Abstract. We investigate a driven diffusive lattice gas model with two oppositely moving species of particle. The model is motivated by bidirectional traffic of ants on a pre-existing trail. A third species, corresponding to pheromones used by the ants for communication, is not conserved and mediates interactions between the particles. Here we study the spatio-temporal organization of the particles. In the unidirectional variant of this model it is known to be determined by the formation and coarsening of ‘loose clusters’. For our bidirectional model, we show that the interaction of oppositely moving clusters is essential. In the late stages of evolution the cluster size oscillates because of a competition between their ‘shredding’ during encounters with oppositely moving counterparts and subsequent ‘coarsening’ during collision-free evolution. We also establish a nontrivial dependence of the spatio-temporal organization on the system size.

Keywords: driven diffusive systems (theory), traffic and crowd dynamics, traffic models
1. Introduction

Systems of interacting driven particles are of current interest in statistical physics for understanding the fundamental principles of spatio-temporal organization far from equilibrium as well as for possible wide-ranging practical applications \[1, 2\]. The simplest model of this type with only one species of particle is the so-called totally asymmetric simple exclusion process (TASEP). In the TASEP, a particle is picked up randomly and moved forward by one lattice spacing, with the hopping probability \( q_+ \), provided the target site on the one-dimensional lattice is empty.

Most of the earlier models with more than one species of particle \([3]–[10]\) mainly addressed questions on the (im)possibility of spontaneous symmetry breaking, phase separation, etc in one-dimensional stochastic driven systems. Here we extend the two-species models like, for example, the ABC model \([4, 5]\) and AHR model \([6]\), to develop a three-species model\(^4\). The density of the new species introduced in our model, which corresponds to the pheromones secreted by the ants for communication, is not conserved by the dynamics of the system and its coupling to the two other conserved variables leads to uncommon features of the spatio-temporal organizations of the conserved particles. For a special choice of the model parameters our model becomes identical to the AHR model classes (see section 3).

Our model is motivated by a real-life situation where bidirectional ant traffic in an effectively one-dimensional system is observed. Figure 1 shows a hanging cable which is part of an ant trail. Ants prefer moving on the upper side of the cable, which would make the motion strictly one-dimensional. If ants moving in opposite directions meet head-on, after short ‘negotiations’ one of them would switch to the lower part of the cable temporarily in order to make passing possible. Due to the ‘negotiations’ this process leads to slowing down of both the ants. We capture this entire process by an exchange of the positions of the two ants with a sufficiently low probability which corresponds to a slower movement of each of them as compared to a freely moving ant. The mathematical formulation of the model in terms of such exchange probabilities is very similar to the formulations of the class of one-dimensional stochastic models of driven-diffusive lattice gases to which the AHR and ABC models belong.

\(^4\) The number of species would be four if vacancies are also regarded as a different species.

Competition of coarsening and shredding of clusters in a driven diffusive lattice gas

Figure 1. A snapshot of an ant trail on a hanging cable. It can be regarded as strictly one-dimensional. But, nevertheless, traffic flow [12]–[14] in opposite directions is possible as two ants, which face each other on the upper side of the cable, can exchange their positions if one of them, at least temporarily, switches over to the lower side of the cable.

The number of particles leaving a site per unit time is called the flux or current; the flux-versus-density relation is often referred to as the fundamental diagram [12]–[14]. We study interplay of spatio-temporal organization and flow (fundamental diagram) in the system by a combination of analytical arguments and extensive computer simulations.

2. The model

In our model the right-moving (left-moving) particles, represented by $R$ ($L$), are never allowed to move towards the left (right); these two groups of particles are the analogues of the outbound and nest-bound ants in a bidirectional traffic on the same trail. Thus, no U-turn is allowed. In addition to the TASEP-like hopping of the particles onto the neighbouring vacant sites in the respective directions of motion, the $R$ and $L$ particles on nearest-neighbour sites and facing each other are allowed to exchange their positions, i.e., the transition $RL \rightarrow LR$ takes place, with the probability $K$. This might be considered as a minimal model for the motion of ants on a hanging cable as shown in figure 1. When an outbound ant and a nest-bound ant face each other on the upper side of the cable, they slow down and, eventually, pass each other after one of them, at least temporarily, switches over to the lower side of the cable. Similar observations have been made for normal ant trails where ants pass each other after turning by a small angle to avoid head-on collision [16,15]. In our model, as commonly observed in most real ant trails, none of the ants is allowed to overtake another moving in the same direction.

