We report an experimental study of a magnetic liquid drop deposited on a superhydrophobic substrate and subjected to vertical vibrations in presence of a static magnetic field. It is well-known that a flattened drop of usual liquid displays oscillating lobes at its periphery when vibrated. By adding ferromagnetic nanoparticles to a water drop and varying the strength of the magnetic field, we are experimentally able to efficiently tune the resonant frequencies of the drop. By using conservation energy arguments, we show that the magnetic field contribution is equivalent to adding an effective negative surface tension to the drop. Our model is found in good agreement with the experiments with no fitting parameter.

PACS numbers: 47.65.Cb,47.55.D-,47.35.Pq

When a drop of liquid is dynamically driven by an external force, its free-surface generally displays an oscillating pattern at the drop resonant frequency. At a fundamental level, the dynamical study of such an oscillating drop occurs in various domains at different scales. Indeed, liquid drop behavior is used to model stellar mass collisions or neutron-star oscillations in astrophysics [1], and nuclei in nuclear fission [2, 3], or in cellular biology [4]. It is also involved in metrology for measuring viscosity of liquids [5] or surface tension of molten materials [6, 7]. At a more practical level, it includes printing (ink drop generation), mixing of drop clouds, droplet manipulations in microfluidic, optofluidic, and pharmaceutical industry [8]. Since the pioneer works of Rayleigh [9], the resonant frequencies of a drop have been studied experimentally by means of different forcing mechanisms: water drop on a vibrating plate [10–12] or on a vibrating bath [13, 14], in microgravity [15], by acoustic or air-flow levitation [16, 17], by levitating it on its own vapor (Leidenfrost drops) [18–20], or by Lorentz force for a metal liquid drop [21, 22]. A new challenge would be to accurately control and tune the free oscillations of a drop in a non-intrusive way. Notably, it would be of primary interest to be able to shift the resonant frequencies of the drop to avoid, for instance, some annoying frequency bands in practical situations.

In this Letter, we study the dynamics of a flattened drop of magnetic fluid deposited on a superhydrophobic substrate vertically vibrated in presence of a weak magnetic field of tunable amplitude. The fluid used is a ferrofluid constituted of a stable suspension of nanometric magnetic particles diluted in a carrier liquid (water). Above a critical acceleration of vibrations, the drop undergoes a parametric instability leading to an azimuthal pattern around the drop that oscillates at half the forcing frequency. A star-shaped drop is then observed made of several oscillating lobes. We observe that the resonant frequencies of the drop depend on the strength of the field. We show quantitatively and theoretically that we are able to shift these frequencies by tuning the effective surface tension of the drop through the field. Indeed the contribution of the magnetic field is equivalent to the one of a negative surface tension. Including nanometric magnetic particles within a drop appears thus as a first step to be able to control and tune the free oscillations of a drop, such a magnetic fluid being known to shift the onsets of usual hydrodynamics instabilities (such as Kelvin-Helmholtz, Rayleigh-Taylor or Rayleigh-Plateau ones) [23, 24]. Finally, note that ferrofluid drop manipulation with a magnet is also an important task in microfluidics or lab on chip technology [25–27], and in dynamic self-assembly phenomena [28].

