Resummation of the Divergent Perturbation Series
for a Hydrogen Atom in an Electric Field

We consider the resummation of the perturbation series describing the energy displacement of a
hydrogenic bound state in an electric field (known as the Stark effect or the LoSurdo–Stark effect),
which constitutes a divergent formal power series in the electric field strength. The perturbation
series exhibits a rich singularity structure in the Borel plane. Resummation methods are presented
which appear to lead to consistent results even in problematic cases where isolated singularities or
branch cuts are present on the positive and negative real axis in the Borel plane. Two resummation
prescriptions are compared: (i) a variant of the Borel–Padé resummation method, with an additional
improvement due to utilization of the leading renormalon poles (for a comprehensive discussion of
renormalons see [M. Beneke, Phys. Rep. 317, 1 (1999)]), and (ii) a contour-improved combination
of the Borel method with an analytic continuation by conformal mapping, and Padé approximations
in the conformal variable. The singularity structure in the case of the LoSurdo–Stark effect in
the complex Borel plane is shown to be similar to (divergent) perturbative expansions in quantum
chromodynamics.

I. INTRODUCTION

Consider the energy shift of the ground state of atomic
hydrogen in an electric field of field strength \( F \) which
we assume to lie along the \( z \)-axis: the energy displacement
can be expressed in perturbation theory as a for-
mal power series. The first nonvanishing perturbation in atomic units, see also Eq. (11) below] is the second-order effect

\[
F^2 \sum_{m \neq 1S} \frac{\langle 1S | z | \phi_m \rangle \langle \phi_m | z | 1S \rangle}{E_{1S} - E_m},
\]

where the sum over \( m \) runs over the entire spectrum,
including the continuum, but excluding the 1S ground
state, and \( E_m \) is the nonrelativistic (Schrödinger) energy
of the \( m \)th state. A well known, but perhaps surprising
result says that the coefficients of the terms of order \( F^4 \),
\( F^6 \), \( F^8 \), ... grow so rapidly that the series in \( F \) ultimately
diverges, irrespective of how small the field strength is.
The convergence radius of the factorially divergent per-
turbation series is zero. The resummation of the diver-
gent series is problematic in the considered case, because
the Borel transform, from which the physically correct,
finite result is obtained by evaluating the Laplace–Borel
integral – see Eq. (11) in Sec. II below –, exhibits a rich
singularity structure in the complex plane.
The purpose of this paper is to present numerical evi-
dence that divergent perturbation series whose Borel
transform exhibits a rich singularity structure in the com-
plex plane, can be resummed to the complete, physi-
cally relevant result. The resummation methods use as
input data only a finite number of perturbative coeffi-
cients. Problematic singularities on the positive real axis
in the Borel plane are treated by appropriate integra-
tion prescriptions. In particular, it is shown that the
Borel transform of the divergent perturbation series for
the LoSurdo–Stark effect involves two cuts in the Borel
plane, generated essentially by the divergent alternating
and nonalternating subcomponents of the perturbation
series. This singularity structure is also expected of the
(divergent) perturbation series in quantum field theory,
notably quantum chromodynamics (in this case, the al-
ternating and nonalternating factorially divergent com-
ponents correspond in their mathematical structure to
the ultraviolet and infrared renormalons).

We present results which suggest that the integration
contours and resummation techniques discussed here may
be of relevance, at least in part, to theories with degener-
ate minima. As a byproduct of these investigations, nu-
merical pseudo-eigenvalues are obtained for the LoSurdo–
Stark effect; selected field strengths and atomic states are
considered.

The LoSurdo–Stark effect and its associated divergent
perturbative expansion including the the nonperturba-
tive, nonanalytic imaginary contributions have attracted
considerable attention, both theoretically and experi-
mentally [1–34]. Experiments have been performed in
field strengths up to a couple of MV/cm [35–38]. One
might be tempted to say that the autoionization decay
width could be interpreted as a paradigmatic example for
a nonperturbative effect which exhibits fundamental lim-
itations to the validity of perturbation theory (unless the
perturbative expansion is combined with resummation
methods). We briefly summarize here: The Rayleigh–
Schrödinger perturbation series for the LoSurdo–Stark

\[ E_{1S} - E_m \]
effect [33, 40] can be formulated to arbitrarily high order [1]. The perturbative coefficients grow factorially in absolute magnitude [3], and the radius of convergence of the perturbation series about the origin is zero. The perturbation series is a divergent, asymptotic expansion in the electric field strength $F$, i.e. about zero electric field. This means that the perturbative terms at small coupling first decrease in absolute magnitude up to some minimal term. After passing through the minimal term, the perturbative terms increase again in magnitude, and the series ultimately diverges.

By the use of a resummation method, it is possible to assign a finite value to an otherwise divergent series, and various applications of resummation methods in mathematics and physics have been given, e.g., in [14–16]. When a divergent series is resummed, the superficial precision limit set by the minimal term can be overcome, and more accurate results can be obtained as compared to the optimal truncation of the perturbation series (see also the numerical results in the Tables of [46]). The divergent perturbation series of the LoSurdo–Stark effect has both alternating and nonalternating components (as explained in Sec. I below). The resummation of nonalternating series or of series which have a leading or subleading divergent nonalternating component, corresponds to a resummation “on the cut” in the complex plane [14, 12].

Rather mathematically motivated investigations regarding the Borel summability of the divergent perturbation series for the LoSurdo–Stark effect were performed in [13] and [17], and it was established that the perturbation series of the LoSurdo–Stark effect is Borel summable in the distributional sense (for the definition of “distributional Borel summability” we refer to [18]). Here, to supplement the mathematically motivated investigations, we consider the calculation of transforms of the divergent series, which use as input data only a finite number of perturbative coefficients and exhibit apparent convergence to the complete, physically relevant result.

