Studies proved that among all $\alpha_1$-adrenoceptors, cardiac myocytes functionally express only $\alpha_{1A}$- and $\alpha_{1B}$-subtype. Scientists indicated that $\alpha_{1A}$-subtype blockade might be beneficial in restoring normal heart rhythm. Therefore, we aimed to determine the role of $\alpha_1$-adrenoceptors subtypes (i.e., $\alpha_{1A}$ and $\alpha_{1B}$) in antiarrhythmic effect of six structurally similar derivatives of 2-methoxyphenylpiperazine. We compared the activity of studied compounds with carvedilol, which is $\beta_1$- and $\alpha_1$-adrenoceptors blocker with antioxidant properties. To evaluate the affinity for adrenergic receptors, we used radioligand methods. We investigated selectivity at $\alpha_1$-adrenoceptors subtypes using functional bioassays. We tested antiarrhythmic activity in adrenaline-induced (20 $\mu$g/kg i.v.), calcium chloride-induced (140 and 25 mg/kg i.v.) and barium chloride-induced (32 and 10 mg/kg i.v.) arrhythmia models in rats. We also evaluated the influence of studied compounds on blood pressure in rats, as well as lipid peroxidation. All studied compounds showed prophylactic antiarrhythmic properties in adrenaline-induced arrhythmia, but only the activity of HBK-16, HBK-17, HBK-18, and HBK-19 ($\text{ED}_{50} = 0.18-0.21$) was comparable to that of carvedilol ($\text{ED}_{50} = 0.36$). All compounds reduced mortality in adrenaline-induced arrhythmia. HBK-16, HBK-17, HBK-18, and HBK-19 showed therapeutic antiarrhythmic properties in adrenaline-induced arrhythmia.

Front. Pharmacol. 7:229. doi: 10.3389/fphar.2016.00229
INTRODUCTION

Arrhythmias are the most common causes of sudden cardiac death (Deo and Albert, 2012). Despite numerous antiarrhythmic drugs, pharmacotherapy is still ineffective in majority of patients. Moreover, all antiarrhythmic agents acting via different ion channels possess life-threatening proarhythmic potential. Thus, scientists are still looking for effective and safe compounds, which will protect against arrhythmia and/or restore normal heart rhythm.

Antiarrhythmic activity of pharmacological agents resulting from their receptor-based mechanisms might be equally efficient and much safer than that observed for classical antiarrhythmic drugs. According to many studies, α₁- adrenolytics may have potential in the treatment of arrhythmias. Scientists agree that the blockade of α₁,- and particularly α₁A-adrenoceptor may be beneficial in restoring normal heart rhythm (reviewed in Hieble, 2000 and Shannon and Chaudhry, 2006). The α₁-adrenoceptor stimulation results in inositol trisphosphate (IP₃) production, and subsequent Ca²⁺ release from the sarcoplasmatic reticulum (SR; Escobar et al., 2012). Although the regulation of Ca²⁺ level in cardiomyocytes mainly depends on ryanodine receptors and SR Ca²⁺ pump, the increased basal level of Ca²⁺ induced by IP₃ may also alter the electrical excitability of cardiomyocytes, thus contributing to the development of arrhythmia e.g., atrial (Zima and Blatter, 2004) or ventricular fibrillation (Proven et al., 2006). Thereby, the blockade of α₁-adrenoceptors may lead to the stabilization of Ca²⁺ level producing antiarrhythmic effect in arrhythmias induced by catecholamines e.g., catecholaminergic polymorphic ventricular tachycardia. The above hypothesis was supported by Suita et al. (2015), who demonstrated that proazosin not only shortened norepinephrine-induced elongation of atrial fibrillation in mice, but also attenuated norepinephrine-induced SR Ca²⁺ leak and spontaneous SR Ca²⁺ release in cultured atrium cardiomyocytes. This proves that α₁-adrenoceptors may have role in preventing cardiac arrhythmias. Numerous animal studies confirmed this theory, showing antiarrhythmic properties of α₁-adrenolytics (Sapa et al., 2011; Kubacka et al., 2013a; Rapacz et al., 2014, 2015b).

Since in our earlier experiments 2-methoxyphenylpiperazine derivatives showed high affinity toward α₁-adrenergic receptors (Pytka et al., 2015), in this study we aimed to determine the role of α₁-adrenoceptors subtypes (i.e., α₁A, α₁B) in antiarrhythmic effect of six structurally similar derivatives of 2-methoxyphenylpiperazine. We compared the activity of studied compounds with carvedilol, which is β₁- and α₁-adrenoceptors blocker with antioxidant properties.

MATERIALS AND METHODS

Animals

The experiments were carried out using male normotensive Wistar rats [Krf: (WI) WU], weighing 200–250 g. Animals were kept in plastic cages (three rats per cage) at constant room temperature of 22 ± 2°C, with 12:12 h light/dark cycle. Rats had free access to food (standard pellet diet) and water. Each experimental and control groups consisted of four to six animals. The animals were killed by cervical dislocation immediately after the experiment. All injections were given in a volume of 1 ml/kg. All experimental procedures were approved by the Local Ethics Committee for Experiments on Animals of the Jagiellonian University in Krakow, Poland (approval numbers 110/2014 and 246/2015) and cared for in accordance with the Guide to the Care and Use of Experimental Animals.