The experimental set-up is shown in Fig. 1. A volume of ferrofluid ($V = 1$ mL) is put on a plate. Due to gravity, the drop is flattened and looks like a puddle (radius, $R = 9.7$ mm, and thickness, $h = 3.4$ mm - see inset of Fig. 1). The plate was coated with a spray [29], to obtain a drop/substrate contact angle measured of roughly 165°. Such superhydrophobic substrate is crucial to minimize the pinning force of the drop at the contact line, and thus to obtain much better reproducible experiments [30, 31]. The plate is then subjected to vertical sinusoidal vibrations by means of an electromagnetic shaker. The frequency and amplitude of vibrations are in the range $0 \leq f_v \leq 52$ Hz and $0 \leq A \leq 3$ mm, respectively. An accelerometer is fixed below the plate to measure the normalized acceleration of vibrations $\Gamma = A \omega^2/g$ with $\omega = 2\pi f_v$ and $g = 9.81$ m.s$^{-2}$ the acceleration of gravity. One has $0 \leq \Gamma \leq 4$. The ferrofluid puddle on the plate is placed between two horizontal coils (38 cm in mean diameter), generating a vertical static magnetic field $B$ in the range $0 \leq B \leq 100$ G, 99% homogeneous in the horizontal plane [32]. The drop oscillations are recorded by means of a high-speed camera (PhantomV10) located above the drop, with a 1000 frames per second sampling and a 1600 × 1200 pixels resolution. The ferrofluid used is an ionic aqueous suspension synthesized with 12.4% by volume of maghemite particles ($\text{Fe}_2\text{O}_3$; 7 ± 0.3 nm in diameter) [33]. Nanoparticle diameter and magnetic field values are small enough to avoid sedimen-
tation or agglomeration due to vibrations, gravity and magnetic fields [23]. Ferrofluid properties are: density, \( \rho = 1550 \text{kg.m}^{-3} \), surface tension, \( \gamma = 43 \pm 3 \text{mN.m}^{-1} \), magnetic susceptibility, \( \chi(B) \approx \chi(B = 0) = 1 \) [34], magnetic saturation, \( M_{\text{sat}} = 36 \times 10^3 \text{A.m}^{-1} \) and dynamic viscosity, \( 1.4 \times 10^{-3} \text{N.s.m}^{-2} \). Its capillary length is then \( l_c = \sqrt{\gamma/(\rho g)} = 1.7 \text{mm} \).

To accurately measure azimuthal drop oscillations, we use large flattened drops (\( R \gg l_c \)), see inset of Fig. 1. The Bond number, quantifying the ratio between gravity and capillary forces acting on the drop, is \( \text{Bo} \equiv (R/l_c)^2 \approx 33 \). The ratio between magnetic and capillary forces is quantified by the magnetic Bond number \( \text{Bo}_m = B^2 R/(\mu_0 \gamma) \) with \( R \) the puddle radius, \( \mu_0 = 4\pi \times 10^{-7} \text{H.m}^{-1} \) the magnetic permeability of the vacuum. For our range of \( B \), one has \( \text{Bo}_m \leq 2 \). Moreover, the magnetic effect is much smaller than gravity one (\( \text{Bo}_m/\text{Bo} \leq 0.06 \)) meaning that the strength of \( B \) is weak enough to not deform the flattened region of the puddle at rest.

We first carry out experiments with no magnetic field (\( B = 0 \)). Figure 2 shows the parametric instability of a ferrofluid puddle subjected to vertical sinusoidal vibrations. Above a critical acceleration of vibration, an azimuthal pattern is observed normal to the vibration direction. When the forcing frequency \( f_e \) is increased (\( 0 \leq f_e \leq 52 \text{Hz} \)), the number \( n \) of lobes, oscillating radially at \( f_e/2 \), increases from \( n = 2 \) to \( 9 \) (from left to right and top to bottom). See [35] for a movie. Magnetic field \( B = 0 \). Volume \( V = 1 \text{mL} \).

![Image](72x585 to 281x740)

**FIG. 1.** (Color online) Experimental setup. Bottom inset shows a schematic of the puddle at two phases of the vibration. Top inset: top view of the ferrofluid puddle at rest.

![Image](362x683 to 445x728)

**FIG. 2.** Top view of the azimuthal pattern displayed around the drop as a function of \( f_e \). Above a critical acceleration of vibration, an azimuthal pattern is observed normal to the vibration direction. The number \( n \) of lobes, oscillating radially at \( f_e/2 \), increases from \( n = 2 \) to \( 9 \) (from left to right and top to bottom). See [35] for a movie. Magnetic field \( B = 0 \). Volume \( V = 1 \text{mL} \).

