(March 21, 2022)

We study transport properties of a non-degenerate two-dimensional system of non-interacting electrons in the presence of a quantizing magnetic field and a short-range disorder potential. We show that the low-frequency magnetoconductivity displays a strongly asymmetric peak at a nonzero frequency. The shape of the peak is restored from the calculated 14 spectral moments, the asymptotic form of its high-frequency tail, and the scaling behavior of the conductivity for $\omega \to 0$. We also calculate 10 spectral moments of the cyclotron resonance absorption peak and restore the corresponding (non-singular) frequency dependence using the continuous fraction expansion. Both expansions converge rapidly with increasing number of included moments, and give numerically accurate results throughout the region of interest. We discuss the possibility of experimental observation of the predicted effects for electrons on helium.

\section{I. INTRODUCTION}

Single-electron dynamics in the lowest Landau level (LLL) broadened by a delta-correlated scalar disorder potential provides the simplest framework for the analysis of the integer quantum Hall effect (IQHE). Wegner's exact calculation\textsuperscript{11} of the density of states raised hopes that the corresponding model may be exactly solvable, and much effort was put into understanding transport in this model. However, in contrast to the density of states, the conductivity is expressed in terms of a two-particle Green's function and depends not only on the energies of single-particle states, but also on their wave functions.

A noteworthy feature of the single-electron wave functions in a strong magnetic field is delocalization near the centers of the disorder-broadened Landau bands. For small energies $E$ counted off from the band center (in the neglect of band mixing), the localization length $\xi$ diverges as a universal power of $|E|$. These are transitions between large-radius states that form the low-frequency conductivity of the system. As a result, for Fermi energies close to a band center, the model displays a universal critical behavior at sufficiently small temperatures and frequencies.

The width of the critical region depends on the properties of the disorder potential and the Landau level number. For the lowest Landau level, it is of the order of the bandwidth $h\gamma$, the only dimensional parameter of the Hamiltonian projected on the LLL (we assume that the cyclotron frequency $\omega_c \gg \gamma$). Outside the scaling region, the spatial extent of the eigenstates is small, of the order of the magnetic length $l = (\hbar/\mu_0)\frac{1}{2}$, and the universality is lost. Therefore the overall frequency dependence of the conductivity is determined by the disorder mechanism and may allow to discriminate between different mechanisms. For this reason, it is interesting to obtain the frequency dependence of the conductivity, including its universal and non-universal parts, at least for some basic models of disorder. It is also of interest to find highly accurate numerical results, as they may be used to test various approximate analytical approaches.

In the present paper we consider the frequency-dependent conductivity for a short-range disorder potential. Short-range disorder is usually a good model of the random potential experienced by electrons trapped on the surface of liquid helium. This potential is due to quasistatic ripplons, slow helium vapor atoms, or, for thin helium films, substrate disorder\textsuperscript{12}. The electron correlations in this system are usually strong. However, it was believed that, for strong enough magnetic fields, the static magnetoconductivity can be described in the single-electron approximation (for a review see Refs.\textsuperscript{2,3}). The corresponding results obtained within the self-consistent Born approximation\textsuperscript{4} (SCBA) appeared to be in reasonable agreement with the experiments\textsuperscript{3,4}.

The SCBA ignores the interference effects which lead to electron localization and to the scaling behavior near the band center. Therefore there is an apparent contradiction between the interpretation of the experimental data on electrons on helium and the phenomenology of the quantum Hall effect. From this point of view, it is important to develop a single-electron theory of magnetotransport that will take localization effects into account and will thus extend the ideas of the IQHE theory to a new parameter range, which is of interest for electrons on helium in particular. The results can serve as a basis for the full many-electron theory of magnetoconductivity at strong magnetic fields\textsuperscript{8,9}.

With this in mind, we will analyze magnetotransport in the regime...
\[ h\gamma \ll k_B T, \quad n\ell^2 \ll 1, \] (1)

where the disorder-induced broadening of the lowest Landau level is small compared to temperature, and simultaneously the filling fraction is small, i.e., the electron system is nondegenerate. Much of the experimental data on electrons on helium refers to the range \( \gamma \ll k_B T \), as the system is very clean, and the experiments are often done at low electron densities \( n \sim 10^8 \text{ cm}^{-2} \). This range is also of interest for low-density electron systems in semiconductors.

In the range \( \gamma \ll k_B T \) all states within a broadened Landau level are nearly equally populated, and one no longer needs to take into account the Boltzmann factor while computing temperature and disorder averages using the Hamiltonian projected on that level. As we show below, this simplification allows us to make accurate calculations of the frequency-dependent conductivity using the method of moments, which was previously suggested for this problem by one of us [2].

The outline of the paper is as follows. In Sec. II we calculate the frequency-dependent conductivity \( \sigma_{xx}(\omega) \) in the temperature range \( h\gamma \ll k_B T, \exp(h\omega_c/k_B T) \gg 1 \) for \( \omega \ll \omega_c \) [these results were previously announced in Ref. [3]]. We find the asymptotics of the conductivity at both small \( \omega \to 0 \) and comparatively large \( \gamma \ll \omega \ll \omega_c \) frequencies, and show that \( \sigma_{xx}(\omega) \) has a peak at a nonzero frequency \( \omega \sim \gamma \). Using an efficient diagram classification scheme, we compute exactly the first 14 spectral moments of this peak. These moments contain information about the short-time \( (\sim \gamma^{-1}) \) dynamics of the system. Combined with the low and high-frequency asymptotics, they allow us to accurately restore the entire function \( \sigma_{xx}(\omega) \) [see Fig. 1]. In Sec. III we investigate the cyclotron resonance, i.e., \( \sigma_{xx}(\omega) \) for \( \omega \approx \omega_c \). We calculate the first 10 frequency moments of the cyclotron resonance absorption peak and use them to accurately restore its shape [see Fig. 2] as a function of frequency detuning \( \Delta \omega \equiv \omega - \omega_c \). To do the restoration, we also calculate the asymptotic form of the tails of the cyclotron resonance using the method of optimal fluctuation [our result differs from that obtained earlier by Ioffe and Larkin [4]]. In Sec. IV we discuss the ways to observe the predicted here behavior in experiment. Technical details are given in the Appendices.

![FIG. 1. Reduced microwave conductivity (*) of a non-interacting 2DES at the lowest Landau level in a short-range disorder potential for \( \omega, \gamma \ll k_B T/h \). For small frequencies, \( \omega \ll \gamma \), the conductivity is singular, \( \sigma_{xx} \sim \omega^2 \). It is determined by spatially large, nearly delocalized states. For \( \omega \gg \gamma \), the conductivity is determined by large optimal fluctuations of the disorder potential as illustrated in the inset. The optimal potential \( V_{\text{opt}}(r) \) is such that \( h\omega \) equals to the energy difference \( E_t - E_b \) between the top and bottom bound states \(|t\rangle, |b\rangle\), and at the same time these states are maximally overlapping.](image)

![FIG. 2. Reduced conductivity at the cyclotron absorption peak [see Eq. (38)] of a non-interacting 2DES in a short-range disorder potential for \( |\omega - \omega_c|, \gamma \ll k_B T/h \ll \omega_c \). The curve is analytic in the center of the peak. The absorption at the tails, \( |\omega - \omega_c| \gg \gamma \), is determined by large optimal fluctuations of the disorder potential as illustrated in the inset.](image)

**II. LOW-FREQUENCY SINGLE-ELECTRON CONDUCTIVITY**

In this section, we calculate the conductivity of a non-degenerate non-interacting two-dimensional electron system (2DES) for low frequencies, \( \omega \ll k_B T/h \). We consider the case of a delta-correlated disorder potential and assume that the broadening of the Landau level \( \gamma \ll \omega_c, k_B T/h \) [cf. Eq. (3)].