Drugs

Six studied compounds (Figure 1): 1-[(2,6-dimethylphenoxy)ethoxyethyl]-4-(2-methoxyphenyl)piperazine hydrochloride (HBK14), 1-[(2-chloro-6-methylphenoxy)ethoxyethyl]-4-(2-methoxyphenyl)piperazine hydrochloride (HBK15), 1N-[3-(2-chloro-5-methylphenoxy)propyl]-4N-(2-methoxyphenyl)piperazine hydrochloride (HBK16), 1N-[3-(2,5-dimethylphenoxy)propyl]-4N-(2-methoxyphenyl)piperazine hydrochloride (HBK17), and 1N-[3-(2,4,6-trimethylphenoxy)propyl]-4N-(2-methoxyphenyl)piperazine hydrochloride (HBK18), 1N-[3-(2,3,5-trimethylphenoxy)propyl]-4N-(2-methoxyphenyl)piperazine hydrochloride (HBK-19) were synthesized in the Department...
of Bioorganic Chemistry, Chair of Organic Chemistry, Faculty of Pharmacy, Jagiellonian University (Waszkielewicz et al., 2015). The investigated compounds were dissolved in saline and administered intraperitoneally (i.p.) or intravenously (i.v.). Thiopental (Rotexmedica, Germany) was dissolved in saline and administered i.p. Chloroethylclonidine (Sigma, Germany), noradrenaline (Sigma, Germany), johimbin (Tocris, United Kingdom), propranolol (Fluka, USA), phentolamine (Sigma, Germany) were dissolved in saline or dimethyl sulfoxide (DMSO, Sigma, Germany) and used in radioligand or biofunctional studies. Adrenaline (Polfa S.A., Warsaw), carvedilol (Sigma, Germany), methoxamine (Sigma, China), calcium chloride (Fluka, Germany), and barium chloride (Sigma, Germany) were dissolved in saline and administered i.v. Heparin (Polfa S.A., Warsaw) was used as anticoagulant during experiments. The control groups received 0.9% NaCl solution. Other chemicals used were obtained from POCh (Polish Chemical Reagents, Poland).

Radioligand Binding Assay

The α1- and β1-adrenoceptor radioligand binding assay was performed on rat cerebral cortex. [3H]-prazosin (19.5 Ci/mmol, α1-adrenoceptor) and [3H]-CGP-12177 (48 Ci/mmol, β1-adrenergic receptor) were used. The brains were homogenized in 20 volumes of an ice-cold 50 mM Tris-HCl buffer (pH 7.6) and were centrifuged at 20,000 × g for 20 min (0–4°C). The cell pellet was resuspended in the Tris–HCl buffer and centrifuged again. Radioligand binding assays were performed in plates (MultiScreen/Millipore). The final incubation mixture (final volume 300 μl) consisted of 240 μl of the membrane suspension, 30 μl of [3H]-prazosin (0.2 nM), [3H]-CGP-12177 (0.2 nM) solution and 30 μl of the buffer containing seven to eight concentrations (10−11–10−3 M) of the tested compounds. In order to measure the unspecific binding, 10 μM phentolamine (for [3H]-prazosin) and 1 μM of propranolol (for [3H]-CGP-12177) were applied. The incubation was terminated by rapid filtration through glass fiber filters (Whatman GF/C) using a vacuum manifold (Millipore). The filters were then washed twice with the assay buffer and placed in scintillation vials with a liquid scintillation cocktail. Radioactivity was measured in a WALLAC 1409 DSA liquid scintillation counter (Perkin Elmer, USA). All the assays were made in duplicate and the inhibitory constants (Ki) were estimated.

Influence on α1A-Adrenoceptors: Rat Tail Artery

Rats were anesthetized with thiopental (75 mg/kg i.p.) and the middle part of the ventral caudal artery was removed, cleaned of surrounded tissues and uncovered of endothelium by gentle
rubbing in the Krebs-Henseleit solution. The isolated artery, cut into ~4 mm long rings, was then horizontally put up between two stainless steel hooks (diameter 0.15 mm). One hook was fastened to the bottom of the chamber and the other to an isometric FDT10-A force displacement transducer (DMT Model 750TOBS, Denmark), linked with Powerlab 4/26 analyzer (ADInstruments), and processed by LabChart 7 software. The isolated rings were incubated in the Krebs-Henseleit solution (20 ml) at the temperature 37°C and pH 7.4 with constant oxygenation (O2/CO2, 19:1). The initial optimal tissues tension was set at 0.75 g. Chloroethylclonidine (3 μM) as the preferential α1B-adrenoceptor alkylating agent was used during incubation and after 30 min it was completely washed off. Through 100 min of equilibration tissues were stimulated with noradrenaline (1 μM) four times with washing out until the contractile response become constant. Two cumulative concentration-response curves to noradrenaline, at an interval of 60 min, were established on each arterial ring both in the presence and absence of antagonist. The incubation with antagonists went on for 30 min. The experiments were carried out in the constant presence of yohimbine (0.1 μM) and propranolol (1 μM) to block α2- and β-adrenoceptors, respectively in order to minimize the involvement of these adrenoceptors in the response to noradrenaline.