The resonant frequencies \( f_e \) of such an inviscid drop are independent of the nature of the forcing and arise from an interplay between inertia and surface tension effects. In the limit \( 2R \gg h \), the flattened drop shape (see inset of Fig. 1) is approximated by a cylindrical column of fluid. The radial amplitude of the lobes \( a_n(t) \) is then governed by an harmonic oscillator equation of eigenfrequency \( \omega_n \) [36, 37]

\[
\frac{d^2 a_n(t)}{dt^2} + \omega_n^2 a_n(t) = 0, \quad \omega_n^2 = \frac{\gamma}{\rho R^3 n(n^2 - 1)} \quad (1)
\]

with \( \omega_n = 2\pi f_n \).

Now, applying a vertical sinusoidal vibration of the substrate forces parametrically the drop by modulating gravity \( g \rightarrow g(t) = g[1 + \Gamma \cos(\omega_e t)] \) with \( \Gamma = A \omega_e^2/g \). Besides, the thickness \( h \) of the puddle is usually given [10, 13] by the quasi-static balance between gravity and capillary energies per unit volume (\( 2\gamma/h \approx \rho gh/2 \)), i.e. \( h \approx 2l_c = 2\sqrt{\gamma/(\rho g)} \). The hypothesis of constant volume of the puddle \( V = \pi R^2 h \), then gives its radius \( R = \sqrt{V/(\pi h)} \). Thus, a temporal modulation of gravity \( g(t) \) induces those of the puddle thickness \( h(t) \sim g(t)^{-1/2} \), radius \( R(t) \sim h(t)^{-1/2} \sim g(t)^{-1/4} \), and eigenfrequencies \( \omega_n^2(t) \sim R(t)^{-3} \sim g(t)^{-3/4} \) using Eq. (1). For weak acceleration of vibrations \( \Gamma \ll 1 \), the parametric oscillator equation governing the amplitude of the lobes \( a_n(t) \) then reads [10]

\[
\frac{d^2 a_n(t)}{dt^2} + \omega_n^2 [1 - \frac{3}{4} \Gamma \cos(\omega_e t)] a_n(t) = 0 \quad (2)
\]

Equation (2) is the Mathieu’s equation whose solutions are marginality curves (or instability “tongues”) separating stable zones (no deformation of the drop) and unstable zones where azimuthal standing waves at the drop periphery oscillates at half the forcing frequency (\( f_e/2 \)), near the resonant frequencies \( f_n \) [37]. This corresponds to the parametric instability shown in Fig. 2.

These tongues of instability are displayed in Fig. 3 in an acceleration/frequency phase space (\( \Gamma_c/\Gamma_{c}^{\text{min}} vs f_e \)) for \( B = 0 \) (open-symbols). Data were obtained experimentally for various \( f_e \) by increasing \( \Gamma \) until we observe
lobes at critical acceleration $\Gamma_c$. $\Gamma_{c\text{\tiny \textit{min}}}$ is the minimum critical acceleration of each tongue. Equation (2) predicts that the increase of the marginality curve occurs at twice the eigenmode $f_c = 2f_n$. Notice that experimental values for $f_n$ are smaller than values given by Eq. (1). This difference ($\leq 18\%$) may be explained by the fact that the quasi-static approximation yielding Eq. (2) is valid only for low-frequency excitation. At higher frequency, the existence of axisymmetric modes shifts the minima of the marginality curves \cite{38,39}. Indeed, we checked that this difference becomes negligible when we remove these axisymmetric modes by performing a control experiment with a superhydrophobic steady plate in contact with the drop top \cite{10}. One can now wonder what is the effect of an applied vertical magnetic field $B$ on the drop dynamics.