In the remarkable investigation [25], whose significance may not have been sufficiently noticed in the field of large-order perturbation theory, it was not only shown that it is possible to perform the required analytic continuation of the Borel transform beyond its radius of convergence by employing Padé approximants, but that it is also possible to reconstruct the full physical result, including the imaginary contribution which corresponds to the autoionization decay width, by integration in the complex plane.

In Sec. II, we discuss the singularity structure of the Borel transform in the complex plane. The structure of a doubly-cut plane has been postulated for quantum chromodynamic perturbation series [49, 50], and this structure has been exploited to devise resummation prescriptions based on conformal mappings [49, 13]. Here, we present results which suggest that the convergence of the transforms obtained by conformal mapping can be improved if Padé approximants in the conformal variable are used (see also [55]). We also discuss improvements of the “pure” Borel–Padé method (these additional improvements take advantage of leading renormalon poles).

As stressed above, it has been another main motivation for the current investigation to establish the singularity structure of the Borel transform in the complex plane, and to demonstrate the analogy of the singularity structure of the perturbation series for the LoSurdo–Stark effect to quantum chromodynamic perturbation series. We also consider a divergent perturbation series generated by a model problem for theories with degenerate minima. In the particular model case discussed here, a perturbation series with real coefficients is summed to a real result — in contrast to the LoSurdo–Stark effect, there is no imaginary part involved in this case. One of the three alternative integration contours introduced in [18] has to be employed.

This paper is organized as follows: In Sec. II, we give a brief outline of the perturbative expansion for the LoSurdo–Stark effect. In Secs. III and IV, we describe the resummation methods which are used to obtain the numerical results presented in Sec. V. In Sec. VI, we consider theories with degenerate minima. We conclude with a summary of the results in Sec. VII. Finally, the connection of the current investigation to quantum field theoretic perturbation series and to double-well oscillators are discussed in the Appendixes A and B.

II. PERTURBATION SERIES FOR THE LOSURDO–STARK EFFECT

In the presence of an electric field, the SO(4) symmetry of the hydrogen atom is broken, and parabolic quantum numbers $n_1$, $n_2$ and $m$ are used for the classification of the atomic states [57]. For the Stark effect, the perturbative expansion of the energy eigenvalue $E(n_1, n_2, m, F)$ reads [see Eq. (59) of [1]],

$$E(n_1, n_2, m, F) \sim \sum_{N=0}^{\infty} E_{n_1 n_2 m}^{(N)} F^N , \quad (1)$$

where $F$ is the electric field strength. For $N \to \infty$, the leading large-order factorial asymptotics of the perturbative coefficients have been derived in [40] as

$$E_{n_1 n_2 m}^{(N)} \sim A_{n_1 n_2 m}^{(N)} + (-1)^N A_{n_2 n_1 m}^{(N)} , \quad N \to \infty , \quad (2)$$

where $A_{n_1 n_2 m}^{(N)}$ is given as an asymptotic series,
The quantities \( a_k^{n_i n_j m} \) are constants. The \( K \)-coefficients in Eq. (3) are given by

\[
K(n_i, n_j, m, N) = -\left[2\pi n^3 n_i (n_j + m)!\right]^{-1} \times \exp \{3 (n_i - n_j)\} 6^{2n_j + m + 1} (3n^3/2)^N. \tag{4}
\]

According to Eq. (3), the perturbative coefficients \( E_{n_1 n_2 m}^{(N)} \), for large order \( N \to \infty \) of perturbation theory, can be written as a sum of a nonalternating factorially divergent series [first term in Eq. (3)] and of an alternating factorially divergent series [second term in Eq. (3)]. Because the \( a_k^{n_i n_j m} \) in Eq. (3) are multiplied by the factorial \( (2n_i + m + N - k)! \), we infer that for large perturbation theory order \( N \), the term related to the \( a_0^{n_i n_j m} \) coefficient \((k = 0)\) dominates. Terms with \( k \geq 1 \) are suppressed in relation to the leading term by a relative factor of \( 1/N^k \) according to the asymptotics

\[
\frac{(2n_j + m + N - k)!}{(2n_j + m + N)!} \sim \frac{1}{N^k} \left[1 + \mathcal{O}\left(\frac{1}{N}\right)\right] \tag{6}
\]

for \( N \to \infty \). The leading \((k = 0)\)-coefficient has been evaluated in [58] as

\[
a_0^{n_i n_j m} = 1. \tag{7}
\]

According to Eqs. (3), (4) and (5), for states with \( n_1 < n_2 \), the nonalternating component of the perturbation series dominates in large order of perturbation theory, whereas for states with \( n_1 > n_2 \), the alternating component is dominant as \( N \to \infty \). For states with \( n_1 = n_2 \), the odd-\( N \) perturbative coefficients vanish [58], and the even-\( N \) coefficients necessarily have the same sign in large order [see Eq. (4)]. According to Eq. (3), there are subleading divergent nonalternating contributions for states with \( n_1 > n_2 \), and there exist subleading divergent alternating contributions for states with \( n_1 < n_2 \). This complicates the resummation of the perturbation series.

III. BOREL–PADÉ RESUMMATION

The resummation of the perturbation series \( (1) \) by a combination of the Borel transformation and Padé approximants proceeds as follows. First we define the parameter

\[
\lambda = 2 \max(n_1, n_2) + m + 1. \tag{8}
\]