In the range \( \gamma \ll k_B T \) all states within the LLL are equally occupied, and the Kubo formula for the dissipative conductivity can be written as a simple trace without the Boltzmann factor,

\[
\sigma_{xx}(\omega) = \frac{n}{h\omega} \Re \int_0^\infty dt e^{i\omega t} \langle j_x(t) j_x(0) \rangle \tag{2}
\]
\begin{equation}
\approx \frac{n\beta}{2\hbar} \int_{-\infty}^{\infty} dt e^{i\omega t} \text{Tr}_0 \{j_x(t) j_x(0)\}, \quad \beta \omega \ll 1. \quad (3)
\end{equation}

Here \(j_x \equiv e\pi_x/m\) is the one-electron current operator, \(\beta \equiv \hbar/k_BT\) the angular brackets \(\langle \cdot \rangle\) denote statistical averaging over the states followed by an averaging over quenched disorder, while the horizontal line denotes only the disorder averaging. The trace \(\text{Tr}_0\) in Eq. (3) is performed over all single-particle states of the lowest Landau level; the energies are measured with respect to its center. Eq. (2) is written for the case of strongly quantizing magnetic fields, \(\exp(\beta \omega_c) \gg 1\), so that only the lowest Landau level is occupied. However, the calculation is readily generalized to the case of arbitrary \(\beta \omega_c\) by replacing \(\text{Tr}_0\) by the sum of traces over the states of each Landau level \(n\) weighted with \(\exp(-n\beta \omega_c) [1 - \exp(-\beta \omega_c)]\).

Calculations within a single Landau level are conveniently done using the formalism of the guiding center coordinates \(\mathbf{R} \equiv (X, Y)\). The electron dynamics in the random potential \(V(\mathbf{r})\) is mapped onto that of a 1D quantum particle with the general momentum and coordinate \(X\) and \(Y\), and with the Hamiltonian

\begin{equation}
H = \hbar \gamma \sum_{\mathbf{q}} \tilde{V}_{\mathbf{q}} \exp(i\mathbf{q}\mathbf{R}), \quad [X, Y] = -i\ell^2. \quad (4)
\end{equation}

Respectively, the guiding center velocity is determined by the potential gradient,

\begin{equation}
\dot{R}_\mu = -i\ell^2 \gamma \sum_{\mathbf{q}} \varepsilon_{\mu\nu} q_\nu \tilde{V}_{\mathbf{q}} e^{i\mathbf{q}\mathbf{R}}, \quad (5)
\end{equation}

where \(\mu, \nu = x, y\), and \(\varepsilon_{\mu\nu}\) is the unit antisymmetric tensor, \(\varepsilon_{xy} = -\varepsilon_{yx} = 1\).

The dimensionless coefficients

\begin{equation}
\tilde{V}_{\mathbf{q}} \equiv \left( \frac{V_{\mathbf{q}}}{\hbar \gamma} \right) \exp(-\ell^2 q^2/4) \quad (6)
\end{equation}

are proportional to the Fourier components of the disorder potential,

\begin{equation}
V_{\mathbf{q}} \equiv S^{-1} \int d^2 \mathbf{r} V(\mathbf{r}) e^{-i\mathbf{q}\mathbf{r}} \quad (7)
\end{equation}

where \(S\) is the area of the system. For higher Landau levels the coefficients \(\tilde{V}_{\mathbf{q}}\) have to be modified as explained in Appendix A [see Eq. (A3)]. We will assume that \(V(\mathbf{r})\) is zero-mean Gaussian and delta-correlated,

\begin{equation}
\langle V(\mathbf{r}) V(\mathbf{r}') \rangle = \sigma^2 \delta(\mathbf{r} - \mathbf{r}'), \quad (8)
\end{equation}

in which case the SCBA width of the lowest Landau band is \(\hbar \gamma = (2/\pi)^{1/2} \ell \sqrt{eD/\hbar}\).

In the simplified Kubo formula (3) the temperature dependence is factorized, and we can rewrite the low-frequency conductivity in the form of the generalized Einstein relation

\begin{equation}
\sigma_{xx}(\omega) = \frac{ne^2 D}{k_B T} \frac{1}{8} \tilde{\sigma}(\omega), \quad (9)
\end{equation}

where \(D = \ell^2 \gamma\) is the characteristic diffusion coefficient and, as discussed in Appendix A,

\begin{equation}
\tilde{\sigma}(\omega) \equiv \frac{2}{\ell^2 \gamma} \int_{-\infty}^{\infty} dt e^{i\omega t} \text{Tr}_0 \left\{ \mathbf{R}(t) \cdot \mathbf{R}(0) \right\} \quad (10)
\end{equation}

is the reduced conductivity. It depends on the ratio \(\omega/\gamma\) of the only two quantities with the dimension of frequency that remain after projection on one Landau level.

The expression (10) can be rewritten with the help of Eq. (11) as

\begin{equation}
\tilde{\sigma}(\omega) = -\frac{2\ell^2 \gamma}{\hbar \gamma} \int_{-\infty}^{\infty} dt e^{i\omega t} \sum_{\mathbf{q}, \mathbf{q}' \neq 0} \langle \mathbf{q} \mathbf{q}' \rangle \langle \mathbf{q} \mathbf{q}' \rangle \times \text{Tr}_0 \left\{ \mathbf{V}_{\mathbf{q}} \mathbf{V}_{\mathbf{q}} \exp[i\mathbf{q} \mathbf{R}(t)] \exp[i\mathbf{q}' \mathbf{R}(0)] \right\}. \quad (11)
\end{equation}

This form is particularly convenient for calculating the frequency moments of the reduced conductivity, see below in Sec. IIC.

Yet another representation of the reduced low-frequency conductivity can be obtained if we describe time evolution of the electron operators in Eq. (11) using the set \(|n\rangle\) of the eigenstates of the full electron Hamiltonian for the lowest Landau level and perform the time integration,

\begin{equation}
\tilde{\sigma}(\omega) = \frac{4\pi \ell^2}{\hbar \gamma} \sum_{n, m} \delta(E_n - E_m - \hbar \omega) \left| \langle n | \nabla V | m \rangle \right|^2, \quad (12)
\end{equation}

where \(E_n\) are the energies of the LLL states \(|n\rangle\) in the potential \(V(\mathbf{r})\) (again, generalization to the case of several occupied Landau levels is straightforward).

We emphasize that, in the chosen parameter range, the Landau-level projection resulted in expressions that do not contain the usual disorder-dependent denominator, and the quenched disorder averaging can be done directly, without invoking supersymmetry or the replica trick.

**A. Tail of the low-frequency conductivity**

We begin with calculating the asymptotic form of the reduced conductivity \(\tilde{\sigma}(\omega)\) for \(\omega \gg \gamma\) from Eq. (12). In the neglect of inter-band mixing, the energies \(E_n\) are symmetrically distributed around the Landau band center \((E = 0)\). The tails of the density of states \(\rho(E)\) are known to be Gaussian, \(\rho(E) \propto \exp(-4E^2/\hbar^2 \gamma^2)\). They are determined by the probability of the optimal (least improbable) potential fluctuation \(V_c(\mathbf{r})\) in which the lowest or highest bound state has energy \(E \geq |E| \gg \gamma\).

