Abstract
Acute basilar artery occlusion (BAO) is a neurological emergency that has a high rate of mortality and poor functional outcome. Endovascular therapy (ET) is the gold standard therapy for large vessel occlusion stroke of the anterior circulation. Whether ET can also be effectively and safely performed in early recurrent large vessel occlusion, especially in BAO, is unclear. We describe a case of successful recanalization and independent functional outcome of a BAO patient treated with intravenous thrombolysis combined with repeated ET. The patients was a 32-year-old man with a history of heavy smoking and drinking who presented to the Emergency Department with dizziness and hypertension, and progressed over the next 13 h to left hemiparesis and mild dysarthria with an NIHSS score of 7. CT angiography demonstrated occlusion of the proximal basilar artery (BA). Intravenous alteplase was given followed by ET. The first intervention failed and over the next 8 h, the patient’s NIHSS score increased to 12. A second attempt with balloon angioplasty managed to reconstitute arterial blood flow with a severe residual stenosis of the proximal BA. Subsequently, the patient progressed into deep
coma with reocclusion of the BA demonstrated on transcranial Doppler. A third intervention with emergent stenting resulted in complete recanalization of the BA and excellent neurological recovery. This patient received three endovascular treatments within 24 h due to reocclusion of the BA and achieved good outcomes. In conclusion, repeated ET for early recurrent BAO is feasible in carefully selected patients.

**Introduction**

The posterior circulation is involved in about a fifth of all ischemic strokes. Blood supply to the posterior circulation depends on one main artery, the basilar artery (BA). The prognosis of acute basilar artery occlusion (BAO) is very poor, with 85–95% mortality if patency of the BA cannot be re-established [1, 2]. Endovascular therapy (ET) has been proven effective for the treatment of large vessel occlusion (LVO) strokes. However, the feasibility and potential benefits of repeated ET for recurrent LVO is unclear. There are only a few reports on repeated thrombectomies for LVO stroke, mostly in anterior circulation [3–5]. Here, we present a patient with recurrent stroke due to occlusion of the BA who was successfully treated by ET thrice within 24 h.

**Case Presentation**

A 32-year-old man, with a history of heavy smoking and excessive drinking (more than 30 cigarettes a day and 30 drinks per week for nearly 14 years) and a 2-year history of poorly controlled hypertension, was brought to the emergency room with complaints of fatigue and dizziness which had started 4 h earlier. Physical examination and non-contrast computer tomography (CT) of the head on arrival were unremarkable except for a high blood pressure of 230/120 mm Hg. Nicardipine was administered to stabilize his blood pressure. After 9 h, the patient developed left-sided weakness, severe vertigo, and vomiting while neurological examination revealed horizontal nystagmus in both eyes, mild dysarthria and ataxia with a National Institute of Health Stroke Scale (NIHSS) score of 7. He was promptly sent for CT angiography which revealed acute proximal BA thrombosis without obvious ischemic changes on non-contrast CT (Fig. 1a, b). The patient was diagnosed with acute BAO and received thrombolysis with intravenous alteplase and was transferred to the angiography suite for mechanical thrombectomy. However, the first intervention failed to restore the flow of BA (Fig. 1c), and the procedure was stopped after good collateral flow from anterior circulation was found. Over the next 8 h, the patient deteriorated further with drowsiness and quadriplegic and his NIHSS score increased to 12. Magnetic resonance imaging (MRI) scan now showed a small pontine infarct. The patient was brought to the endovascular suite for a second time and dilation of the proximal BA was performed twice with a 2.5 × 15 mm balloon. Although arterial flow was reconstituted, residual severe stenosis persisted in the proximal BA with impaired distal flow (Fig. 1d). The patient regained consciousness temporarily after the procedure. At 24-h post-thrombolysis, we administered a loading dose of aspirin and clopidogrel combined with a high dose of statin. Unfortunately, in the following morning, the patient became progressively debilitated with quadriplegia and bilateral Babinski sign, and his Glasgow Coma Scale (GCS) score was 6. Immediate CT of the brain and transcranial Doppler (TCD) excluded
cerebral hemorrhage but confirmed reocclusion of the BA. After multidisciplinary discussion among neurologists and interventionists, we proceeded to immediate angioplasty and stenting of the BA. This time the vessel became fully patent with an excellent angiographic recanalization of TICI 3 (Fig. 1e). After the procedure, the patient was transferred to the intensive care unit and on the following day, he was conscious, spoke clearly with only mild weakness in the limbs and his NIHSS score decreased to 5. On review of repeat MRI and TCD, there was no progression of ischemic stroke or symptomatic intracerebral hemorrhage (Fig. 2), and his BA remained patent. The patient was discharged on the 7th day of hospitalization with dual antiplatelet therapy and a high dose of statin amongst other risk factor control measures.