The large-order growth of the perturbative coefficients [see Eqs. (3) and (4)] suggests the definition of the (generalized) Borel transform [see Eq. (4) in [58]]

\[
E_B(z) = E_B(n_1, n_2, m, z) = B^{(1,\lambda)}[E(n_1, n_2, m); z]
= \sum_{N=0}^{\infty} \frac{E_{n_1 n_2 m}^{(N)}}{\Gamma(N + \lambda)} z^N, \tag{9}
\]

where we consider the argument \( z \) of \( E_B(z) \) as a complex variable and \( \lambda \) is defined in Eq. (5). The additive constant (in this case \( \lambda \)) in the argument of the Gamma function is chosen in accordance with the notion of an “asymptotically improved” resummation (see also [58]). It is observed that the additive constant \( \lambda \) can be shifted by a small integer without affecting the convergence of the Borel resummed series. Because the perturbative coefficients \( E_{n_1 n_2 m}^{(N)} \) diverge factorially in absolute magnitude, the Borel transform \( E_B(z) \) has a finite radius of convergence about the origin. The evaluation of the (generalized) Laplace–Borel integral [see Eq. (11) below] therefore requires an analytic continuation of \( E_B(z) \) beyond the radius of convergence. The “classical” Borel integral is performed in the \( z \)-range \( z \in (0, \infty) \), i.e. along the positive real axis [see e.g. Eqs. (8.2.3) and (8.2.4) of [41]]. It has been suggested in [58] that the analytic continuation
of \( [x] \) into regions where \( F \) retains a nonvanishing, albeit infinitesimal, imaginary part can be achieved by evaluating Padé approximants. Using the first \( M + 1 \) terms in the power expansion of the Borel transform \( E_B(z) \), we construct the Padé approximant (we follow the notation of [13])

\[
\mathcal{P}_M(z) = \left[ \left[ M/2 \right]/\left[ (M + 1)/2 \right] \right]_{E_B} (z),
\]

where \( \left[x \right] \) denotes the largest positive integer smaller than \( x \). We then evaluate the (modified) Borel integral along the integration contour \( C_{+1} \) shown in Fig. 1 in order to construct the transform \( TE_M(F) \) where

\[
TE_M(F) = \int_{C_{+1}} dt \, t^{\lambda - 1} \exp(-t) \mathcal{P}_M(F \, t).
\]

The successive evaluation of transforms \( TE_M(F) \) in increasing transformation order \( M \) is performed, and the apparent convergence of the transforms is examined. This procedure is illustrated in Tables I and II of [14]. In the current evaluation, a slightly modified scheme is used for selecting the poles in the upper right quadrant of the complex plane as compared to [14].

The contour \( C_{+1} \) is supposed to encircle all poles at \( t = z_i \) in the upper right quadrant of the complex plane with \( \arg z_i < \pi/4 \) in the mathematically negative sense. That is to say, the contribution of all poles \( z_i \) with \( \text{Re} \, z_i > 0, \text{Im} \, z_i > 0 \) and \( \text{Re} \, z_i > \text{Im} \, z_i \),

\[
-2 \pi i \sum_{t = z_i} \text{Res} \, t^{\lambda - 1} \exp(-t) \mathcal{P}_M(F \, t),
\]

is added to the principal value (P.V.) of the integral \( (11) \) carried out in the range \( t \in (0, \infty) \). Note the further restriction (\( \text{Im} \, z_i < \text{Re} \, z_i \) or equivalently \( \arg z_i < \pi/4 \)) with regard to the selection of poles in comparison to the previous investigation [15]. In practical calculations, this modification is observed not to affect the numerical values of the transforms \( TE_M(F) \) defined in Eq. \( (11) \) in higher transformation order \( M \geq 10 \) [i.e. for large \( M \), see also Eq. \( (14) \) below], because the poles are observed to cluster near the real axis in higher transformation order, and so the contribution of poles with \( \pi/4 < \arg z_i < \pi/2 \) gradually vanishes. We have,

\[
TE_M(F) = (\text{P.V.}) \int_0^\infty dt \, t^{\lambda - 1} \exp(-t) \mathcal{P}_M(F \, t)
-2 \pi i \sum_{t = z_i} \text{Res} \, t^{\lambda - 1} \exp(-t) \mathcal{P}_M(F \, t).
\]

The principal-value prescription [first term in Eq. \( (12) \)] for the evaluation of the Laplace–Borel integral has been recommended in [15, 13]. This prescription leads to a real (rather than complex) result for the energy shift and cannot account for the width of the quasistationary state. The additional pole contributions [second term in Eq. \( (12) \)] are responsible for complex-valued (imaginary) corrections which lead, in particular, to the decay width.

By contour integration (Cauchy Theorem) and Jordan’s Lemma, one can show that the result obtained along \( C_{+1} \) is equivalent to an integration along the straight line with \( \text{arg} \, z = \pi/4 \),

\[
TE_M(F) = c^\lambda \int_0^\infty dt \, t^{\lambda - 1} \exp(-c \, t) \mathcal{P}_M(F \, c \, t)
\]

where \( c = \exp(i \, \pi/4) \). This contour has been used in [23] (see also p. 815 in [43]). The exponential factor \( \exp(-c \, t) \) and the asymptotic behavior of the Padé approximant \( \mathcal{P}_M(F \, c \, t) \) as \( t \to \infty \) together ensure that the integrand falls off sufficiently rapidly so that the Cauchy Theorem and Jordan’s Lemma can be applied to show the equivalence of the representations \( (12) \) and \( (13) \).

The representation \( (13) \) illustrates the fact that the integration in the complex plane along \( C_{+1} \) analytically continues the resummed result in those cases where the evaluation of the standard Laplace–Borel integral is not feasible due to poles on the real axis. The representations \( (11) \) and \( (12) \) serve to clarify the role of the additional terms which have to be added to the result obtained by the principal-value prescription in order to obtain the full physical result, including the nonperturbative, nonanalytic contributions. Note that, as stressed in [19], the pole contributions in general do not only modify the imaginary, but also the real part of the resummed value for the perturbation series.

Formally, the limit of the sequence of the \( TE_M(F) \) as \( M \to \infty \), provided it exists, yields the nonperturbative result inferred from the perturbative expansion \( (1) \),

\[
\lim_{M \to \infty} TE_M(F) = E(F) \equiv E(n_1, n_2, m, F).
\]

Because the contour \( C_{+1} \) shown in Fig. 1 extends into the complex plane, the transforms \( TE_M(F) \) acquire an imaginary part even though the perturbative coefficients in Eq. \( (1) \) are real.