When $B$ is increased for a fixed $n$, we observe that the instability tongue is shifted towards a lower frequency (see arrows in Fig. 5). The minimum of this curve and thus the eigenfrequency $f_n(B)$ are found to decrease with $B$. For $n = 5$, a relative shift of $f_n$ of $16\%$ is observed between extreme values of $B$ used. One defines the absolute shift of the eigenfrequency as $\Delta \omega_n(B) \equiv \omega_n^2(B = 0) - \omega_n^2(B)$, taking thus positive values. We plot in the inset of Fig. 4 the frequency shift $\Delta \omega_n(B)$ as a function of $B$ for different $n$. We find that $\Delta \omega_n(B) \sim B^2$ for our range of $B$ regardless of $n$. All data in the inset of Fig. 4 are found to collapse on a single curve when plotting $\Delta \Omega_n(B)$ as a function of $B^2n^3$ (not shown). In order to compare with the model described below, $\Delta \Omega_n(B)$ is then displayed in the main Fig. 4 as a function of $B^2n(n^2 - 1)$, noting that $n(n^2 - 1) \approx n^3$ for $n \geq 3$.

This frequency shift is not due to a geometrical effect mediated by $B$ such as a drop lengthening along the field direction \cite{24,11,12}. Indeed, using Eq. (1), a decrease of the puddle radius $R$ with $B$ (up to $6\%$ here) would lead to an increase of the resonant frequency, a situation opposite to our observations (see Fig. 5). Moreover, the results of Fig. 4 are found again when adding a steady plate above the drop. Finally, note that no clear dependence of the critical acceleration $\Gamma_{c\text{\tiny \textit{min}}}$ on $B$ is observed.

An elegant way to understand the physical origin of the drop eigenfrequency shift with $B$ is to balance energies involved in this system. In a first step, we assume $B = 0$ and follow Rayleigh’s model \cite{4}. The flattened drop shape is approximated by a cylinder of fluid (see Fig. 5). We denote $S_\perp$ its surface area normal to gravity and magnetic field (i.e. top plus bottom areas) and $S_\parallel$ the peripheral surface area. At rest, they are denoted $S_{\perp,0}$ and $S_{\parallel,0}$. We consider small radial deformations of the peripheral surface of amplitude $a_n(t) \ll R$ around an instantaneous radius $\bar{R}(t)$. In polar coordinates, this reads $r(\theta, t) = \bar{R}(t) + a_n(t)\cos(n\theta)$ (see Fig. 5). $\bar{R}$ is assumed constant with time and thus also $S_\parallel$ due to volume conservation. It is known, since Rayleigh \cite{8}, that the radial deformation $a_n$ induces an increase in $S_\parallel$ (see Figs. 5a-b) as

$$\Delta S_\parallel(t) \equiv S_\parallel(t) - S_{\parallel,0} = \frac{\pi h a_n^2(t)(n^2 - 1)}{2R}$$

where $h$ is the thickness of the drop. This gives an increase of the drop volume $\Delta V \approx 2\pi h a_n^2(t)\bar{R}(t) - \pi a_n^2(t)\bar{R}(t)^3$ that changes by $\Delta V \approx \pi h a_n^2(t)\bar{R}(t) - \pi a_n^2(t)\bar{R}(t)^3$. The fluid mass conservation implies that

$$\Delta \rho V \approx 0$$

where $\rho \approx \rho_f$ is the fluid density and $V \equiv V_0 + \Delta V$. One deduces

$$\frac{\Delta \rho V}{\rho V} \approx \frac{\Delta \rho}{\rho} \approx 0$$

and

$$\frac{\Delta V}{V} \approx \frac{\Delta V}{\rho V} \approx \frac{\Delta \rho V}{\rho V} \approx 0$$

that is valid for large $\rho$.

A second step is to consider the balance of the magnetic and gravitational forces. One defines the critical acceleration $\Gamma_{c\text{\tiny \textit{mag}}}$ by $\Gamma_{c\text{\tiny \textit{mag}}} = \omega_n^2(B = 0)$ for the model of Eq. (1) with no fitting parameter. Inset: Unrescaled frequency shift vs. $B$. Dashed lines have a slope 2.