If we ignore the matrix element in Eq. (12) altogether (as we show below, this only affects the prefactor), the tail of the conductivity will be proportional to the probability to find two states \(E_n, E_m\) such that \(E_n - E_m = \hbar \omega\).
The major contribution comes from states at the opposite ends of the energy band with energies close to $E_n = E_m = \hbar \omega / 2$, giving
\[
\tilde{\sigma}(\omega) \propto \left[ \rho(\hbar \omega / 2) \right]^2 \times \exp(-2\omega^2 / \gamma^2). \tag{13}
\]

To check this approximation, we will apply the method of optimal fluctuation. The averaging over disorder in Eq. (12) will be done using the path integral representation
\[
\mathcal{F}[V] \equiv \int DV(r) \mathcal{F}[V(r)] \exp\{-\mathcal{R}[V(r)]\}, \tag{14}
\]
where, for a delta-correlated Gaussian potential with the correlator $\langle \delta(r-r') \rangle = \frac{1}{2\hbar\omega} \int dr V^2(r), \tag{15}
\]

For large $\omega$, the leading contribution to the sum (12) comes from transitions between the states $|\psi_1\rangle$ and $|\psi_2\rangle$ with energies $E_1$ and $E_2$ at the top and bottom of the Landau band, respectively,
\[
E_{1,2} = \frac{1}{2\hbar\omega} \int dr V^2(r). \tag{16}
\]

To logarithmic accuracy, the conductivity is given by the solution of the variational problem of finding the optimal potential $V(r)$ which minimizes the functional $\mathcal{R}[V]$ and maximizes the matrix element of the transition subject to the constraint $E_1 - E_2 = \hbar \omega$, i.e.,
\[
\tilde{\sigma}(\omega) \propto \max \left\{ \exp\{-\mathcal{R}[V] + \lambda (E_1 - E_2 - \hbar \omega)\} \times \|\psi_1 | \nabla V | \psi_2\|^2 \right\}, \tag{17}
\]
where $\lambda$ is a Lagrange multiplier. Variation with respect to $V(r)$ gives the equation
\[
\frac{V(r)}{v^2} = \lambda \left( |\psi_1|^2 - |\psi_2|^2 \right) + \frac{\delta}{\delta V(r)} \ln \|\psi_1 | \nabla V | \psi_2\|^2 \tag{18}
\]
(for brevity, we do not give the explicit form of the last term).

We have analyzed the variational problem using a simple and tractable direct variational method, and also by finding the maximum in Eq. (17) numerically. To see the qualitative features of the solution, we first discuss it ignoring the contribution of the matrix element. In this case the Lagrange multiplier $\lambda$ is given by the consistency equation,
\[
\hbar \omega = E_1 - E_2 = v^2 \lambda \int dr \left( |\psi_1|^2 - |\psi_2|^2 \right)^2, \tag{19}
\]
and then the conductivity (17) is
\[
\ln \tilde{\sigma}(\omega) = \hbar^2 \omega^2 \left[ 2v^2 \int dr \left( |\psi_1|^2 - |\psi_2|^2 \right)^2 \right]^{-1}. \tag{20}
\]

The solution (18) corresponds to a potential of the form of a well and a hump, far away from each other (cf. Fig. 1). The potential is antisymmetric, the well and the hump have the same Gaussian shape $\left[ \exp(-r^2/2l^2) \right. \exp(-r^2/4l^2), with r counted off from the corresponding extremum and opposite signs. The wave functions $\psi_1$ and $\psi_2$ are localized at the hump and the well of $V(r)$, respectively, and are given just by the most “localized” wave function of the lowest Landau level, namely that with zero angular momentum, $\psi_{00}(r) \propto \exp(-r^2/4l^2)$, centered at the appropriate potential extremum. The overlap of these wave functions is negligibly small, and Eqs. (19), (20) give
\[
\hbar \omega = 2v^2 \lambda A, \quad \ln \tilde{\sigma}(\omega) = \frac{\hbar^2 \omega^2}{4v^2 A} = \frac{\omega^2}{2\pi^2 l^2 A}.
\]

The prefactor in Eq. (17) prevents the well and the hump of $V(r)$ from being too far away from each other. Nevertheless, the full variational equation (18) has a solution with an antisymmetric optimal potential $V(r) = -V(-r)$ and symmetric wave functions $\psi_i(r) = \psi_i(-r)$; respectively, $E_i = -E_h = \hbar \omega / 2$. To estimate the role of the overlap integral we used the direct variational method in which we sought the potential in the form $V(r) = \tilde{V}(r - r_0) - \tilde{V}(r + r_0)$ with $\tilde{V}(r) = V_0 \exp(-r^2/2l^2)$. The distance $2r_0$ separating the hump and the well was used as a variational parameter. Given the potential, one has to solve the Schrödinger equation, looking for the wave functions projected on the lowest Landau level. We took the functions $\psi_{1,2}$ in the simplest form of orthogonal combinations of the zero-momentum wave functions centered close to $\pm r_0$ (the positions were found using a variational procedure). The distance $r_0$ scales with frequency logarithmically. The overall asymptotic expression for the exponent in $\tilde{\sigma}$ was the same as in Eq. (13); the overlap integral gave only a prefactor,
\[
\langle \psi_1 | \nabla V | \psi_2 \rangle^2 \sim (\hbar r_0^2 / l \omega) \ln(\omega / \gamma).
\]

[An extra $\omega$-dependent contribution to the overall prefactor in $\tilde{\sigma}$ comes from the prefactor in the path integral (14). It actually increases with the increasing $\omega$. However, an evaluation of this prefactor goes beyond the scope of this paper, and in some sense is superseded by the results obtained below with the method of moments.]

To further check the accuracy of the asymptotic behavior of $\tilde{\sigma}(\omega)$, we maximized (14) the functional in Eq. (17) numerically. We used the variational equation (18) to represent the optimal potential as a bilinear combination of the
LLL wave functions \( \psi_{0m}(r) \propto r^m \exp(i m \phi) \exp(-r^2/4l^2) \) with different magnetic quantum numbers \( m \geq 0 \),

\[
V(r) = \sum_{m,m'} u_{mm'} \psi^*_{0m}(r) \psi_{0m'}(r).
\]

The corresponding eigenfunctions \( \psi_{k,b} \) were written as linear combinations of the same functions \( \psi_{0m}(r) \).

Both the exponent and the prefactor of the variational functional \( \mathcal{F} \) calculated numerically become close to the result of the direct variational method for \( \omega/\gamma \gtrsim 3 \).

The shape of the optimal potential found numerically for two values of \( \omega/\gamma \) is illustrated in Fig. 3.

**FIG. 3.** Density plot of the optimal potential for \( \omega = 3\gamma \) (a) and \( \omega = 8\gamma \) (b). The distances are measured in units of the magnetic length \( l \).

**B. Conductivity at small frequencies.**

An entirely different set of states defines the conductivity for very small frequencies, \( \omega \ll \gamma \). In this regime the constraint imposed by conservation of energy is not very restrictive, and it is the matrix element that determines relative contributions of different pairs of states. Close to the static limit the contribution to the conductivity increases dramatically with the typical size of a wavefunction. As a result, \( \tilde{\sigma} \) [Eq. \( \mathcal{F} \)] is primarily determined by a narrow energy interval at the center of the Landau band where the states are nearly delocalized. The energy of the band center \( (E = 0) \) is a critical energy, similar to the critical value of the control parameter in the theory of classical percolation transition. At small deviations from the critical energy (parametrized by dimensionless energy \( \varepsilon \equiv E/\hbar\gamma \)) the correlation length diverges, \( \xi \sim |\varepsilon|^{-\nu} \), where \( \nu = 2.33 \pm 0.03 \) is the localization exponent.

Were it not for localization, propagation of a wavepacket in a random potential would be diffusive,

\[
\langle \Delta R^2(t) \rangle \sim D t.
\]  

Localization corrections are least important near the critical energy, but even there they modify the form of a wavepacket at very large times. However, for not too large times the r.m.s. displacement, which is primarily determined by small momenta, retains the diffusive form. This can be used to find the conductivity at small frequencies.

To this end, let us rewrite Eq. \( \mathcal{F} \)

\[
\tilde{\sigma}(\omega) = \frac{2\omega^2}{l^2 \gamma} \lim_{\delta \to +0} \Re \int_0^\infty \! dt \, e^{i \omega t - \delta t} \text{Tr}_0 \Delta R^2(t),
\]

in terms of the squared displacement \( \Delta R^2(t) \equiv |\mathbf{R}(t) - \mathbf{R}(0)|^2 \), where \( \mathbf{R}(t) \equiv \exp(iHt) \mathbf{r} \exp(-iHt) \) is the Heisenberg operator of the guiding center. For an eigenstate \( |n\rangle \) of the Hamiltonian \( \mathcal{H} \) randomly chosen not too far from the critical energy, \( \langle n| \Delta R^2(t) |n\rangle \) has the diffusive form \( \mathcal{F} \) at small enough \( t \), but it eventually saturates at the distance of the order of the localization length \( \xi_{\varepsilon_n} \).