In the context of numerical analysis, the concept of incredulity [51] may be used for the analysis of the convergence of the transforms \( TE_M(F) \) of increasing order \( M \). If a certain number of subsequent transforms exhibit apparent numerical convergence within a specified relative accuracy, then the calculation of transforms is stopped, and the result of the last calculated transformation is taken as the numerical limit of the series under investigation. It has been observed in [45, 53] that for a number of physically relevant perturbation series, the apparent numerical convergence of the transforms \( (11) \), with increasing transformation order, leads to the physically correct results.

It is observed that the rate of convergence of the transforms \( (11) \) can be enhanced if instead of the unmodified Padé approximants \( (10) \) leading “renormalon” poles are explicit used for the construction of modified approximants. For the ground state, this entails the following replacement in Eq. \( (11) \):

\[
\int_{C_{+1}} dt \, t^{\lambda - 1} \exp(-t) \mathcal{P}_M(F \, t)
-2 \pi i \sum_{t = z_i} \text{Res} \, t^{\lambda - 1} \exp(-t) \mathcal{P}_M(F \, t).
\]
\[ \mathcal{P}_M(z) \rightarrow \mathcal{P}'_M(z), \]

where

\[ \mathcal{P}'_M(z) = \frac{1}{1 - z^2} \left[ \frac{M + 4}{2} \right] \left[ \frac{M - 3}{2} \right] E'_B(z), \]

(15)

where \( E'_B(\zeta) = (1 - \zeta^2) E_B(\zeta) \). For the excited state with quantum numbers \( n_1 = 3, n_2 = 0 \) and \( m = 1 \), we replace

\[ \mathcal{P}_M(z) \rightarrow \mathcal{P}''_M(z), \]

where

\[ \mathcal{P}''_M(z) = \frac{1}{1 - z^2} \left[ \frac{M + 2}{2} \right] \left[ \frac{M - 1}{2} \right] E''_B(z), \]

(16)

where \( E''_B(\zeta) = (1 - \zeta^2) E_B(\zeta) \). The resummation method by a combination of Borel and Padé techniques – current Section – will be referred to as “method I” throughout the current paper.

**IV. DOUBLY–CUT BOREL PLANE AND RESUMMATION BY CONFORMAL MAPPING**

According to Eqs. (2) and (3), the perturbative coefficient \( E_{n_1 n_2 m}^{(N)} \), for large \( N \), can be written as the sum of an alternating and of a nonalternating divergent series. In view of Eqs. (4) and (7), we conclude that the series defined in Eq. (9),

\[ E_B(z) = \sum_{N=0}^{\infty} \frac{E_{n_1 n_2 m}^{(N)}}{\Gamma(N + \lambda)} z^N, \]

has a radius of convergence

\[ s = \frac{2}{3n^4} \]

(17)

about the origin, where \( n \) is the principal quantum number [see Eq. (3)]. Therefore, the function

\[ \mathcal{E}_B(w) = \sum_{N=0}^{\infty} \frac{E_{n_1 n_2 m}^{(N)}}{\Gamma(N + \lambda)} w_N, \]

(18)

has a unit radius of convergence about the origin. It is not \( a \ priori \) obvious if the points \( w = -1 \) and \( w = +1 \) represent isolated singularities or branch points. The asymptotic properties (2) and (3) together with Eq. (6) suggest that the points \( w = -1 \) and \( w = +1 \) do not constitute poles of finite order. We observe that the leading factorial growth of the perturbative coefficients in large perturbation order \( N \) is divided out in the Borel transform (8), which is a sum over \( N \). The perturbative coefficient \( E_{n_1 n_2 m}^{(N)} \) can be written as an asymptotic series over \( k \) [see Eq. (18)]. We interchange the order of the summations over \( N \) and \( k \), we use Eq. (8) and take advantage of the identity

\[ \sum_{N=0}^{\infty} \frac{w^N}{N^k} = \text{Li}_k(w). \]

(19)

The Borel transform \( \mathcal{E}_B(w) \) can then be written as a sum over terms of the form \( T_k(w) \) where \( k \rightarrow \infty \),

\[ T_k(w) \sim C(n_i, n_j, m) a_k^{n_i n_j m} \text{Li}_k(w). \]

(20)

The coefficient \( C(n_i, n_j, m) \) is given by

\[ C(n_i, n_j, m) = - \binom{2\pi i n! (n_j + m)!}{2} \times \exp \{3(n_i - n_j)\} 2^{n_i + m + 1}. \]

(21)

These considerations suggest that the points \( w = -1 \) and \( w = +1 \) represent essential singularities (in this case, branch points) of the Borel transform \( \mathcal{E}_B(w) \) defined in Eq. (18). For the analytic continuation of \( \mathcal{E}_B(w) \) by conformal mapping, we write \( w \) as

\[ w = \frac{2y}{1 + y^2} \]

(22)

(this conformal mapping preserves the origin of the complex plane). Here, we refer to \( w \) as the Borel variable, and we call \( y \) the conformal variable. We then express the \( M \)-th partial sum of (18) as

\[ \mathcal{E}_B^M(y) = \sum_{N=0}^{M} \frac{E_{n_1 n_2 m}^{(N)}}{\Gamma(N + \lambda)} w_N \]

\[ = \sum_{N=0}^{M} C_N y^N + O(y^{M+1}), \]

(23)

where the coefficients \( C_N \) are uniquely determined [see, e.g., Eqs. (36) and (37) of (19)]. We define the partial sum of the Borel transform, re-expanded in terms of the conformal variable \( y \), as

\[ \mathcal{E}_B^M(y) = \sum_{N=0}^{M} C_N y^N. \]

(24)

We then evaluate (lower-diagonal) Padé approximants to the function \( \mathcal{E}_B^M(y) \),

\[ \mathcal{E}_B^{M}(y) = \left[ \frac{[(M+1)/2]}{[(M+1)/2]} \right] \mathcal{E}_B^M(y). \]

(25)

We define the following transforms,

\[ T^{\alpha} E_M(F) = s^\lambda \int_{C_{+1}} dw w^{-1 - \lambda} \exp(-w) \mathcal{E}_B^{M}(y(w)) \]

(26)
At increasing $M$, the limit as $M \to \infty$, provided it exists, is then again assumed to represent the complete, physically relevant solution,

$$E(F) = \lim_{M \to \infty} T^0 E_M(F).$$

(27)

We do not consider the question of the existence of this limit here (for an outline of questions related to these issues we refer to [50]; potential problems at excessively strong coupling are discussed in Sec. IIC of [52]).