FIG. 4. (Color online) Eigenfrequency shift $\omega_n^2(B = 0) - \omega_n^2(B)$ as a function of $B^2n(n^2 - 1)$ for different modes $n = 3 (\bullet), 4 (\bigtriangleup), 5 (\bigcirc)$ and $7 (\blacksquare)$. Solid line is the prediction from the model of Eq. (10) with no fitting parameter. Inset: Unrescaled frequency shift vs. $B$. Dashed lines have a slope 2.
Besides, kinetic energy of the liquid reads

\[ \Delta E_k(t) = \gamma \Delta S_\parallel(t). \]  

(4)

Thus, capillary energy increases by

\[ \Delta E_c(t) = \gamma \Delta S_\parallel(t). \]

Besides, kinetic energy of the liquid reads

\[ E_k(t) = \left( \frac{d_\gamma}{dt} \right)^2 \frac{\pi \rho h R^2}{2}. \]  

(5)

The conservation of energy \( d(E_k + E_c)/dt = 0 \) then leads to Eq. (1).

Let us now introduce the magnetic energy \( E_m \) in the Rayleigh’s model. For a linearly permeable ferrofluid of volume \( V \), one has \( E_m = -B \cdot f V \cdot M dV/2 \), with \( B \) the external magnetic field and \( M \) the local ferrofluid magnetization. The determination of \( M \) needs to take into account the ferrofluid boundary conditions. For instance, for a plane parallel to \( B \), one has \( E_m = -\chi V B^2 / (2\mu_0) \) (see Fig. 5a) and for a plane normal to \( B \), \( E_m = -\chi V B^2 / [2\mu_0(1 + \chi)] \) (see Fig. 5b). Thus, the magnetic energy of a ferrofluid layer is smaller when \( B \) is parallel rather than normal to its surface.

For an arbitrary ferrofluid shape, \( M \) is nonuniform and an effective demagnetizing factor \( D \) is usually defined, with \( 0 \leq D \leq 1 \) (depending on the shape), such that

\[ E_m = -\frac{\chi V B^2}{2\mu_0(1 + \chi D)}. \]  

(6)

For volumes bounded by surfaces either parallel or normal to \( B \), we can define the ratio between surface area normal to \( B \) and total surface area, \( r_S = S_\perp / (S_\parallel + S_\perp) \). Using known theoretical values of \( D \) for different geometries, we show in Fig. 6 that \( D \approx r_S \) over the whole range of aspect ratios. This means that \( E_m \) decreases when the aspect ratio favors surfaces parallel to \( B \), i.e. \( D \to 0 \) when \( r_s \to 0 \).

We can then replace the demagnetizing factor \( D \) by \( r_S \) in Eq. (4). The variation of \( S_\parallel \) due to the presence of peripheral lobes induces a variation of \( E_m \) through \( r_s \). Noticing that \( S_{\perp,0} = 2\pi R^2 \) and \( S_{\parallel,0} = 2\pi Rh \) at rest, a first-order Taylor expansion in \( \Delta S_\parallel \) for small deformations \( (a_n \ll R) \) leads to

\[ \Delta E_m(t) = \gamma_m \Delta S_\parallel(t) \]

with

\[ \gamma_m = -\frac{\chi^2 h B^2}{4\mu_0(1 + \chi + h/R)^2}. \]  

(8)

a quantity always negative. Then, using \( \Delta S_\parallel \) from Eq. (3) and energies from Eqs (4), (5) and (7), the conservation of energy \( d(E_k + E_c + E_m)/dt = 0 \) finally leads to the resonant frequencies of the ferrofluid drop

\[ \omega_n^2(B) = \gamma + \gamma_m(B^2) / 2\mu_0 R^3 n(n^2 - 1). \]  

(9)

Using Eq. (1) then leads to

\[ \omega_n^2(B = 0) - \omega_n^2(B) = -\frac{\gamma_m(B^2)}{\rho R^3} n(n^2 - 1). \]  

(10)

The \( B^2 n(n^2 - 1) \) scaling is in good agreement with the one found experimentally (see Fig. 1) as well as for the theoretical prefactor without fitting parameter.