Influence on α1B-Adrenoceptors: Mouse Spleen

The influence on α1B-adrenoceptors was evaluated using the isolated mouse spleen. The spleen was removed from male mice right after killing the anesthetized animal by cervical dislocation. The isolated tissue was incubated in 20 ml cup filled with the Krebs-Henseleit solution at the temperature 37°C and pH 7.4 with constant oxygenation (O2/CO2, 19:1). The initial optimal tissues tension was set at 1.0 g. Through the 100 min of equilibration tissues were stimulated with noradrenaline (0.1–10.0 μM) three times with washing out until the contractile response become constant. Two cumulative concentration-response curves to noradrenaline, at an interval of 60 min, were established on each tissue both in the presence and absence of antagonist. The incubation with antagonists went on for 30 min. The experiments were carried out in the constant presence of yohimbine (0.1 μM) and propranolol (1 μM) to block α2- and β-adrenoceptors, respectively in order to minimize the involvement of these adrenoceptors in the response to noradrenaline.

Influence on α1D-Adrenoceptors: Rat Aorta

Finally, the influence on α1D-adrenoceptors was investigated using the isolated rat aorta. Rats anesthetized with thiopental and killed by cervical dislocation had aorta removed, denuded of endothelium and incubated in the Krebs-Henseleit solution at the temperature 37°C and pH 7.4 with constant oxygenation (O2/CO2, 19:1). The aorta rings were maintained at optimal tension of 2.0 g. During 3 h of equilibration tissues were stimulated with noradrenaline three times (0.3 μM). Two cumulative concentration-response curves to noradrenaline, at an interval of 60 min, were established on each tissue both in the presence and absence of antagonist. The incubation with antagonists went on for 30 min. The experiments were carried out in the constant presence of yohimbine (0.1 μM) and propranolol (1 μM) to block α2- and β-adrenoceptors, respectively.

Prophylactic Antiarrhythmic Activity in Adrenaline-, Barium Chloride-, and Calcium Chloride-Induced Arrhythmias

The procedures were performed according to the method described by Szekeres and Papp (1975). The heart rate disturbances were evoked by the intravenous administration of adrenaline (20 μg/kg), barium chloride (32 and 10 mg/kg) or calcium chloride (140 and 25 mg/kg) solution into the caudal vein in anesthetized rats (thiopental, 75 mg/kg). The studied compounds were administered i.p. 45 min before the injection of adrenaline, calcium chloride, or barium chloride. The electrocardiogram (ECG) was recorded during the first 2 min as well as in the 5th, 10th, and 15th min after the arrhythmogen injection. The criterion of antiarrhythmic activity was the lack of extrasystoles and inhibition of cardiac arrhythmia in comparison with the control group in adrenaline-induced arrhythmia or the progressive disappearance of the arrhythmia and reinstatement of the sinus rhythm in barium chloride- and calcium chloride-induced arrhythmias. The ID50 (a dose producing a 50% inhibition of ventricular contractions) with 95% confidence limits was determined by computer log-probit analysis according to Litchfield and Wilcoxon (1949) and Szekeres and Papp (1975). The compounds were administered at the dose 10 mg/kg. We gradually decreased the dose by half until the disappearance of antiarrhythmic activity.

Therapeutic Antiarrhythmic Activity in Adrenaline-Induced Arrhythmia

The experiment was performed according to the method described by Szekeres and Papp (1968). The arrhythmia was evoked by the intravenous administration of adrenaline (20 μg/kg) into the caudal vein in anesthetized rats (thiopental, 75 mg/kg). The tested compounds were injected i.v. at the peak of arrhythmia directly after adrenaline injection, at the ED50 (a dose producing a 84% inhibition of premature ventricular contractions established in prophylactic adrenaline-induced arrhythmia). The range of doses was 0.325–0.504 mg/kg. The ECG was recorded constantly for 5 min as well as in the 10th and 15th min of the experiment. The criterion of antiarrhythmic activity was the reduction of premature ventricular contractions in comparison with the control group (Sapa et al., 2011).

The Effect on Normal Electrocardiogram in Rats

The experiment was carried out to exclude the influence of tested compounds on normal ECG. The ECG was recorded (ASPEL ASCARD B5 apparatus, standard lead II and paper speed of 50 mm/s) prior and also 5, 10, 15, 20, 30, 40, 50, and 60 min after the i.p. administration of tested compounds. The influence on QRS complex, PQ interval, heart rate (HR), and QTc interval was determined. The QTc was calculated according to the
Bazzett’s formula: QTc = QT/√RR (De Clerck et al., 2002). The compounds were administered at the ED84 (a dose producing a 84% inhibition of premature ventricular contractions established in prophylactic adrenaline-induced arrhythmia).