Inverting Eq. (22) yields [see Eq. (22)]

$$y(w) = \frac{\sqrt{1+w} - \sqrt{1-w}}{\sqrt{1+w} + \sqrt{1-w}}.$$  

(28)

The conformal mapping given by Eqs. (22) and (28) maps the doubly cut $w$-plane with cuts running from $w = 1$ to $w = \infty$ and $w = -1$ to $w = -\infty$ into the unit circle in the complex $y$-plane. The cuts themselves are mapped to the edge of the unit circle in the $y$-plane.

In comparison to the investigations [61] and [62], we use here a different conformal mapping defined in Eqs. (22) and (28) which reflects the different singularity structure in the complex plane [cf. Eq. (27) in [19]]. We also mention the application of Padé approximants for the numerical improvement of the conformal mapping performed according to Eq. (23). In comparison to a recent investigation [53], where the additional Padé–improvement in the conformal variable is also used, we perform here the analytic continuation by a mapping whose structure reflects the double cuts suggested by the asymptotic properties of the perturbative coefficients given in Eqs. (2), (3) and (1) [cf. Eq. (5) in [63]].

The method introduced in this Section will be referred to as “method II”. It is one of the motivations for the current investigation to contrast and compare the two methods I and II. A comparison of different approaches to the resummation problem for series with both alternating and nonalternating divergent components appears useful, in part because the conformal mapping (without further Padé improvement) has been recommended for the resummation of quantum chromodynamic perturbation series [62, 63].

We do not consider order-dependent mappings here [61, 62]. For an order-dependent mapping to be constructed, the conformal mapping in Eq. (22) has to be modified, and a free parameter $\rho$ has to be introduced. The coefficients $C_N$ in the accordingly modified Eq. (24) then become $\rho$-dependent. The free parameter $\rho$ is chosen so that the $\rho$-dependent coefficient $C_M(\rho)$ of order $M$ vanishes. Consequently, the choice of $\rho$ depends on the order $M$ of perturbation theory, and in this way the mapping becomes order-dependent. Certain complications arise because $\rho$ cannot be chosen arbitrarily, but has to be selected, roughly speaking, as the first zero of the $\rho$-dependent coefficient $C_M(\rho)$ for which the absolute magnitude of the derivative $C_M'(\rho)$ is small (this is explained in [63], p. 886). It is conceivable that with a judicious choice of $\rho$, further acceleration of the convergence can be achieved, especially when the order-dependent mapping is combined with a Padé approximation as it is done here in Eq. (23) with our order-independent mapping. In the current investigation, we restrict the discussion to the conformal order-independent mapping [63] which is nevertheless optimal in the sense discussed in [49, 50].

V. NUMERICAL CALCULATIONS

In this section, the numerical results based on the resummation methods introduced in Secs. [II] and [IV] are presented. Before we describe the calculation in detail, we should note that relativistic corrections to both the real and the imaginary part of the energy contribute at a relative order of $(Z\alpha)^2$ compared to the leading nonrelativistic effect which is treated in the current investigation (and in the previous work on the subject, see e.g. [14, 23]). Therefore, the theoretical uncertainty due to relativistic effects can be estimated to be, at best, 1 part in $10^3$ (for an outline of the relativistic and quantum electrodynamic corrections in hydrogen see [53, 54]). Measurements in very high fields are difficult [55]. At the achievable field strengths to date (less than 0.001 a.u. or about 5 MV/cm), the accuracy of the theoretical prediction exceeds the experimental precision, and relativistic effects do not need to be taken into account.

The perturbative coefficients $E^{(N)}_{n_1 n_2 m}$, defined in Eq. (1) for the energy shift can be inferred, to arbitrarily high order, from the Eqs. (9), (13–15), (28–33), (59–67) and (73) in [1]. The atomic unit system is used in the sequel, as is customary for this type of calculation [1, 4, 11]. The unit of energy is $\alpha^2 m_e c^2 = 27.211$ eV where $\alpha$ is the fine structure constant, and the unit of the electric field is the field strength felt by an electron at a distance of one Bohr radius $a_{\text{Bohr}}$ to a nucleus of elementary charge, which is $1/(4\pi \epsilon_0)$ ($e^2/a^2_{\text{Bohr}} = 5.142 \times 10^3$ MV/cm (here, $\epsilon_0$ is the permittivity of the vacuum).

We consider the resummation of the divergent perturbative expansion (1) for two states of atomic hydrogen. These are the ground state $(n_1 = n_2 = m = 0)$ and an excited state with parabolic quantum numbers $n_1 = 3$, $n_2 = 0$, $m = 1$. We list here the first few perturbative coefficients for the states under investigation. For the ground state, we have (in atomic units),

$$E_{000}(F) = -\frac{1}{2} - \frac{9}{4} F^2 - \frac{3555}{64} F^4$$

$$- \frac{2512779}{512} F^6 - \frac{13012777803}{16384} F^8 + \ldots$$

(29)

The perturbation series for the state $n_1 = 3$, $n_2 = 0$, $m = 1$ is alternating, but has a subleading nonalternating component [see Eq. (1)]. The first perturbative terms read
and an imaginary component, pseudoeigenvalue (resonance) contrast to the real perturbative coefficients, the energy $F$ Note that for $E = 0$, the unperturbed nonrelativistic energy is recovered, which is $-1/(2n^2)$ in atomic units. In contrast to the real perturbative coefficients, the energy pseudoeigenvalue $E(n_1, n_2, m, F)$ has a real and an imaginary component,

$$E(n_1, n_2, m, F) = \text{Re} E_{n_1, n_2, m}(F) - i \frac{\Gamma}{2} n_1, n_2, m(F),$$  \hspace{1cm} (31)

where $\Gamma_{n_1 n_2 m}(F)$ is the autoionization width.