**Discussion**

BAO is a relatively infrequent but devastating condition which can lead to severe neurological deficits. The most common clinical manifestations of BAO are a reduced level of consciousness, hemiparesis or quadriplegia, gaze abnormalities, and cranial nerve palsies. Disruption in the BA’s blood supply to the reticular activating system can result in catastrophic locked-in syndrome with quadriplegia and anarthria. Occlusion of a major artery, such as the BA, is challenging to treat because of suboptimal response to thrombolysis with intravenous tPA and high rates of reocclusion following successful initial recanalization, especially in the presence of underlying intracranial atherosclerotic disease (ICAD) prevalent in Asian stroke patients. In this situation, repeated ET with balloon angioplasty and stenting can be considered as rescue therapy. Without early recanalization, the prognosis of acute BAO is usually very poor. As the collateral circulation of the posterior circulation was more abundant compared to anterior circulation, it has been argued that the thrombolysis time window can potentially be prolonged in posterior circulation stroke [5]. Several studies suggested that recanalization therapies for BAO can potentially benefit patients up to 12–24 h after symptom onset [6–8]. As a result, our center has adopted a thrombolysis time window up to 24 h in BAO and posterior circulation infarcts without evidence of large ischemic lesions on neuroimaging. In our patient, intravenous alteplase was administered 14 h after onset of his first symptoms that was immediately bridged with endovascular treatment. The guidewire could not pass through the occlusion and we failed to achieve recanalization at the first intervention. During the procedure, good collateral flow from the anterior circulation was shown, which could explain the slow progression of neurological symptoms. During the second attempt, balloon angioplasty resulted in partial recanalization of the BA, and aggressive medical management as recommended in the SAMMPRIS trial was initiated 24 h post-thrombolysis [9]. We tried to avoid emergency stenting, as antithrombotic therapy given within 24 h of alteplase treatment could increase the risk of intracranial hemorrhage, and this procedure was previously reported to increase the risk of hemorrhage and reocclusion [10, 11]. The patient further deteriorated to a comatose state due to BA reocclusion. Angioplasty and stenting in the third attempt resulted in complete recanalization (TICI 3) of the BA accompanied with excellent neurological recovery. Our patient with acute posterior circulation infarction and underlying ICAD underwent ET of the same occluded BA thrice within 24 h. Data on repeated ET for early recurrent stroke caused by the occlusion of the same affected vessel are scarce. To our knowledge, there are only a few case reports [3–5, 12] and two retrospective studies with repeated ET due to recurrent LVO [13, 14], but mostly in the anterior circulation. Our case report is the first on repeated ET within the BA. Repeated ET may lead to more severe
disruption of the vascular endothelium, thereby increasing the risk of complications such as vasospasm, arterial dissection, as well as perforation [15]. However, no intraprocedural complication was recorded in our patient. Evidence on the safety and effectiveness of repeated thrombectomy in elderly patients compared with younger patients is unclear due to limited data. Our case demonstrates that even repeated ET can be technically feasible and safe and may result in remarkable clinical improvement in BAO.

The most common causes of BAO are atherosclerotic disease resulting from local thrombosis due to severe stenosis and thromboembolism from cardiac and large artery sources. The mechanism differs depending on the affected segment. Lodging of an embolic source is much more frequent in the distal third of the BA, especially at the top of the BA. Atherosclerosis often involves both vertebral arteries and leads mostly to occlusion of the proximal and middle segments of the BA, which is presented in this case. Rare causes of BAO, including vascular dissection, vasospastic syndrome had no evidence on DSA imaging. Other follow-up test results included high LDL-c lipid profile, nonsignificant carotid artery stenosis, sinus rhythm on the 24 h electrocardiogram, negative PFO under TCD, and normal cardiac ultrasound, which confirmed the intracranial atherosclerosis cause of the vascular occlusion.

In conclusion, repeated ET for early recurrent LVO stroke, especially in acute BAO appears feasible in carefully selected patients. A previous thrombectomy should not discourage repeated aggressive treatment as these patients may achieve similar rates of good clinical outcome as those who undergo single thrombectomy. In addition, angioplasty with stenting could be considered in the primary treatment in future cases with underlying ICAD to prevent reocclusion.