Replacing the trace by the integral over energy weighted with the (non-critical) density of states, we obtain the overall long-time \( (\gamma t \gg 1) \) r.m.s. displacement

\[
\text{Tr}_0 \Delta R^2(t) \sim \hbar \gamma \int \! d\varepsilon \, \rho(\hbar \gamma \varepsilon) \min(Dt, \xi_{\varepsilon_n}^2)
\]

\[
\propto l^2 (\gamma t)^{1-1/(2\nu)}.
\]  

This average is determined by the states with energies \( |\varepsilon| \lesssim (\gamma t)^{-1/2\nu} \); the integral rapidly converges outside this region.

With asymptote \( \mathcal{F} \), time integration in Eq. \( \mathcal{F} \) gives:

\[
\tilde{\sigma}(\omega) = C \frac{\omega^2}{l^2 \gamma}, \quad \mu \equiv (2\nu)^{-1}.
\]  

The same result can be obtained from the scaling form \( \mathcal{F} \) of the zero-temperature conductivity of the non-interacting system at a given chemical potential, which can be written as

\[
\sigma_{xx}(\varepsilon, \omega) = \frac{e^2}{\hbar} \mathcal{G}_0 \left( \frac{\omega \xi^2}{\gamma l^2} \right),
\]  

where the dimensionless scaling function \( \mathcal{G}_0(X) \) rapidly vanishes for \( X \to 0 \) and approaches a constant value for large \( X \). Indeed, the conductivity for \( \beta \omega \ll 1 \) can be written as a convolution of the scaling function \( \mathcal{G}_0 \) with the derivative of the Fermi distribution function.
\[
\tilde{\sigma}(\omega) = \frac{8 k_B T}{\pi e^2 l^2 \gamma} \int d\varepsilon \left(-\frac{d\eta_F}{d\varepsilon}\right) \sigma_{xx}(\varepsilon, \omega)
\]  
(26)

[cf. Eq. (1)]. For \( k_B T \gg h\gamma \), all energies within the stripe of width \( d\varepsilon \sim (\omega/\gamma)^mu \) contribute equally, and in the limit \( \omega \to 0 \) we obtain Eq. (24) with the coefficient

\[
C = 16\pi\mu \int_{-\infty}^{\infty} \frac{dX}{|X|^{1+2\mu}} \tilde{g}_0(X). 
\]  
(27)

Here we have assumed that \( \varepsilon' \xi_\varepsilon \to \text{const} \) for \( \varepsilon \to 0 \), and \( \tilde{g}_0(X) \equiv \lim_{\varepsilon \to 0} g_0(X e^{2\nu_\xi \varepsilon^2/l^2}) \). The integration converges both at zero and infinity.

C. Spectral moments

Since the single-particle conductivity goes to zero both for \( \omega \to 0 \) and for \( \omega \gg \gamma \), its frequency dependence displays a peak, with a maximum at a nonzero frequency \( \omega \sim \gamma \). Such a peak is of central interest from the point of view of experiment, it does not occur in the SCBA. This peak was previously found and briefly discussed in our communication [12]. Here we present the results and provide some details of the full calculation of the low-frequency conductivity based on the method of spectral moments (MOM). The advantageous feature of this method is that, instead of solving the full time-dependent problem of the electron motion in a random field [13], one has to evaluate only equal-time correlation functions.

We first calculate the spectral moments of the reduced conductivity \( \tilde{\sigma}(\omega) \) [Eq. (1)]. They are defined as

\[
M_k = \frac{1}{2\pi\gamma} \int_{-\infty}^{\infty} d\omega \left(\frac{\omega}{\gamma}\right)^k \tilde{\sigma}(\omega). 
\]  
(28)

For \( \omega, \gamma \ll k_B T/h \), the states within the broadened Landau level are equally populated, and the conductivity is an even function of frequency, \( \tilde{\sigma}(\omega) = \tilde{\sigma}(-\omega) \). Therefore all odd moments vanish, \( M_{2k+1} = 0 \). For even moments, we use the Hamiltonian (3) to obtain from Eqns. (11), (12), (19),

\[
M_{2k} = -2l^2 \sum \langle{q_1}{q_{2k+2}}\rangle \tilde{V}_{q_1} \ldots \tilde{V}_{q_{2k+2}} \]  
(29)
\[
\times \left[ \ldots \left[ e^{i{q_1R}}, e^{i{q_2R}} \right] \ldots \right] e^{i{q_{2k+1}R}} e^{i{q_{2k+2}R}}. 
\]

The summation is performed over all \( q_1, \ldots, q_{2k+2} \). The commutators (29) can be evaluated recursively using

\[
[e^{i{qR}}, e^{i{q'R}}] = 2i \sin \left(\frac{1}{2} l^2 q \land q'\right) e^{i(q+q')R}. 
\]  
(30)

For Gaussian random potential, the disorder average in Eq. (29) can be computed by Wick’s theorem. From Eqns. (3)–(5),

\[
\langle{\tilde{V}_q}{\tilde{V}_{q'}}\rangle = (\pi l^2/2S) \exp(-l^2q^2/2) \delta_{q+q',0} = S, 
\]

where \( S \) is the area of the system. Then,

\[
M_{2k} = -\pi \left(-\frac{l^2}{2\pi}\right)^{k+2} \sum \left[\varepsilon'(q_1)\right] \int dq_1 \ldots dq_{2k+2} C(\{q\}) 
\times (q_1q_{2k+2}) \exp \left(-\frac{l^2}{4}(q_1^2 + \ldots + q_{2k+2}^2)\right) 
\times \sin \left(\frac{l^2}{2} (q_1 \land q_2) \sin \left(\frac{l^2}{2} (q_1 + q_2) \land q_3\right) \ldots 
\times \sin \left(\frac{l^2}{2} (q_1 + q_{2k+1}) \land q_{2k+1}\right) 
\]  
(31)

where the sum is taken over all \( (2k+1)!! \) ways to choose pairs out of the set of \( 2k+2 \) variables, and

\[
C(\{q\}) \equiv \delta(q_{i_1} + q_{j_1}) \ldots \delta(q_{i_{k+1}} + q_{j_{k+1}}) 
\]

is the corresponding contraction function.

\[\text{FIG. 4. Examples of diagrams. Dashed lines indicate which variables are paired, double lines represent an arbitrary internal structure. (a) A symmetric diagram. Diagrams whose contribution is equal to zero: (b) disconnected diagrams, and (c) diagrams which vanish because the associated function is odd in } q_{2k+2}. \]

To classify different terms in the sum (31), it is convenient to depict the contraction procedure graphically as illustrated in Fig. 4. (These diagrams merely represent the contraction function \( C \) and should not be confused with Feynman diagrams for the Green’s functions.) First, we note that the sequence of \( q \) paired in a diagram may be reversed, \( q_i \to q_{2k+3-i} \), without changing the overall value of the diagram. The diagrams obtained by such
a reversal are equivalent, which reduces the computation cost by a factor of two [this reduction does not occur, however, for symmetric diagrams shown in Fig. 3]. Additional simplification comes from the fact that disconnected diagrams (Fig. 3b) and the diagrams with the structure shown in Fig. 3c are equal to zero. The number of diagrams of different sorts is given in Ref. 17; for example, for the 14th moment there are 2027035 diagrams, out of which 5937 are symmetric, 318631 are disconnected; the contribution of the diagrams with \( q_1 = -q_2 \) is \( \approx 72.559 \), whereas the contribution of all other diagrams is \( \approx -8.809 \).