Using a computer algebra system [70, 71], the first 50 nonvanishing perturbative coefficients are evaluated for the ground state, and for the state with parabolic quantum numbers $n_1 = 3, n_2 = 0, m = 1$, we evaluate the first 70 nonvanishing perturbative coefficients. The apparent convergence of the transforms defined in Eqs. (11) and (24) in higher order is examined. In the case of the Borel–Padé transforms defined in Eqs. (11) and (24), use is made of the replacements in Eqs. (15) and (26) ["leading renormalon poles are being put in by hand"][1]. This procedure leads to the numerical results listed in Tables III and IV. The numerical error of our results is estimated on the basis of the highest and lowest value of the four highest-order transforms.

An important result of the comparison of the methods introduced in Secs. III and IV is the following: Both methods appear to accomplish a resummation of the perturbation series to the physically correct result. Method I (Borel–Padé with leading renormalon poles, see Sec. III) and method II (Borel–Padé–improved conformal mapping, see Sec. IV) appear to lead to results of comparable accuracy.

To date, a rigorous theory of the performance of the resummation methods for divergent series of the type discussed in this work (with alternating and nonalternating components) does not exist. The logarithmic singularities introduced by the branch points of higher-order polylogarithms [see the index $k$ in Eq. (19)] are difficult to approximate with the rational functions employed in the construction of Padé approximants. A solution to the problem of approximating the logarithmic singularities, based on finite number of perturbative coefficients, would probably lead to further optimization of the rate of convergence of the transformed series. Within the current scheme of evaluation, the problematic logarithmic singularities may be responsible, at least in part, for certain numerical instabilities at higher transformation order, e.g., in the result for $\mathcal{TE}_{70}(F = 2.1393 \times 10^{-4})$ in Eq. (32) below.

For the atomic state with quantum numbers $n_1 = 3, n_2 = 0$ and $m = 1$, the evaluation of the transforms $\mathcal{TE}_M(F)$ defined in Eq. (11) (method I) and of the transforms $\mathcal{TE}_M(F)$ defined in Eq. (26) (method II) in transformation order $M = 67, 68, 69, 70$ for a field strength of $F = 2.1393 \times 10^{-4}$. Method I leads to the following results,

$$\mathcal{TE}_{67}(F = 2.1393 \times 10^{-4}) = -0.015 860 468 199 2$$
$$- i 0.529 048 \times 10^{-6},$$

$$\mathcal{TE}_{68}(F = 2.1393 \times 10^{-4}) = -0.015 860 468 200 9$$
$$- i 0.529 047 \times 10^{-6},$$

$$\mathcal{TE}_{69}(F = 2.1393 \times 10^{-4}) = -0.015 860 468 198 9$$
$$- i 0.529 048 \times 10^{-6}$$ and

$$\mathcal{TE}_{70}(F = 2.1393 \times 10^{-4}) = -0.015 860 468 194 5$$
$$- i 0.529 015 \times 10^{-6}. \hspace{1cm} (32)$$

**TABLE I.** Real and imaginary part of the energy pseudoeigenvalue $E_{\text{auto}}(F)$ for the ground state of atomic hydrogen (parabolic quantum numbers $n_1 = 0, n_2 = 0, m = 0$).

| $F$ (a.u.) | $\text{Re} E_{\text{auto}}(F)$ | $\text{Im} E_{\text{auto}}(F)$ |

| 0.36      | -0.604(5)                   | 3.46(3) $10^{-1}$           |
| 0.40      | -0.608(5)                   | 4.00(5) $10^{-1}$           |
Method II yields the following data,

\[ T'' E_{67}(F = 2.1393 \times 10^{-4}) = -0.015 860 468 200 4 \\
- i 0.529 047 \times 10^{-6}, \]

\[ T'' E_{68}(F = 2.1393 \times 10^{-4}) = -0.015 860 468 200 3 \\
- i 0.529 047 \times 10^{-6}, \]

\[ T'' E_{69}(F = 2.1393 \times 10^{-4}) = -0.015 860 468 200 4 \\
- i 0.529 047 \times 10^{-6} \text{ and} \]

\[ T'' E_{70}(F = 2.1393 \times 10^{-4}) = -0.015 860 468 203 3 \\
- i 0.529 046 \times 10^{-6}. \]  

(33)

Numerical results obtained by resummation are presented in Tables II and III for a variety of field strengths and for the two atomic states under investigation here. Results are compared to the numerical calculation [9], which yields very accurate data for all experimentally accessible electric field strengths to date. In addition, it should be noticed that the inaccuracies at excessively large field strengths have been pointed out by the same authors in [27]. However, not all atomic states considered in [9] were treated in the later investigation [27]. Our data for the ground state indicated in Table I are consistent with the numerical results obtained in [27]. However, it should be noted that the later work [27] leaves out the excited state with quantum numbers \( n_1 = 3, n_2 = 0 \) and \( m = 1 \) for which results are given here here in Table II. To the best of our knowledge, the numerical discrepancy with [9] for the excited state with quantum numbers \( n_1 = 3, n_2 = 0 \) and \( m = 1 \) has not been recorded in the literature. We do not claim here that it would have been impossible to discern this discrepancy with the other methods which have been devised for the theoretical LoSurdo–Stark problem. Notably, it appears likely that the approach from [27] or the method presented in [19] could easily be generalized to the particular excited state considered here, and that such a generalization would lead to very accurate results. We merely include Table II here in order to illustrate the utility of the rather unconventional resummation method for the regime of large coupling, where even rather sophisticated numerical methods, which avoid the intricacies of a small-field perturbative expansion, have been shown to be problematic [9, 27]. We confirm that the numerical data given in [9] are accurate up to a field strength of \( F \approx 0.1 \) for the ground state and up to \( F \approx 3 \times 10^{-4} \) for the excited \((n = 5)\)-state with \( n_1 = 3, n_2 = 0 \) and \( m = 1 \).