**Influence on Blood Pressure in Normotensive Rats**

Normotensive rats were anesthetized with thiopental (75 mg/kg ip). The right carotid artery was cannulated with a polyethylene tube filled with heparin solution to allow pressure measurements, using a Datamax apparatus (Columbus Instruments, USA; Kubacka et al., 2013b). The tested compounds were administered i.p. after 15 min of stabilization period. The compounds were administered at the dose 10 mg/kg. We gradually decreased the dose by half until the disappearance of antiarrhythmic activity.

**Influence on Blood Vasopressor Response in Rats**

To verify if the hypotensive activity was a result of \(\alpha\)-adrenolytic properties, we studied the influence of tested compounds on the pressor response to methoxamine (150 \(\mu\)g/kg). The experiment was carried out for all active compounds, which were administered (i.v.) to the caudal vein at the lowest hypotensive dose (Kubacka et al., 2013b). Pressor response to methoxamine injected i.v. was measured before (control) and 5 min after the tested compounds. We administered the tested compounds at the lowest possible doses, not to lose selectivity for \(\alpha_1\)-adrenoceptors.

**Antioxidant Effect—Lipid Peroxidation in Rat Brain Homogenate**

This experiment was performed according to the method described by Yue et al. (1992). The rat brain homogenate containing 10 mg tissue/ml was prepared in 0.9% saline. The rates of membrane lipid peroxidation were measured by the formation of thiobarbituric acid reactive substances (TBARS). Rat brain homogenates (1 ml) were incubated at 37°C for 5 min with 10 \(\mu\)l of a tested compound or vehicle. Lipid peroxidation was initiated by the addition of 50 \(\mu\)l of 0.5 mM FeCl₂ and 50 \(\mu\)l of 2.0 mM ascorbic acid. After 30 min of incubation, the reaction was stopped by adding 0.1 ml of 0.2% butylated hydroxytoluene (BHT). Thiobarbituric acid reagent was then added and the mixture was heated for 15 min in a boiling water bath. Carvedilol was used as reference compound. The compounds were tested at a concentration of 10⁻³ M. The TBARS were measured at 532 nm.

**Data Analysis**

In radioligand binding studies, the obtained data were fitted to a one-site curve-fitting equation with Prism 6.0 (GraphPad Software), and inhibition constants (Ki) values were estimated from the Cheng–Prusoff equation (Cheng and Prusoff, 1973):

\[
K_i = \frac{IC_{50}}{1 + \frac{L_0}{K_D}}
\]

\(L_0\)–labeled ligand concentration, \(K_D\)–dissociation constant of labeled ligand

In functional bioassays the concentration–response curves were analyzed using GraphPad Prism 6.0 software (GraphPad Software Inc., San Diego, CA, USA) as previously described by Kubacka et al. (2013b). Data are means ± S.E.M. of at least 4 separate experiments. To establish Hill slopes for the agonist concentration–response curves and calculate EC50 values, curves were fitted to all the data by non-linear regression. The EC50 value in the presence and absence of antagonists was used to ascertain the concentration ratio (CR). Schild analysis was performed. If the slope was not significantly different from unity, the relative antagonistic potencies (pA2: -log of the concentration of an antagonist that doubles the concentration of the agonist needed to elicit the original submaximal response obtained in the absence of agonist) were determined by plotting the log (CR-1) against the -log of antagonist concentration (Arunlakshana and Schild, 1959).

In case of in vivo experiments the results are presented as the means ± S.E.M. Statistically significant differences between groups were calculated using one-way analysis of variance (ANOVA) with repeated measurements followed by Dunnett’s or Bonferroni’s test post-hoc or Student’s t-test. The criterion for significance was set at \(p < 0.05\).

Antioxidant activity was expressed as the percentage reduction of the sample absorbance during the reaction at wavelength 532 nm.

The log-probit method described by Litchfield and Wilcoxon (1949) was used to determine median effective doses (ED50—doses producing 50% inhibition of premature ventricular contractions) and doses producing 84% of the maximal effect (ED84) for compounds in arrhythmia models.

**RESULTS**

**Affinity for Adrenoceptors**

All studied compounds possessed high affinity for \(\alpha_1\)-adrenoceptors but none of them bound to \(\beta_1\)-adrenoceptors (Table 1).

**Functional Affinity for \(\alpha_{1A}\)-, \(\alpha_{1B}\)-, and \(\alpha_{1D}\)-adrenoceptors**

The tested compounds antagonized noradrenaline evoked contraction in isolated rat aorta and tail artery, as well as mouse spleen, and concentration-dependently, shifted the noradrenaline response to the right, without affecting the maximum response. The obtained pA2 values with Schild slopes not significantly different from unity indicated a competitive antagonism at \(\alpha_{1A}\)-, \(\alpha_{1B}\)-, and \(\alpha_{1D}\)-adrenoceptors (Tables 2A,B).

