are required to confirm its efficacy and tolerability in general, and in particular we have identified two important areas for further research: first to confirm the efficacy of intradermal NSAIDs in localized pain to reduce the risk of the known systemic effects of this class of drugs and second the use of intradermal opioids in order to improve our understanding of how to extend the effectiveness of these analgesics in musculoskeletal painful conditions.