Despite the reductions, the number of terms to be calculated remains very large for large \( k \). Moreover, each term in Eq. (31) is a sum of \( 2^k \) Gaussian integrals. Each integral can be calculated algebraically but at a high computational cost. To accelerate the calculation, we have devised an efficient numeric classification scheme, which sorts diagrams inexpensively into bins according to their approximate values calculated with double precision. A representative diagram is evaluated algebraically for each bin. Finally, the diagrams are summed up with proper multiplicity, giving exact numerical values of the moments. The procedure is outlined in Appendix B. Calculating algebraically only non-equivalent Gaussian integrals reduces computational time tremendously. This allowed us to evaluate the moments up to \( M_{14} \). For \( k = 0, 1, \ldots, 7 \) we obtain

\[
M_{2k} = 1; \quad 3.443; 25003; 13608949709; 298681273551508807; 566602308094143977186611746328326698099; 258900891167704930828461075265328752472466933109372792412270459939701; 406119740082323608381355617240666314144290787406293503186042880000 \quad (32)
\]

and the corresponding approximate values,

\[
M_{2k} \approx 1; 0.375; 0.385; 0.651; 1.522; 4.478; 15.72; 63.75 .
\]

D. Reconstruction of frequency-dependence

Since the conductivity is asymptotically Gaussian, one is tempted to restore \( \tilde{\sigma}(\omega) \) from the moments \( M_n \) in a standard way, writing an expansion in Hermite polynomials \( \tilde{\sigma}(\gamma x) = \sum_n B_n H_n(\sqrt{2}x) \exp(-x^2) \). The coefficients \( B_n \) can be expressed recursively in terms of the moments \( M_k, k \leq n \). However, for the moments (32), this expansion does not converge rapidly, see Fig. 3. This is consistent with nonanalyticity of the conductivity at \( \omega = 0 \).

Given the exponent \( \mu \) in Eq. (24), a much more rapidly convergent expansion can be constructed in terms of a different set of orthogonal polynomials. Specifically, with Eqns. (13), (24), we write the conductivity at the lowest Landau level as

\[
\tilde{\sigma}(\omega) = x^\mu G(x) \exp(-2x^2), \quad x \equiv |\omega|/\gamma . \quad (33)
\]

The function \( G(x) (x \geq 0) \) can be expanded in Laguerre polynomials \( L_n^{(\mu - 1)/2}(2x^2) \), which are orthogonal for the weighting factor in Eq. (13). It is important that the expansion coefficients can also be recursively restored from the moments \( M_{2k}, k \leq n \).

For the presently accepted value of the localization exponent \( \nu \approx 2.33 \), the value of the conductivity exponent \( \mu \) is 0.215. The expansion for \( G \) converges rapidly for \( \mu \) between 0.19 and 0.28, whereas outside this region the convergence deteriorates, as illustrated in Fig. 3. This could be considered as an indirect indication of the consistency of our approach.

The resulting conductivity calculated with \( \mu = 0.215 \) is shown in Fig. 3. The estimated deviation from the obtained curve due to the finite number of moments and also to the uncertainty in the value of \( \mu \) (its effect is discussed in Ref. 17) is smaller than the width of the line.
Landau levels, one should keep only the part in infinite level degeneracy. The disorder can be described in the same way as scattering between different Landau levels resembles that of Jahn-Teller centers is the method of moments. For the effective methods of the theory of absorption spectra. The reduced cyclotron conductivity can be conveniently written in a form conventional for this theory by introducing the “perturbation” Hamiltonian

\[ \delta H_d \equiv H_d^{(1)} - H_d^{(0)} = -\hbar \gamma \sum_{q} \left( \frac{q^2 T^2}{2} \right) P_N, \]

where \( \tilde{V}_q \) is defined by Eq.\,[1] and \( P_N = P_N^2 \) is the operator of projection to the \( N \)th Landau level, as in Eq.\,[2]. With the Hamiltonian (\[3\]), oscillations at the cyclotron frequency can be singled out in Eq.\,[4],

\[ p_{\pm}(t) = e^{\pm i \omega \tau} e^{i H_d \tau / \hbar} p_{\pm} e^{-i H_d \tau / \hbar}. \]

Then, from Eq.\,[5], we can write

\[ \sigma_c(\omega) = \frac{n e^2}{2 m \gamma} \tilde{\sigma}_c(\omega), \]

where

\[ \tilde{\sigma}_c(\omega) = \gamma \int_{-\infty}^{\infty} dt e^{i \Delta \omega \tau} \text{Tr}_0 \left[ e^{i H_d \tau / \hbar} p_- e^{-i H_d \tau / \hbar} p_+ \right] \]

is the reduced conductivity, and \( \Delta \omega \equiv \omega - \omega_c \) is the frequency detuning, \( |\Delta \omega| \ll \omega_c \).

The major difference of Eq.\,[6] from its counterpart (4) for the low-frequency conductivity is that the Hamiltonians for direct and inverse time propagation (corresponding to the factors \( e^{\pm i H_d \tau} \)) are now different, which is again familiar from the theory of impurity absorption spectra. The reduced cyclotron conductivity can be conveniently written in a form conventional for this theory by introducing the “perturbation” Hamiltonian

\[ \delta H_d \equiv H_d^{(1)} - H_d^{(0)} = -\hbar \gamma \sum_{q} \left( \frac{q^2 T^2}{2} \right) \tilde{V}_q e^{i q R}. \]

In the interaction representation, \( \tilde{\sigma}_c \) can be then simply expressed in terms of a time-ordered exponential,

\[ \tilde{\sigma}_c(\omega) = \gamma \int_{-\infty}^{\infty} dt e^{i \Delta \omega \tau} \text{Tr}_0 \left[ T_\tau \exp \left( -i \int_0^\tau d\tau' \delta H_d(\tau) \right) \right]. \]

Here, time dependence of the operator \( \delta H_d \),

\[ \delta H_d(\tau) \equiv e^{i H_d / \hbar} \delta H_d e^{-i H_d / \hbar}, \quad H \equiv H_d^{(0)}, \]

is generated by the disorder Hamiltonian projected on the LLL, which is given by Eq.\,[7] of the previous section.

We can now define the spectral moments of the cyclotron peak as

\[ M_k^c = \frac{1}{2 \pi \gamma} \int_{-\infty}^{\infty} d\omega \left( \frac{\omega - \omega_c}{\gamma} \right)^k \tilde{\sigma}_c(\omega). \]

Using Eq.\,[8] we write
$$M_k^\ell = \text{Tr}_0 \left( \frac{i}{\gamma} \frac{d}{dt} \right)^k T_\tau \exp \left( -\frac{i}{\hbar} \int_0^\tau \delta H_d(\tau) \ d\tau \right) \bigg|_{t=0}. \quad (43)$$

We note that, similar to the case of the peak of low-frequency conductivity discussed in the previous section, we are calculating here the moments of the cyclotron peak only, whereas the small ($\propto \gamma/\omega_c$) background from the correlators neglected in obtaining Eq. (34) is projected away, as are also the peaks of $\sigma_{xx}(\omega)$ at $\omega \approx n\omega_c$ with $n \neq 1$.

### A. Tails of the cyclotron resonance peak

As in the previous section, let us first discuss the asymptotic form of the cyclotron peak comparatively far from resonance, $|\Delta \omega| \gg \gamma$ (yet $|\Delta \omega| \ll \omega_c$). If we introduce the exact eigenstates of the Hamiltonian (35) for the lowest $|0, m\rangle$ and the first excited $|1, m\rangle$ Landau levels, with energies $E_m^{(0)}$ and $E_m^{(1)}$, respectively, the expression (33) for the reduced conductivity can be written in the form

$$\tilde{\sigma}_c(\omega) = 2\pi\hbar\gamma \sum_{m,n} \delta(E_m^{(1)} - E_n^{(0)} - h\omega)|\langle 1, m|p_+|0, n\rangle|^2.$$  

(44)

As for the low-frequency conductivity considered in the previous section, the conductivity tail is determined by large optimal fluctuations of the disorder potential. The problem of the optimal potential for cyclotron resonance was previously considered by Ioffe and Larkin [14]. They used an ansatz of a rotationally-symmetric optimal potential

$$V_{opt}^{IL} = 2\pi V_0|\Phi_0|^2 + 2\pi V_1|\Phi_1|^2,$$  

(45)

where $\Phi_0 = \psi_{0,0}(r)$, $\Phi_1 = \psi_{1,-1}(r)$ are the functions of the lowest and first excited Landau levels centered at the same origin, with magnetic quantum numbers 0 and $-1$, respectively. This results in the asymptotic form of the cyclotron resonance absorption peak $\sigma_c \propto \exp(-8\Delta\omega_2/\gamma^2)$, for the range $\hbar\gamma \ll k_BT$.