Ants drop a chemical (generically called pheromone) on the substrate as they move forward [11]. They can follow the trail by picking up the ‘smell’ of the trail pheromone provided the pheromone evaporates sufficiently slowly with time. We now introduce a third species of particle, labelled by the letter $P$, which is intended to capture the essential features of pheromone. The $P$ particles are deposited on the lattice by the $R$ and $L$ particles when the latter hop out of a site; an existing $P$ particle at a site disappears when an $R$ or $L$ particle arrives at the same location. The $P$ particles cannot hop but

Figure 2. Nontrivial transitions and their transition rates. Transitions from initial states PL, 0L and 0P are not listed. They can be obtained from those for LP, L0 and P0, respectively, by replacing $R \leftrightarrow L$ and, then, taking the mirror image.

can evaporate, with a probability $f$ per unit time, independently from the lattice. None of the lattice sites can accommodate more than one particle at a time. From now onwards, we shall refer to this model as the PRL model. The state of the system is updated in a random-sequential manner. Because of the periodic boundary conditions, the densities of the $R$ and the $L$ particles are conserved. In contrast, the density of the $P$ particles is a non-conserved variable. The distinct initial states and the corresponding final states for pairs of nearest-neighbour sites are shown in figure 2 together with the respective transition probabilities.

3. Results

Suppose $N_+$ and $N_- = N - N_+$ are the total numbers of $R$ and $L$ particles, respectively. For a system of length $M$ the corresponding densities are $c_+ = N_+ / M$ with the total density $c = c_+ + c_- = N / M$. Of the $N$ particles, a fraction $\phi = N_+ / N = c_+ / c$ are of the type $R$ while the remaining fraction $1 - \phi$ are $L$ particles. The corresponding fluxes are denoted by $F_\pm$. In both the limits $\phi = 1$ and $\phi = 0$ this model reduces to our earlier model [17, 18], motivated by unidirectional ant traffic, which is closely related to the bus-route models [19, 20] and the models of pedestrian dynamics [21, 22].

doi:10.1088/1742-5468/2006/06/P06012
Competition of coarsening and shredding of clusters in a driven diffusive lattice gas

One unusual feature of this PRL model is that the flux does not vanish in the dense-packing limit $c \to 1$. In fact, in the full-filling limit $c = 1$, the exact nonvanishing flux $F_+ = K c_+ c_- = F_-$ at $c_+ + c_- = c = 1$ arises only from the exchange of the $R$ and $L$ particles, irrespective of the magnitudes of $f, Q$ and $q$.

In the special case $Q = q = q_H$ the hopping of the ants become independent of pheromone. This special case of the PRL model is identical to the AHR model [6] with $q_+ = q_0 = \kappa$. A simple homogeneous mean-field approximation (HMFA) yields the estimates

$$F_\pm \simeq c_\pm [q_H (1 - c) + K c_\mp]$$

(1)

irrespective of $f$, for the fluxes $F_\pm$ at any arbitrary $c$. On the other hand, the exact expression for the flux of the AHR model, parameterized [7] by a rapidity variable $\xi \in [0, 1/(1 - a)^2]$, is given by

$$J(\xi) = \frac{2a^2 \xi}{N},$$

(2)

$$\rho(\xi) = \frac{2a(1 + a)\xi [(1 + a)\sqrt{1 + 4a\xi} - (1 - a)]}{N\sqrt{1 + 4a\xi}}$$