HBK-14, HBK-15, HBK-16, HBK-17, and HBK-18 showed stronger antagonistic properties at \(\alpha_{1D}\)- than \(\alpha_{1A}\)- or \(\alpha_{1B}\)-adrenoceptors. HBK-19 antagonized \(\alpha_{1A}\)-adrenoceptors stronger than other subtypes. All compounds antagonized \(\alpha_{1A}\)-adrenoceptors stronger than \(\alpha_{1B}\)-subtype. Among the studied compounds the strongest antagonist of \(\alpha_{1A}\)-adrenoceptor was HBK-19, \(\alpha_{1B}\)-adrenoceptor—HBK-18, and \(\alpha_{1D}\)-adrenoceptor—HBK-16.
The Effect on Normal Electrocardiogram in Rats

Table 3 shows the influence of tested compounds on normal ECG in rats.

HBK-14 and HBK-15 administered at the dose 6.154 and 20.218 mg/kg, respectively did not influence the ECG parameters throughout the experiment. HBK-16 at the dose 0.363 mg/kg did not influence PQ interval, QRS complex or QTc interval but it significantly reduced heart rate by 11—13%, since the 40th min of the observation. Similarly, HBK-17 at the dose 0.504 mg/kg significantly decreased heart rate by 9—12%, 20 min after administration, without affecting PQ interval, QRS complex or QTc interval. HBK-18 at the dose 0.325 mg/kg significantly reduced the heart rate by 13—23%, since the 15th min of the observation and did not affect PQ interval, QRS complex or QTc interval. HBK-19 at the dose 0.444 mg/kg between the 15th and 30th min after administration reduced heart rate by 21—22% without the influence on PQ interval, QRS complex, or QTc interval.

Prophylactic Antiarrhythmic Activity in Adrenaline-, Barium Chloride-, and Calcium Chloride-Induced Arrhythmias

In anesthetized rats i.v. injection of adrenaline (20 µg/kg) caused atrioventricular disturbances, ventricular and supraventricular extrasystoles in 100% of the animals, which led to the death of ~70% of the animals. The studied compounds administered 45 min (i.p.) prior to adrenaline, decreased the number of extrasystoles and mortality (Figures 2, 3, Table 4). Table 5 shows the ED₅₀ values (doses producing 50% inhibition of premature ventricular contractions).

The injection (i.v.) of barium chloride (32 mg/kg) caused rapid ventricular extrasystoles in all animals (100%), which led to the death within 3—5 min. Lower dose of barium chloride (10 mg/kg) caused ventricular extrasystoles in around 60% of rats and did not lead to the death of animals. We did not observe a reproducible negative effect on heart rhythm when barium chloride was used at the dose 10 mg/kg. None of the tested compounds administered (i.p.) 45 min before barium chloride were active in barium chloride-induced model of arrhythmia (data not shown).

In anesthetized rats injection (i.v.) of calcium chloride (140 mg/kg) caused rapid ventricular fibrillation in all animals (100%), which led to death within 3—5 min. The intravenous administration of calcium chloride (25 mg/kg) caused ventricular fibrillation in all animals, but did not lead to the death of rats.
None of the tested compounds administered (i.p.) 45 min prior to calcium chloride were active in the above model of arrhythmia (data not shown).

Therapeutic Antiarrhythmic Activity in Adrenaline-Induced Arrhythmia
All tested compounds administered i.v. at the peak of adrenaline-induced arrhythmia (20 μg/kg) reduced the number of premature ventricular contractions (Figure 4).

Influence on Blood Pressure in Normotensive Rats
Table 6 presents the lowest dose of each tested compound, which significantly lowered systolic and diastolic blood pressure in rats.

HBK-14 at the dose of 0.625 mg/kg, 10 min after injection, significantly reduced systolic blood pressure by 5–10%, and diastolic blood pressure by 9–14% since the 20th min of the observation. HBK-15 at the dose 5.0 mg/kg significantly reduced systolic blood pressure by 13–19%, and diastolic blood pressure by 13–20%, 5 min after administration. HBK-16 at the dose 0.1 mg/kg, 20 min after administration, significantly reduced systolic blood pressure by 8–11% and diastolic blood pressure by 6–10%. HBK-17 at the dose 0.1 mg/kg significantly reduced systolic blood pressure by 8–11% and diastolic blood pressure by 10–16%, 20 min after administration. HBK-18 at the dose 0.01 mg/kg, from the 20th min of the observation, significantly reduced systolic and diastolic blood pressure by 23–28 and 16–18%, respectively. HBK-19 at the dose 0.625 mg/kg since the 5th min after i.p. administration, significantly reduced systolic blood pressure by 5–17%, whereas diastolic blood pressure by 9–15% since the 10th min of the observation.

Influence on Blood Vasopressor Response in Rats
In the control group the increase of blood pressure after methoxamine (150 μg/kg) was ranging from 62.7 ± 10.4 to 94.2 ± 2.7 mmHg. Figure 5 shows that all tested compounds at the lowest hypotensive doses, significantly antagonized the pressor response to methoxamine.