We argue that the transition probability between the states with energy separation $E_n^{(1)} - E_m^{(0)} = \Delta\omega + \omega_c$ is exponentially increased if the cyclotron orbit centers of these states are permitted to shift with respect to each other. This happens despite the associated decrease of the overlap integral.

The calculation of the tails of the cyclotron resonance absorption peak is very similar to that in Sec. II A. We begin by writing the averaging in terms of a functional integral [14], with the energy conservation taken into account using a Lagrange multiplier [as in Eq. (17)] but with different Hamiltonians for $E_i$ and $E_0$. If we neglect the dependence of the transition matrix element on $V(r)$, then for the optimal potential we obtain an equation similar to Eq. (45). However, in contrast to Ref. [14], we permit the centers of the wave functions $\Phi_0$ and $\Phi_1$ to be shifted with respect to each other.

A remarkable feature of this simplified variational problem is that, in the neglect of overlapping of the displaced wave functions, the same value of the variational functional [except for the overlap term] is obtained for the trial wave functions of the first Landau level with the magnetic quantum numbers -1 or 0, i.e., $\psi_{1,-1}$ or $\psi_{1,0}$, or for any their linear combination.

For a displacement $R$ between the centers of the hump and well of the optimal potential, the transition matrix element is $|\langle \psi_1|p_+|\psi_0\rangle| \approx \exp(-R^2/4l^2)$. The optimal distance $R^2 \approx 4l^2 \ln[(\omega - \omega_c)^2/\gamma^2]$ is found by maximizing the expression with the matrix element present. As in the case of the low-frequency conductivity, this distance increases as the frequency is tuned away from resonance.

The variational result for the conductivity tail is

$$\tilde{\sigma}_c(\omega) \propto \exp\left(-\frac{8}{3\gamma^2}(\omega - \omega_c)^2\right).$$  

(46)

This tail is much broader, with the exponent reduced by a factor of 3, compared to the result of Ref. [14].

### B. The center of the cyclotron absorption peak

Generally, we do not expect $\tilde{\sigma}_c(\omega)$ to display a non-analytic dip at the center of the cyclotron absorption peak. Indeed, the power-law singularity (24) of the low-frequency conductivity can be associated with quantum interference which leads to eventual localization of all states except for one (or maybe a few) at the band center. The expression [14] for the cyclotron resonance absorption has a structure which differs from that for the low-frequency conductivity. In particular, it contains an extra phase factor from the Hamiltonian $\delta H_d$ [14] which represents the difference in the random potential experienced by an electron at the two Landau levels. This phase factor should give rise to an exponential damping, and related suppression of the interference effects at long times. Consequently, the conductivity is expected to be smooth near $\omega_c$.

Another way to see this is based on the following arguments. The suppression of the low-frequency conductivity for $\omega \to 0$ may be attributed to level repulsion between overlapping localized states. This repulsion is comparatively small for states of relatively large radii, with energies close to the band center. Indeed, only such states contribute to the low-frequency conductivity, as we saw in Sec. [14]. On the other hand, resonant cyclotron absorption is due to transitions between different Landau levels. Although the central part of the absorption
peak is formed by transitions between strongly overlapping states, the involved states are eigenstates of different Hamiltonians, with random parts \( H_d^{(0)} \) and \( H_d^{(1)} \). Their wave functions have different spatial structures and their energies are essentially uncorrelated, except for states deep in the tails of the Landau levels. Consequently, we expect no suppression of transitions at frequencies close to \( \omega_c \). This argument is in agreement with the results of the method of moments presented in the next subsection and Fig. 2.

C. Spectral moments of the cyclotron peak

We will now calculate the spectral moments \( \bar{\sigma}_c(\omega) \). Because all states of the lowest Landau level are equally populated, the reduced conductivity is symmetric with respect to \( \omega_c \), i.e., \( \bar{\sigma}_c(\omega_c + \Delta \omega) = \bar{\sigma}_c(\omega_c - \Delta \omega) \). Therefore all odd moments vanish, \( M_{2k+1} = 0 \). The main difference is that the prefactor now is a complicated polynomial, a combination of products of terms which are linear in the squared wave numbers \( q^2 \).

This strongly complicated the numerical procedure. In particular, we failed to find any symmetries to reduce the computational overhead, and graphical representations were of little help. We were also unable to categorize different terms as described in Appendix B for the low-frequency conductivity. Instead, we developed the computer algebra package GaussInt for Mathematica, capable of handling the integration of high dimensional Gaussian integrals in a manageable time frame, and used the brute-force approach calculating all terms analytically. For \( k = 0, 1, \ldots, 5 \) we obtained:

\[
M_{2k} = 1; \frac{1}{2}; \frac{37}{64}; \frac{52043}{55296}; \frac{52043}{248832000000}; \frac{2969405418835327}{648069633391411761172111687680000000},
\]

(47)

and the corresponding approximate values

\[
M_{2k} \approx 1.000; 0.500; 0.578; 0.941; 1.909; 4.582.
\]

The values of the moments with \( k = 0, 1, 2 \) were also independently confirmed analytically.

D. Reconstruction of frequency-dependence

As a first step, we reconstructed \( \bar{\sigma}_c(\omega) \) using a standard expansion in Hermite polynomials,

\[
\bar{\sigma}_c(\gamma x) = \sum_n B_n H_n(\sqrt{8/3} x) \exp(-8x^2/3).
\]

The coefficients \( B_n \) were recursively expressed from the calculated moments. We discovered that although the convergence is fast far from the center of the peak, it is noticeably slower close to the center [we emphasize, however, that we reached convergence, in contrast to the similar expansion for the low-frequency conductivity in Fig. 2, where the convergence was not reached for 14 moments]. Within this approach, the number of calculated moments is apparently insufficient for restoring the entire function \( \bar{\sigma}_c \) with desired accuracy. The corresponding result is shown with dashed line in Fig. 2.

Much faster convergence was achieved when \( \bar{\sigma}_c(\omega) \) was restored using a continued fraction expansion. We applied an algorithm similar to that used to reconstruct the LLL density of states from its frequency moments for an arbitrary correlated random potential. The steps involved in this process are summarized in Appendix C. As one can see from Fig. 2, the convergence is very fast.

The resulting shape of the cyclotron absorption peak is shown in Fig. 2. We believe that the deviation from the exact value is within the width of the curve.

![Fig. 7. Approximating \( \bar{\sigma}_c \) with continued fractions. (a) The convergence with increasing number of moments \( M_{2k} \) is extremely fast: the curves lie on top of each other already for \( k = 3,4,5 \). (b) A comparison between the continued-fraction (solid line) and the Hermite polynomial approximation (dashed line) for \( k = 5 \). Convergence is much faster with continued fractions.](image-url)
IV. CONCLUSION

In conclusion, we have analyzed the low-frequency single-electron magnetoconductivity and cyclotron resonance absorption of a nondegenerate 2D electron system in a quantizing magnetic field. We considered the experimentally important parameter range where the width of the Landau levels is less than temperature, so that all states within the lowest Landau level are equally populated. In this range, by combining the ideas of the scaling theory of the IQHE, the method of optimal fluctuation, and the method of spectral moments, we obtained highly accurate numerical results throughout the frequency domain where the conductivity displays peaks.

We found that, in contrast to the prediction of the SCBA or other mean-field theories, the low-frequency conductivity displays a peak at a nonzero frequency, as shown in Fig. 1. For short-range disorder, the position of the peak is given by

\[ \omega_m \approx 0.26\gamma. \]  

(48)

For \( \omega \to 0 \), the single-electron conductivity displays a universal power-law dispersion \( \sigma_{xx} \propto \omega^{\mu} \), which is related to the scaling behavior of the localization length as a function of the distance in energy from the center of the disorder-broadened Landau level. On the other hand, the peak of the cyclotron resonance does not display such singular behavior and is not shifted away from \( \omega_c \), as seen from Fig. 2. Both peaks have Gaussian tails, with different exponents [see Eqs. (13), (46)].