(3)

where

$$N = 1 + a^2 + 2a(1 + a)^2 \xi - (1 - a^2)\sqrt{1 + 4a\xi}$$

(4)

for $1/2 \leq q_H \leq 1$, where $a = (1 - q_H)/q_H$ and the unit of elementary timescale has been set by choosing $K = 1$. A comparison of the equation (1) (with $K = 1$) and the exact result (3) in figure 4 shows that the flux in the HMFA, although an underestimate, is a reasonably good approximation for all $q_H \geq 1/2$. Deviation from the exact values for $q_H < 1/2$ indicates the presence of stronger correlations at smaller values of $q_H$. For the generic case $q \neq Q$, the flux in the PRL model depends on the evaporation rate $f$ of the $P$ particles. In figure 3 we plot the fundamental diagrams for wide ranges of values of $f$ (in figure 3(a)) and $\phi$ (in figure 3(b)), corresponding to one set of hopping probabilities. First, note that the data in figures 3 are consistent with the physically expected value of $F_\pm (c = 1) = K c_+ c_-$, because in the dense packing limit only the exchange of the oppositely moving particles contributes to the flux. Moreover, the sharp rise of the flux over a narrow range of $c$ observed in both figures 3(a) and (b) arises from the nonmonotonic variation of the average speed with density, an effect which was also observed in our earlier model for unidirectional ant traffic [17,18]. This nonmonotonicity was shown to be a consequence of the formation of so-called loose clusters. These are regions in space where the particle density $c_{lc}$ is larger than the average density $c$, but not maximal, i.e., $c < c_{lc} < 1$. These loose cluster dominate the behaviour at intermediate particle densities $c$ and small evaporation rates $f$ where they are formed due to effectively longer-ranged attractive interactions introduced by the pheromones.

In the special limits $\phi = 0$ and 1, over a certain regime of density (especially at small $f$), the particles are known [17,18] to form ‘loose’ (i.e., non-compact) clusters [18] which are defined to be regions of the system with a density $c_{lc}$ that is larger than the average global density, i.e., $c < c_{lc} < 1$. If the system evolves from a random initial condition at $t = 0$, then during coarsening of the cluster, its size $R(t)$ at time $t$ is given

doi:10.1088/1742-5468/2006/06/P06012
Competition of coarsening and shredding of clusters in a driven diffusive lattice gas

Figure 3. The fundamental diagrams in the steady state of the PRL model for several different values of (a) $f$ (for $\phi = 0.5$) and (b) $\phi$ (for $f = 0.001$). The other common parameters are $Q = 0.75, q = 0.25, K = 0.5$ and $M = 1000$. 

by $R(t) \sim t^{1/2}$ [19, 20]. Therefore, in the absence of an encounter with oppositely moving particles, $\tau_{\pm}$, the coarsening time for the right-moving and left-moving particles would grow with system size as $\tau_+ \sim \phi^2 M^2$ and $\tau_- \sim (1 - \phi)^2 M^2$.

In the PRL model with periodic boundary conditions, the oppositely moving ‘loose’ clusters ‘collide’ against each other periodically. Let us define $\tau_g$ to be the time gap between the successive collisions of the two clusters which is the time interval between the end of one collision and the beginning of the next collision. It is straightforward to see that $\tau_g$ increases linearly with the system size following $\tau_g \sim M$; we have verified this scaling relation numerically as in shown in figure 5. During a collision each loose cluster ‘shreds’ the oppositely moving cluster; both clusters shred the other equally if $\phi = 1/2$.
Competition of coarsening and shredding of clusters in a driven diffusive lattice gas

**Figure 4.** Fundamental diagram in the special case $Q = q = q_H$. The continuous curves, marked by $\ast$, $+$ and $\times$, are the exact results corresponding to $q_H = 0.90, 0.75, 0.60$, respectively. The corresponding HMFA results have been shown by the dotted, dashed and dashed–dotted curves, respectively. The points marked by $\ast$, $+$ and $\times$ have been obtained from computer simulations.

**Figure 5.** Time gap $\tau_g$ between successive collisions as a function of system size $M$ for $Q = 0.75, q = 0.25, K = 0.5, f = 0.005, c = 0.2$ and $\phi = 0.3$.

(figure 6(a)). However, for all $\phi \neq 1/2$, the minority cluster suffers more severe shredding than that suffered by the majority cluster (figure 6(b)) because each member of a cluster contributes in the shredding of the oppositely moving cluster.