Influence on Lipid Peroxidation in Rat Brain Homogenate
Carvedilol, HBK-16, HBK-17, HBK-18, and HBK-19 inhibited lipid peroxidation (Table 7). HBK-14 and HBK-15 were inactive in this test.

DISCUSSION
We found that the studied 2-methoxyphenylpiperazine derivatives that possessed stronger α1A-adrenolytic properties (i.e., HBK-16, HBK-17, HBK-18, and HBK-19) were the most active compounds in adrenaline-induced arrhythmia. Their antiarrhythmic (but not antioxidant) activity was comparable to that of carvedilol. The tested compounds showed hypotensive effect resulting from their α1-adrenolytic properties. HBK-19 was the only compound in the group that did not lower blood pressure at antiarrhythmic doses.

Scientists reported that 2-methoxyphenylpiperazine derivatives often interact with adrenergic receptors (Handzik et al., 2008; Kubacka et al., 2013a; Rapacz et al., 2014, 2015a,b). Thus, we evaluated the affinity of the studied compounds for α1- and β1-adrenoceptors. The radioligand studies revealed that HBK-16, HBK-17, HBK-18, and HBK-19 possessed high affinity for α1-, but not β1-adrenoceptors. This is in agreement with our previous experiments on 2-methoxyphenylpiperazine derivatives i.e., HBK-14 and HBK-15, which showed no affinity for β1- and high affinity for α1-adrenoceptors (Pytka et al., 2015).

Studies proved that cardiac myocytes functionally express α1A- and α1B-adrenoceptors. O’Connell et al. (2003) demonstrated that despite the presence of α1D-adrenoceptors mRNA, rodent cardiac myocytes did not express α1D-subtype protein by binding. However, Chalothorn et al. (2003) showed that α1D-adrenoceptors might be expressed in the coronary vasculature. Thus, α1A- and α1B-adrenoceptors may play important role in the development of arrhythmias induced by catecholamines, while α1D-subtype in ischemia-induced arrhythmias.

Scientists indicated that agents which block α1A-adrenoceptors may have antiarrhythmic potential (Hieble, 2000). Harrison et al. (1998) showed that hearts from transgenic rats expressing constitutively active α1B-adrenoceptors, and having 50% reduced α1A-mRNA levels, were less sensitive to ischemia-induced ventricular tachycardia than normal rats. Lee and Rosen (1993) proved that the blockade of α1B receptors by chlorothalidone increased the amplitude of delayed afterdepolarizations induced by calcium and phenylephrine. Altogether, these findings suggest that agents, which block α1A-adrenoceptors stronger than α1B subtype, may have antiarrhythmic potential.

Therefore, we determined the selectivity of studied compounds at α1-adrenoceptor subtypes. Biofunctional assays revealed that all compounds competitively blocked α1A, α1B, and α1D subtypes. HBK-19 and HBK-16 were the strongest α1A-adrenoceptor antagonists, while HBK-14 and HBK-15 were the weakest. Although we did not find highly selective compounds, all 2-methoxyphenylpiperazine derivatives antagonized α1A-adrenoceptors stronger than α1B subtype.
HBK-19 showed the greatest difference in pA2 values—it blocked $\alpha_{1A^{-}}$-adrenoceptors around seven-fold stronger than $\alpha_{1B}$ subtype.

Since all studied compounds blocked $\alpha_{1A^{-}}$ and $\alpha_{1B}$-adrenoceptors, we decided to examine their antiarrhythmic activity. We also investigated whether antiarrhythmic activity depended on the strength of $\alpha_{1A^{-}}$-adrenoceptor blockade or the differences between pA2 values for $\alpha_{1A^{-}}$ and $\alpha_{1B}$-adrenoceptors. To determine antiarrhythmic effect, we used three models of arrhythmia i.e., adrenaline-, barium chloride-, and calcium chloride-induced.

All compounds showed antiarrhythmic activity in adrenaline-induced model of arrhythmia, and reduced mortality of rats. HBK-18 possessed the strongest prophylactic antiarrhythmic properties, but ED50 values for HBK-16, HBK-17, and HBK-19 were also very low. Except for HBK-14 and HBK-15, prophylactic antiarrhythmic activities of compounds in adrenaline-induced arrhythmia were comparable to that of carvedilol (reference drug). We think that the weak antiarrhythmic activity of HBK 14 and HBK 15 may be due to their weaker $\alpha_{1}$-adreno lytic properties (see Table 2), which are crucial for antiarrhythmic effect in the applied model of arrhythmia. Since the compounds used in the

### Table 3: The influence of the tested compounds on ECG.

| Compound | Parameters | Time of observation (min) |
|----------|------------|--------------------------|

Rats were anesthetized with intraperitoneal (i.p.) injection of thiopental (75 mg/kg). The tested compounds were administered (i.p.) 45 min before the experiment. The observation was carried out for 15 min after the intravenous injection of adrenaline (20 μg/kg) i.e., during the first 2 min, in the 5, 10, and 15th min. n = 5—6 animals per group.