**TABLE II.** Real part and imaginary part of the energy pseudoeigenvalue \( E_{301}(F) \) for the excited state with parabolic quantum numbers \( n_1 = 3, n_2 = 0, m = 1 \). The field strength \( F \) is given in atomic units. The data are compared to Ref. [9]. Discrepancies are observed at large electric field strength.

VI. MODEL EXAMPLE FOR DEGENERATE MINIMA

We consider the generating functional in a zero-dimensional theory (in this case, the usual path integral reduces to an ordinary integral). First, we briefly consider the \( \Phi^4 \)-theory in zero dimensions [see Eq. (9-177) ff. in [72]]; the generating functional reads

\[
Z(\Phi) = \int_{-\infty}^{\infty} \frac{d\Phi}{\sqrt{2\pi}} \exp \left[ -\frac{1}{2} \Phi^2 - g \Phi^4 \right]. \tag{34}
\]

The strictly alternating divergent asymptotic expansion in powers of \( g \) for \( g \to 0 \) reads,

\[
Z(\Phi) \sim \sum_{N=0}^{\infty} \frac{4^N \Gamma(2N + 1/2)}{\sqrt{\pi} \Gamma(N + 1)} (-g)^N. \tag{35}
\]

On using the known asymptotics valid for \( N \to \infty \), which is this case yield the “large-order” asymptotics of the perturbative coefficients,

\[
\frac{\Gamma(2N + 1/2)}{\Gamma(N + 1)} \sim \frac{4^N}{\sqrt{2\pi}} \Gamma(N) \left[ 1 + O\left( \frac{1}{N} \right) \right] \tag{36}
\]

it is easy to explicitly establish the factorial divergence of the series (see also p. 888 of [60]). The generating functional in zero dimensions has been proposed as a paradigmatic example for the divergence of perturbation theory in higher order. It can be resummed easily to the non-perturbative result; in particular it is manifestly Borel summable, and no singularities are present on the positive real axis.

Complications are introduced by degenerate minima. As a second example, we consider the modified generating functional [compare with Eq. (2.6) on p. 15 of [73] and with Eq. (40.1) on p. 854 of [60]]:

\[
Z'(\Phi) = \int_{-\infty}^{\infty} \frac{d\Phi}{\sqrt{2\pi}} \exp \left[ -\frac{1}{2} \Phi^2 + \sqrt{g} \Phi^3 - \frac{1}{2} g \Phi^4 \right]. \tag{37}
\]

The expansion of the exponential in powers of the coupling \( g \) leads to a divergent asymptotic series

\[
Z'(\Phi) = \sum_{N=0}^{\infty} \frac{1}{N!} \int_{-\infty}^{\infty} \frac{d\Phi}{\sqrt{2\pi}} e^{-1/2 \Phi^2} \left( \sqrt{g} \Phi^3 - \frac{1}{2} g \Phi^4 \right)^N
\]

\[
= \sum_{N=0}^{\infty} \int_{-\infty}^{\infty} \frac{d\Phi}{\sqrt{2\pi}} e^{-1/2 \Phi^2} \sum_{j=0}^{N} \frac{(-1)^j}{\Gamma(2N - j + 1)} \binom{2N - j}{j} \left( \sqrt{g} \Phi^3 \right)^{2(N-j)} \left( \frac{g \Phi^4}{2} \right)^j
\]

\[
= \sum_{N=0}^{\infty} 2^{\sqrt{\pi} / \Gamma(\sqrt{2})} (-1)^N C_N^{N+1/2}(1) g^N
\]

\[
= \sum_{N=0}^{\infty} 8^N \Gamma(2N + 1/2) \Gamma(N - 1/2) / \Gamma(N + 1) g^N, \tag{38}
\]

where \( C_N^M(x) \) denotes a Gegenbauer (ultraspherical) polynomial. Note that terms of half-integer power of \( g \) entail an odd power of the field and vanish after integration. The first few terms of the asymptotic expansion read,

\[
Z'(\Phi) = 1 + g + 6 g^2 + 210 g^3 + 13860 g^4 + 1351350 g^5 + 174594420 g^6 + 28109701620 g^7 + 5421156741000 g^8 + O(g^9). \tag{39}
\]
For the perturbative coefficients
\[ C_N = \frac{8^N \Gamma(2N + 1/2)}{\sqrt{\pi} \Gamma(N + 1)}, \]
we establish the following asymptotics,
\[ C_N \sim \frac{1}{\pi\sqrt{2}} N^{-1} 32^N \Gamma(N + 1). \]

Due to the nonalternating character of the expansion (38), it is not Borel summable in the ordinary sense. Rather, it is Borel summable in the distributional sense (17) [45]. Here, we present numerical evidence supporting the summability of the divergent expansion (38) based on a finite number of perturbative coefficients. The final integration is carried out along the contour \( C_0 \) introduced in [44] [see also Eq. (14) below]. The same contour has also been used for the resummation of divergent perturbation series describing renormalization group (anomalous dimension) \( \gamma \) functions [46]. As explained in [44], the integration along \( C_0 \), which is based on the mean value of the results obtained above and below the real axis, leads to a real final result if all perturbative coefficients are real.