Figures 7(a) and (b) show magnified view of the first and second collision area respectively in the space–time plot figure 6(c) where only right-moving ants are present. Figures 7(a) and (b) demonstrate that the phenomenon of shredding is such that the total number of clusters, their sizes as well as their individual velocities just after the collision

doi:10.1088/1742-5468/2006/06/P06012
Competition of coarsening and shredding of clusters in a driven diffusive lattice gas

Figure 6. Space–time plot of the PRL model for $Q = 0.75$, $q = 0.25$, $f = 0.005$, $M = 4000$, $c = 0.2$ and (a) $\phi = 0.5$, $K = 0.2$, (b) $\phi = 0.3$, $K = 0.2$, (c) $\phi = 0.3$, $K = 0.5$. The red and green dots represent the right-moving and left-moving ants, respectively.

are usually different from those of the clusters before the collision. But, at present, we do not have any theory to predict the changes in these properties caused by the collision.

In small systems the ‘shredded’ clusters get the opportunity for significant re-coarsening before getting shredded again in the next encounter with the oppositely moving particles. But, in sufficiently large systems, the shredded appearance of the clusters persists. This is demonstrated clearly by the space–time plots for two different system sizes in figure 8. However, we observed practically no difference in the fundamental diagrams for $M = 1000$ and 4000 (see figure 9). Following the methods of [20], we have computed $R(t)$ starting from random initial conditions. The data corresponding to $\phi = 1$ are consistent with the asymptotic growth law $R(t) \sim t^{1/2}$. In the beginning $R(t)$ grows as $t^{1/3}$ (the dotted line in figure 10 corresponds to a slope of $t^{1/3}$); however, in the later stage it grows as $t^{1/2}$ (the dashed line in figure 10 corresponds to a slope of $t^{1/2}$). In sharp contrast, for $\phi = 0.5$, $R(t)$ saturates to a much smaller value that is consistent with the highly shredded appearance of the clusters in figure 6(a).
Competition of coarsening and shredding of clusters in a driven diffusive lattice gas

Figure 7. Magnified view of the first and second collision area respectively of figure 6(c).

Figure 8. Space–time plot of the PRL model for $Q = 0.50$, $q = 0.25$, $f = 0.005$, $c = 0.2$, $\phi = 0.3$, $K = 1.0$ and (a) $M = 1000$, (b) $M = 4000$. The red and green dots represent the right-moving and left-moving ants, respectively.

Thus, coarsening and shredding phenomena compete against each other and this competition determines the overall spatio-temporal pattern. Therefore, in the late stage of evolution, the system settles to a state where, because of the alternate occurrence of shredding and coarsening, the typical size of the clusters varies periodically. Moreover, comparing figures 6(b) and (c), we find that, for given $c$ and $\phi$, increasing $K$ leads to sharper speeding up of the clusters during collision so long as $K$ is not much smaller than $q$. Both the phenomena of shredding and speeding during collisions of the oppositely moving loose clusters arise from the fact that, during such collisions, the dominant process is the exchange of positions, with probability $K$, of oppositely moving ants that face each other.

doi:10.1088/1742-5468/2006/06/P06012
4. Conclusions

The PRL model reported in this paper is motivated by bidirectional ant traffic. In a spatially constrained situation, e.g., on a hanging cable (figure 1), such a single-lane model is adequate, whereas otherwise a full two-lane model [23] is required.

The main effect of the new species of particles $P$ is that coupling of its non-conserving dynamics with the conserved dynamics of the $L$ and $R$ species of particles gives rise to an effective pheromone-mediated interaction between the particles of the same species. This pheromone-mediated interactions between the $L$ ($R$) particles gives to a left-moving
Competition of coarsening and shredding of clusters in a driven diffusive lattice gas

(right-moving) cluster. This tendency for ‘coarsening’, induced by the pheromones, then competes with the ‘shredding’ process which occurs during collision of oppositely moving clusters in a finite system with periodic boundary conditions.

The most surprising finding is a nontrivial and, at first sight, counterintuitive, system size dependence of the spatio-temporal organization which, we believe, could be relevant also for other driven systems with competing aggregation and disintegration. It would be interesting to obtain a more quantitative description of the shredding process that allows one to quantify this size dependence. Work in this direction is currently under progress.