Carvedilol showed comparable properties in adrenaline-induced arrhythmia model. Thus, we claim that the potent blockade of α1A-receptor subtype is essential to attenuate adrenaline-induced arrhythmia, but the role of α1B-adrenoceptor blockade needs further studies. Carvedilol is a potent β1- and α1-adrenoceptors blocker with antioxidant activity. Surprisingly, despite the fact that carvedilol blocked both β1- and α1-adrenoceptors, and the studied compounds only α1-adrenoceptors, their antiarrhythmic effect was comparable. Therefore, we suggest that this may indicate more important role of α1- than β1-adrenoceptors blockade in adrenaline-induced arrhythmia model.

Arrhythmia models induced by calcium or sodium chloride are associated with the changes in intracellular ion concentration. These changes are ion channel dependent, and their dynamics and amplitude are high. In arrhythmias induced by adrenaline, the stimulation of adrenergic receptors also leads to ion level changes (primarily Ca2+), but these changes are not as rapid. Their amplitude and dynamics are much lower than the above. None of the compounds showed activity in barium chloride- or calcium chloride-induced arrhythmias. Therefore, we can assume that the blockade of sodium or calcium channels was not the predominant mechanism of antiarrhythmic effect of the studied compounds.

We decided to test therapeutic antiarrhythmic potential of the most active compounds (i.e., HBK-16, HBK-17, HBK-18, HBK-19).
and HBK-19) in adrenaline-induced model of arrhythmia. The studied compounds restored normal heart rhythm administered at the peak of arrhythmia, but the strongest therapeutic antiarrhythmic activity showed HBK-18. The results of this experiments correlate with the results obtained in prophylactic adrenaline-induced arrhythmia model.

Antiarrhythmic agents have proarrhythmic potential, thus we evaluated the influence of studied compounds on normal ECG in rats. Only HBK-14 and HBK-15 did not influence ECG at ED₈₄ obtained in prophylactic adrenaline-induced arrhythmia model. The rest of compounds significantly decreased heart rate. Williamson et al. (1994) proved that stimulation of α₁A-adrenoceptors resulted in positive chronotropic effect. This suggests that the decrease in heart rate observed after treatment with HBK-16, HBK-17, HBK-18, and HBK-19 was a result of α₁A-receptor blockade.

The QT interval represents electrical depolarization and repolarization of ventricles. The prolongation of QT interval indicates the potential of a drug to cause ventricular tachyarrhythmias like torsades de pointes. The QTc adjusts the QT interval for heart rate extremes. In this study we used Bazett’s equation to calculate QTc. Nevertheless, we need to point out that even though Bazett's formula is very often used for QT-correction, it has many limitations (e.g., over- and under-correction of high or low heart rhythms). Rodents' heart rate values can be several times higher than those observed in humans (Kmečova and Klimas, 2010). Since heart rhythm significantly influences QTc, this might be the reason for the observed differences in baseline QTc in our experiments. We showed that none of the compounds affected QTc at ED₈₄, therefore we can assume that they did not have proarrhythmic potential at antiarrhythmic doses.

Our findings are in agreement with the results obtained by other researchers, showing that phenylpiperazine derivatives possessed α₁-adrenolectic properties, as well as prophylactic and/or therapeutic activity in adrenaline-induced arrhythmia (Dylag et al., 2004; Handzlik et al., 2012; Kubacka et al., 2013a,b).

When discussing adrenaline-induced arrhythmias we could neglect the role of α₁D-adrenoceptors, since their blockade should not have a direct influence on cardiac myocytes. Nevertheless, in animal studies on drug candidates, we cannot entirely ignore the role of α₁D-subtype. α₁D-Adrenoceptors blockade in blood vessels might significantly lower blood pressure, which due to the baroreflex might increase heart rate, and contribute to arrhythmia.

Since all studied compounds blocked α₁D-adrenerceptor, and these receptors among others regulate blood pressure, we evaluated their influence on blood pressure in rats. All tested compounds showed hypotensive properties. HBK-18 showed the strongest hypotensive activity, while HBK-15 the weakest. Interestingly, the results of this experiment did not correlate with the functional bioassays, where the strongest α₁D-adrenoceptor blocking properties showed HBK-16. We suspect that this may be due to the differences in receptor binding dynamics, but this issue would require further experiments. Regarding the case of HBK-19, the lowest dose that reduced blood pressure was around three-fold higher than ED₈₄ value in prophylactic adrenaline-induced arrhythmia. For antiarrhythmic drugs, hypotensive activity is not desirable, since α₁-adrenoceptor blockers acting in the periphery, may induce reflex tachycardia, and contribute
to cardiac arrhythmias. In our opinion, the lack of hypotensive properties at antiarrhythmic doses makes HBK-19 the most interesting compound in the studied group. Our results suggest that the receptor profile of HBK 19 (the highest affinity for α1A and the lowest for α1D) is the most beneficial in preventing adrenaline-induced arrhythmia. Interestingly, this suggests that in vivo conditions the selectivity between α1A and α1D is much more important in achieving the optimal profile of α1-adrenolecty as acting as antiarrhythmic agents, than the selectivity between α1A and α1B.