Experimentally, it is more feasible to investigate the magnetoconductivity at a given nonzero frequency \( \omega \) as a function of the external magnetic field \( B \). The corresponding representation of our results is given in Fig. 3 for the scaled conductivity \( \sigma_s(B;\omega) \),

\[ \sigma_s \equiv \sigma_s(B;\omega) = \left[ \frac{B_0(\omega)}{B} \right]^{1/2} \frac{\tilde{\sigma}(\omega)}{\sigma(\gamma)}, \]  

(49)

where the scaling factor \( \tilde{\sigma}(\gamma) \approx 1.08 \), and the scaling field \( B_0(\omega) \) is defined by the equation \( \gamma(B_0) = \omega \). The magnetoconductivity \( \sigma_{xx} \) is related to \( \sigma_s(B;\omega) \) by a factor which is independent of \( B \) (but depends on \( \omega \)),

\[ \sigma_{xx}(\omega) = \frac{\tilde{\sigma}(\gamma)}{4\pi} \frac{\hbar}{k_B T} \frac{n e^2}{m \omega \tau_0} \sigma_s(B;\omega). \]  

(50)

Here, \( \tau_0^{-1} = mv^2/\hbar^3 \) is the rate of electron scattering by the short-range potential in the absence of the magnetic field. The frequency-dependent scaling field in Eq. (19) is related to \( \omega \) and \( \tau_0 \) by the expression \( B_0(\omega) = \pi ne^2/\hbar^2 c \).

In the self-consistent Born approximation, the function \( \sigma_s(B;\omega) \) decays with the increasing magnetic field as \( B^{-1/2} \), for \( B \gg B_0(\omega) \). With the localization effects taken into account, this dependence becomes steeper, with \( B^{1/2}\sigma_s \propto B^{-\nu/2} \), as illustrated in Fig. 8.

Within the single-electron approximation, the restriction on the magnetic field from above is imposed by the condition \( \hbar \gamma \ll k_B T \), which is equivalent to \( \omega_c \ll \tau_0 (k_B T/\hbar)^2 \), for the short-range disorder potential. This inequality can be fulfilled simultaneously with \( B \gg B_0(\omega) \) provided \( h\omega \ll k_B T \). The restriction on the magnetic field from below necessary for the system to be in the lowest Landau level, \( h\omega_c \gg k_B T \), can hold for \( B \sim B_0(\omega) \) and \( h\omega \ll k_B T \) provided \( k_B T \gg h\tau_0^{-1} \).

The latter inequality is often fulfilled for electrons on helium surface. In this case, for \( T < 0.9 \) K the random potential \( V(r) \) is due mostly to capillary waves, ripplons. It has a small correlation length and is quasistatic. For electron densities \( n \approx 0.5 \times 10^8 \) cm\(^{-2} \) and \( T = 0.7 \) K, the value of \( \tau_0 \) is as big as \( \approx 2 \times 10^{-8} \) s (see Refs. 3, 28). For lower \( T \), the mobility which corresponds to the effective \( \tau_0 \approx 10^{-7} \) s has been observed by Shirahama et al. [9]. The condition \( h\tau_0^{-1} \ll k_B T \) can thus be easily met. Therefore the results of the present paper fully apply to electrons on helium as long as one can use the single-electron approximation.

![FIG. 8. Reduced ac magnetoconductivity \( \sigma_s \) (Eq. 50) at a nonzero frequency \( \omega \) as a function of the reduced magnetic field \( B/B_0(\omega) \propto B \omega^{-2} \). In order to demonstrate the anomalous single-electron behavior, \( \sigma_s \) is also plotted with an extra factor \( (B/B_0)^{1/2} \). For large \( B \), the single-electron conductivity displays scaling behavior, \( B^{1/2}\sigma_s \propto B^{-\nu/2} \).](image)
APPENDIX A: GUIDING CENTER FORMALISM

Here we remind the basic expressions of the guiding center formalism needed to derive simplified expressions for the low-frequency conductivity at a given Landau level. Time evolution of the momentum operator \( p = -i\hbar \nabla + (|e|/c)A \) in Eq. (B1) is determined by the Hamiltonian \( H_0 + V(r) \) where \( V(r) \) is the scattering potential and

\[
H_0 = \hbar \omega_c \left( p_+ + p_- + \frac{1}{2} \right).
\]

Here, \( p_\pm \) are the Landau level raising and lowering operators

\[
p_\pm = (p_x \mp ip_y)/\sqrt{2}\hbar m\omega_c, \quad [p_-, p_+] = 1.
\]

The choice of signs corresponds to \( B_2 = -|B| < 0 \).

The guiding center coordinates are defined as

\[
R \equiv (X, Y): \quad X = x + \frac{p_y}{m\omega_c}, \quad Y = y - \frac{p_x}{m\omega_c}.
\]

They commute with the momentum operator, \([R, p] = 0\), but not with each other, \([X, Y] = -i\hbar^2\). To express the disorder potential in terms of these variables we expand it in Fourier series, \( V(r) = \sum_q V_q \exp(iqr) \), which gives

\[
V(r) = \sum_q V_q e^{iqR - q^2\hbar^2/2} e^{i(q-p+e^{-1}q+q_-,1)}(A1)
\]

where \( q_\pm = (q_x \mp iq_y)/\sqrt{2} \). Introducing the operators of projection to the \( n \) th Landau level \( P_N \), we can write the projected disorder potential as

\[
\tilde{V}^{(N)}(r) \equiv P_N V(r) P_N = \hbar \gamma P_N \sum_q V_q e^{iqR}, \quad (A2)
\]

\[
\tilde{V}_q^{(N)} = (V_q/\hbar\gamma) L_N(q^2\hbar^2/2) \exp(-q^2\hbar^2/4), \quad (A3)
\]

where \( L_N(z) \) is the \( N \) th Laguerre polynomial.

Using the commutation relation \([e^{iqr}, p_\pm] = lq_\pm e^{iqr}\), we can evaluate the Fourier-transformed current-current correlator in Eq. (B1) as

\[
\left[1 - \left(\frac{\omega}{\omega_c}\right)^2\right] \langle p_x(t) p_x(0) \rangle \omega = \frac{i\omega}{\omega_c} \tilde{V}^{(X)}(r(t)) \tilde{V}^{(X)}(r(t)) - \frac{1}{\omega_c} \frac{\partial^2}{\partial y^2} V(r(t)) p_x(0), \quad (A4)
\]

where we use the notation

\[
\langle p_x(t) p_x(0) \rangle \omega = \int_{-\infty}^{\infty} dt e^{i\omega t} \langle p_x(t) p_x(0) \rangle.
\]

The correlators in the r.h.s. of Eq. (A4) can be iterated similarly, and the whole current-current correlator can be expressed in terms of the correlators of the derivatives of the potential \( V \) (cf. Ref. [13]).