Notice that Eq. (9) includes the usual capillary contribution \( (\gamma) \) and a magnetic one \( (\gamma_m) \) that depends on \( B \). The magnetic term thus plays the role of a negative
surface tension ($\gamma_m < 0$) that thus reduces the drop resonant frequencies. The magnetic field can be then used to tune the effective surface tension, $\gamma_{eff} = \gamma + \gamma_m$, and thus $\omega_n$. For our ranges of $B$, using ferrofluid properties and geometry, one has $\gamma_m \in [-8.5, 0]$ mN.m$^{-1}$, that is up to 20% of $\gamma$. The analogy with surface tension arises from $\Delta E_m = \gamma_m (B^2) \Delta S_{\parallel}$. This means that an increase of the drop surface area parallel to $B$ favors its magnetization and thus decreases $E_m$ since $\gamma_m < 0$. Consequently, $B$ has a stabilizing effect on the lobes. Finally, note that a model of the dynamics of a ferrofluid drop confined between two plates has mentioned such a possible negative surface tension effect, but requires $\chi \ll 1$ and thus cannot apply here where $\chi = 1$.

To conclude, we have studied the dynamics of parametric oscillations of a centimetric ferrofluid drop on a superhydrophobic plate subject to vertical sinusoidal vibrations and a constant magnetic field. By adding ferromagnetic nanoparticles to a water drop, we are able to shift significantly its eigenfrequencies by tuning the magnetic field strength. Using energy conservation, we extend the Rayleigh’s model and show that the resonant frequency shift is well captured by our model with no fitting parameter. We also show that the magnetic field acts as a negative surface tension, and is a way to tune the effective surface tension of the drop. Finally, the weakness of the field strength and the small size of ferromagnetic particles are favorable to miniaturization to plan to control the oscillations of centimeter-to-micro-scale drop in a new non-intrusive way for potential applications.

We thank D. Talbot for the ferrofluid synthesis, M. Berham, P. Brunet, M. Costalonga, and C. Laroche for fruitful discussions, and A. Lantheaume, Y. Le Goas and M.-A. Guedeau-Boudeville for technical help. T. J. was supported by the DGA-CNRS Ph.D. program. This work was partially financed by ANR Turbulon 12-BS04-0005.

[32] The coils are in quasi-Helmholtz configuration and cooled with water circulation, see J. Browaeys, J.-C. Bacri, C. Flamant, S. Neveu and R. Perzynski, “Surface waves in ferrofluids under vertical magnetic field,” Eur. Phys. J. B. 9, 335 (1999).

[33] The ferrofluid synthesis has been performed by D. Talbot, Laboratory LI2C, University Pierre & Marie Curie, Paris according to Massart’s method: R. Massart, ”Preparation of aqueous magnetic liquids in alkaline and acidic media,” IEEE Trans. Magn. 17, 1247 (1981).

[34] For our range of values of $B$, the magnetic susceptibility of the ferrofluid $\chi(B)$ varies less than 3%, thus one fixes $\chi(B) = \chi(B = 0)$.

[35] See Supplemental Material at [URL will be inserted by publisher] for an illustrative movie of oscillations of a ferrofluid puddle ($R \approx 1$ cm in radius) on a superhydrophobic plate (top view). When the vibrating plate frequency increases, the eigenmode number, $n$, increases showing azimuthal waves constituting of $n$ lobes oscillating radially. Vibration acceleration $0 \leq \Gamma \leq 4$. Magnetic field $B = 0$.