In order to prove that hypotensive properties of tested compounds were a result of their α1-adrenolytic properties, we performed the experiments with methoxamine (selective α1-adrenoceptor agonist). Drugs that selectively block α1-adrenergic receptors significantly inhibit pressor response to methoxamine. All studied compounds blocked the effect caused by methoxamine, thus we concluded that their hypotensive activity was due to α1-adrenolytic properties.

Oxidative stress plays an important role in arrhythmias (Dudek et al., 2014; Sovari, 2016). Reactive oxygen species (ROS) prolong action potential duration, induce early afterdepolarizations, and delayed afterdepolarizations in rats and guinea-pigs (Beresewicz and Horackova, 1991). Scientists indicated that oxidative stress activated Ca2+/CaM-dependent kinase II (CaMKII), and consequently caused arrhythmias (Xie et al., 2009). Rabbits with cardiac hypertrophy pretreated with CaMKII inhibitor were less likely to develop ventricular arrhythmias (Ke et al., 2007). Kirshenbaum et al. (1990) showed that vitamin E (antioxidant) protected rats with chronic heart hypertrophy against adrenaline-induced arrhythmias. This suggests that oxidative stress plays role in adrenaline-induced arrhythmias.

Given the significant antiarrhythmic effect of the studied compounds, we decided to investigate whether 2-methoxyphenylpiprazine derivatives possess additional antioxidant activity. Strong antioxidant activity might have contributed to their antiarrhythmic effect. This would explain their significant effect in adrenaline-induced model of arrhythmia. Our experiments showed that among all studied compounds only HBK-16, HBK-17, HBK-18, and HBK-19 weakly inhibited lipid peroxidation. The effect elicited by HBK-19 was the strongest in the group. However, its activity was around eight-fold weaker than the effect caused by carvedilol. Although HBK-16, HBK-17, HBK-18, and HBK-19 possessed weaker antioxidant properties than carvedilol, they showed stronger antiarrhythmic activity. This confirms that in adrenaline-induced arrhythmia model, the blockade of α1-adrenoceptors is more important for antiarrhythmic activity than antioxidant properties of the compound. Moreover, our findings suggest that antiarrhythmic properties of studied compounds resulted predominantly from α1-adrenolytic properties.

The levels of cardiac α1-adrenoceptor are around 10-fold higher in rats than in humans. This may suggest that the role of α1-adrenoceptor blockade in arrhythmia is not as significant in humans. Interestingly, despite lower expression of α1-adrenoceptors in human heart, scientists proved that they play a significant role in arrhythmias (Furushina et al., 2001). Kurtzwald-Josefson et al. (2014) identified a contribution of α-adrenergic pathway to pathogenesis of catecholamine-induced arrhythmia, and suggested α-blockade as an effective therapy in the murine model of catecholaminergic polymorphic ventricular tachycardia. The Authors suggested α-adrenolytics as an alternative treatment in humans resistant to β-blockers. Thus, it would be reasonable to keep searching for antiarrhythmic agents among α1-adrenolectics.

Since structural similarity of studied compounds reduces the likelihood of various mechanisms of action, in future studies we plan to investigate another set of structurally similar 2-methoxyphenylpiprazine derivatives with higher selectivity toward α1A-adrenoceptor subtype. This might give more insight into the role of α1A-adrenoceptor subtype in antiarrhythmic effect.

### TABLE 7 | The influence of the tested compounds on lipid peroxidation in rat brain homogenate—antioxidant effect.

| Compound | Absorbance | % reduction of absorbance (% antioxidant activity) |
|----------|------------|--------------------------------------------------|
| HBK-14   | 0.939 ± 0.007 | –4.10                                           |
| HBK-15   | 0.891 ± 0.008 | 1.22                                            |
| HBK-16   | 0.752 ± 0.007 | 16.63                                           |
| HBK-17   | 0.773 ± 0.009 | 14.30                                           |
| HBK-18   | 0.731 ± 0.004 | 13.41                                           |
| HBK-19   | 0.688 ± 0.007 | 22.62                                           |
| Carvedilol | 0.034 ± 0.002 | 89.58                                           |

The rates of membrane lipid peroxidation were measured using rat brain homogenate by the formation of thiobarbituric acid reactive substances (TBARS). The studied compounds were tested at a concentration of 10^{-3} M. The TBARS were measured at 532 nm. Statistical analysis: Student’s t-test; *p < 0.05, **p < 0.01, compared to the initial maximal response (obtained before the administration of tested compounds), n = 5–6 animals per group.
In conclusion, the studied 2-methoxyphenylpiperazine derivatives possessed high affinity for α1-adrenoceptors and competitively antagonized α1A, α1B, and α1D receptor subtypes. The compounds that possessed stronger α1A-adrenolytic properties (i.e., HBK-16, HBK-17, HBK-18, and HBK-19) were the most active compounds in adrenaline-induced arrhythmia. We suggest that their antiarrhythmic activity results predominantly from strong α1A-adrenolytic properties.