In the adiabatic limit, \( \omega \ll \omega_c \), the first term in the r.h.s. of Eq. (A4) vanishes, and from this equation or directly from the equation of motion, for times slow compared to \( \omega_c^{-1} \), we can identify

\[
p_x(t) \to -\frac{1}{\omega_c} \frac{\partial}{\partial y} V(r(t)) = -\frac{i}{\omega_c} \sum_q q_y V_q e^{iqr(t)}.
\]

The rightmost part of this expression is proportional to the time derivative of the guiding center coordinate,

\[
\dot{X}(t) = -(l^2/\hbar) \sum_q q_y V_q e^{iqr(t)}
\]

[in the right-hand sides of the last two equations one should keep only the terms which do not contain fast-oscillating factors \( \exp(iN\omega_c t) \) with \( N \neq 0 \). We can then further identify the projected part of \( p \) with \( m\dot{R} \), which gives Eqns. (10) and (11).]
The inner sum is taken over all binary sequences \( b = (b_1, b_2, \ldots, b_{2k}) \), with \( b_i = 0, 1 \). They label possible combinations of signs which arise from writing the sines in Eq. (51) in terms of exponentials. The quantity \( \sigma\{b\} = \sum b_i \). The antisymmetric \((2k+2)\)-dimensional square matrix \( \hat{B}^{(b)} \) has the following structure:

\[
\hat{B}^{(b)} = \begin{pmatrix}
0 & c_1 & c_2 & \cdots & c_{2k} & 0 \\
-c_1 & 0 & c_2 & \cdots & c_{2k} & 0 \\
-c_2 & -c_1 & 0 & \cdots & c_{2k} & 0 \\
\vdots & \ddots & \ddots & \ddots & \ddots & \vdots \\
-c_{2k} & -c_{2k} & \cdots & -c_{2k} & 0 & 0 \\
0 & \cdots & \cdots & \cdots & 0 & 0
\end{pmatrix}, \quad (B2)
\]

where \( c_i = (-1)^i b_i \).

Because of the \( \delta \)-functions in the contraction function \( C\{q\} \), integration in (B1) has to be performed over \( k+1 \) independent wave vectors. Up to a pre-factor \( \langle q_1 q_{2k+2} \rangle \), the integrand is an exponential of the quadratic form \( (b^2)/2 \sum q_i A_{ij} q_j \), where \( i, j = 1, \ldots, k+1 \). The matrix elements \( A_{ij} \) are themselves \( 2 \times 2 \) matrices, \( A_{ij} = -i \delta_{ij} + a_{ij} \sigma_y \), where \( \sigma_y \) is the Pauli matrix, and \( a_{ij} = -a_{ji} = 0, \pm 1 \).

For a given contraction \( C\{q\} \) and a given vector \( b \) in (B1), \( i.e. \), for the corresponding matrix \( a_{ij} \), the Gaussian integrals can be evaluated exactly, giving

\[
I[a] = -\frac{1}{4^k} \prod_{i=1}^{k+1} (1 + \lambda_i^2)^{-1/2} \sum_{m=1}^{k+1} \frac{u_{m,1} u_{m,x}}{1 + \lambda_m^2}, \quad (B3)
\]

where \( i \lambda_m \) are the eigenvalues of the antisymmetric matrices \( a_{m,m} \), and \( u_{m,n} \) are the components of the corresponding eigenvectors. The subscript \( x \) takes on the value \( x = k+1 \) if \( q_1 \) and \( q_{2k+2} \) are independent variables in the pairing procedure, whereas for \( q_1 = -q_{2k+2} \) we should set \( x = 1 \) and additionally multiply Eq. (B3) by \( (-1)^i \).

Given the large number of terms and the computational price of calculating the exact values in each term, we did not calculate each integral exactly. Instead, the value of a given term (specified by the choice of contraction \( C\{q\} \) and the binary sequence \( b \)), was calculated numerically with double precision. With integer-valued matrices \( a_{ij} \), the number of different values was not exceedingly large, and we used the obtained approximate values (B3) to assign each term to an equivalence class. The individual weights can be positive or negative, depending on the parity of \( \sigma\{b\} \). This procedure was used instead of much more tedious manual classification of high-order diagrams. (In addition, we checked for several values of \( k \) that the weights corresponding to special diagrams in Fig. 4 are indeed equal to zero.

After the classification of diagrams was completed, the exact value of the integral in each class was obtained by taking a representative contracted matrix \( a_{ij} \) and calculating the Gaussian integral \( I[a] \) algebraically. These integrals have rational values; the final answer for \( M_{2k} \) was obtained as a weighted sum of these rational numbers with their respective bin weights. As a test, we compared the results for \( k = 0, 1, 2 \) with explicit analytic calculation.

**APPENDIX C: CONTINUED FRACTION EXPANSION**

The Stieltjes transform of the conductivity \( \tilde{\sigma}_c \) is defined by

\[
R(z) = \frac{1}{2\pi i} \int_{-\infty}^{\infty} d\omega \tilde{\sigma}_c(\omega + \omega_c), \quad \Re \omega > 0, \quad (C1)
\]

while the inverse transformation has the form

\[
\tilde{\sigma}_c(\omega + \omega_c) = 2 \lim_{\varepsilon \to 0^+} \Re [R(\varepsilon + i\omega/\gamma)], \quad (C2)
\]

The function \( R \) is related to the moments \( \{2\} \) by the expression

\[
R(z) = \sum_{k=0}^{\infty} e^k M_k z^{-k-1}. \quad (C3)
\]

We now construct an approximation for \( \{2\} \) which applies for an even function \( \tilde{\sigma}(\omega + \omega_c) = \tilde{\sigma}(-\omega + \omega_c) \), allows for the Gaussian asymptotics \( \{1\} \)

\[
\lim_{\omega \to \pm \infty} \frac{\gamma^2}{\omega^2} \ln \tilde{\sigma}_c(\omega + \omega_c) = -\frac{1}{2\alpha}, \quad \alpha = \frac{3}{16}, \quad (C4)
\]

and requires only a finite number of moments.

It is known [15] that an odd function \( R(z) \) can be expanded into a Jacobi-type continued fraction,

\[
R(z) = \frac{\sum_{j=1}^{\infty} \frac{\Delta_j}{z}}{\Delta_j \geq 0}, \quad (C5)
\]

where we use the notation

\[
\frac{\sum_{j=1}^{\infty} \frac{\Delta_j}{z}}{\Delta_j \geq 0} = \frac{1}{z + \frac{\Delta_1}{z + \frac{\Delta_2}{z + \cdots}}}, \quad (C6)
\]

for the continued fraction with coefficients \( \Delta_j \) and variable \( z \). The first \( J \) continued-fraction coefficients \( \Delta_1, \ldots, \Delta_J \) are obtained from the normalized moments \( M_2, \ldots, M_{2J} \) by expanding the power series \( \{C\} \) into the continued fraction \( \{C\} \) using an efficient recursive algorithm [16]. Having obtained only a finite number of coefficients \( \Delta_j \), we need to estimate the remaining ones. Fortunately, the asymptotic behavior \( \{C\} \) implies the following asymptotically linear growth for the continued-fraction coefficients
\[
\lim_{j \to \infty} \frac{\Delta_j}{j} = \alpha.
\]  
(C7)

Therefore, if the first \(J\) coefficients \(\Delta_1, \ldots, \Delta_J\) are found, one can then construct an approximation \(R^{(J)}(z)\) to \(R(z)\) by linearly continuing \(\Delta_j\) for \(j > J\),

\[
R^{(J)}(z) = \infty \prod_{j=1}^{\infty} \left( \frac{\Delta_j}{z} \right),
\]  
(C8)

where

\[
\Delta_j^{(J)} = \begin{cases} 
\Delta_j & \text{for } j \leq J \\
\Delta_j + \alpha(j-J) & \text{for } j > J
\end{cases}
\]  
(C9)

A continuous fraction with a linearly increasing coefficient can be written in terms of the Whittaker parabolic cylinder function \(D_\nu\),

\[
T(\beta, \alpha, z) = \infty \prod_{k=1}^{\infty} \left( \frac{\beta + \alpha j}{z} \right) = \frac{D_{-\beta/\alpha-1}(\alpha^{-1/2}z)}{\alpha^{1/2}D_{-\beta/\alpha}(\alpha^{-1/2}z)},
\]

which is valid if \(\alpha > 0, \beta + \alpha > 0\) and \(\Re z > 0\), so that we can write Eq. (C8) as

\[
R^{(J)}(z) = \frac{1}{z + \frac{\Delta_1}{\Delta_1^{(J)}} \cdots \frac{\Delta_{J-1}}{\Delta_{J-1}^{(J)}} \frac{\Delta_J}{z + \Delta_J T(\Delta_J, \alpha, z)}},
\]  
(C10)

Applying the inversion formula (C2) immediately gives the restored cyclotron resonance absorption \(\tilde{\sigma}_c(\omega)\) as shown in Fig. 7.