In particular, the resummation of the divergent expansion (38) is accomplished as follows. We first define the Borel transform of the generating functional by [see Eq. (4) in [45] and the discussion after Eq. (1)]
\[ Z'_B(z) \equiv B^{(1,1)} [Z'; z] \]
\[ = \sum_{N=0}^{\infty} \frac{C_N}{\Gamma(N + 1)} z^N. \] (42)

Padé approximants to this Borel transform are evaluated,
\[ P'_M(z) = \left[ [M/2]/[(M + 1)/2] \right] z'_B(z), \] (43)
where \([x]\) denotes the largest positive integer smaller than \(x\). We then evaluate the (modified) Borel integral along the integration contour \( C_0 \) introduced in [46]; specifically we define the transform \( TZ_M(g) \)
\[ TZ_M(g) = \int_{C_0} dt \exp(-t) P'_M(g t). \] (44)

In this case, poles above and below the real axis must be considered, and the final result involves no imaginary part. The particular case of \( g = 0.01 \) is considered. Values for the partial sums of the perturbation series (39) and the transforms defined in Eq. (44) are shown in Tab. 11. The transforms exhibit apparent convergence to 6 decimal places in 20th order, whereas the partial sums of the perturbation series diverge. Between the second and forth term of the perturbation series, (the forth term constitutes the minimal term), the partial sums provide approximations to the exact result. It might seem surprising that the minimal term in the perturbative expansion is reached already in forth order, although the coupling assumes the small value \( g = 0.01 \). This behavior immediately follows from the large geometric factor in Eq. (11) which leads to a “resultative coupling strength parameter” of \( g_{\text{res}} = 0.32 \). “Nonperturbative effects” of the order of \( \exp(-1/g_{\text{res}}) \) provide a fundamental limit to the accuracy obtainable by optimal truncation of the perturbation series; this is consistent with the numerical data in Table 11.

We have also investigated the resummation of the divergent series (39) via a combination of a conformal mapping and Padé approximants in the conformal variable. The situation is analogous to the LoSurdo–Stark effect: Results are consistent than those presented in Table 11 obtained by the “pure” Borel–Padé and in this case slightly more accurate. The radius of convergence of the Borel transform \( Z'_B(z) \) defined in Eq. (12) is \( s = 1/32 \) [cf. Eq. (7) for the LoSurdo–Stark effect], and the appropriate conformal mapping in this case reads
\[ w = \frac{4y}{(1 + y)^2} \] (45)
[cf. Eq. (22)]. The inverse reads
\[ y(w) = \frac{1 - \sqrt{1 - w}}{1 + \sqrt{1 - w}} \] [cf. Eq. (28)]. The conformal mapping (45) maps the complex \( w \)-plane with a cut along \((1, \infty)\) unto the unit circle in the complex \( y \)-plane. While the zero-dimensional model example given in Eq. (7) does not exhibit all problematic features of degenerate anharmonic double-well oscillators, certain analogies can be established; these comprise in particular the need to evaluate the mean value of Borel transforms above and below the real axis (see Appendix B).

VII. CONCLUSION

We discuss the resummation of the divergent perturbation series of the LoSurdo–Stark effect, and of a divergent model series describing a zero-dimensional theory with degenerate minima, using two methods. Method I, which uses a variant of the contour-improved Borel–Padé technique introduced in [23], is described in Sec. 11. The integration contour is modified so that the additional terms which have to be added to the principal value of the Laplace–Borel integral are clearly identified [see also the discussion in [23] and Eq. (12)]. Use is made of the leading infrared renormalon pole. Method II, which comprises an analytic continuation by conformal mapping with additional improvement by Padé approximants in the conformal variable [see Eq. (23)], is discussed in Sec. 11. This method is a variant of the method introduced in [19, 20, 21] which has been shown to
accelerate convergence of perturbative quantum chromodynamics (by optimal conformal mapping of the Borel plane). We find that both methods accomplish a resummation of the divergent perturbation series $\mathcal{I}$ for the LoSurdò–Stark effect, and the decay width of the quasistationary states is obtained (see Sec. V). Numerical results are given in Tables I and II. A main result of the current investigation is the demonstration of the analogous mathematical structure (double-cut Borel plane) of the perturbative expansion for the LoSurdò–Stark effect and perturbative expansions in quantum chromodynamics (renormalon theory $\mathcal{A}$). The series investigated here exhibit a nontrivial singularity structure in the Borel plane. In particular, we encounter poles and branch cuts on the positive real axis.

In quantum electrodynamics, we encounter nonperturbative effects in the electron-positron pair-production amplitude in a background electric field $\mathcal{B}$. The vacuum-to-vacuum amplitude acquires an imaginary part, whose magnitude is related to the production rate per space-time volume of fermion-antifermion pairs. This nonperturbative, imaginary contribution can be inferred from the perturbative expansion of the effective action by contour-improved resummation (see $\mathcal{R}$ and the discussion in Appendix $\mathcal{A}$). Nonperturbative effects typically involve a nonanalytic factor of $\exp(-1/g)$ where $g$ is an appropriate coupling parameter for the physical system under investigation (in the case of the LoSurdò–Stark effect, the coupling parameter is the electric field strength $F$). The existence of nonperturbative contributions is intimately linked with the failure of the Carleman criterion for a particular perturbation series (see for example $\mathcal{A}$, Theorems XII.17 and XII.18 and the definition on p. 43 in $\mathcal{A}$, p. 410 in $\mathcal{B}$, or the elucidating discussion in Ref. $\mathcal{B}$). The Carleman criterion determines, roughly speaking, if nonanalytic contributions exist for a given effect which is described by a specified perturbation series.

The current investigation illustrates the utility of resummation methods in those cases where perturbation theory breaks down at large coupling. As explained in Sec. $\mathcal{A}$, even in situations where the perturbation series diverges strongly, it can still be used to obtain meaningful physical results if it is combined with a suitable resummation method. In a relatively weak field, it is possible to obtain more accurate numerical results by resummation than by optimal truncation of the perturbation series (see also $\mathcal{A}$). In a strong field, it is possible to obtain physically correct results by resummation even though the perturbation series diverges strongly (see the discussion in Sec. $\mathcal{A}$ and the data in Tables I and II). By resummation, the perturbation series which is inherently a weak-coupling expansion can be given a physical interpretation even in situations where the coupling is large. Returning to the analogy to quantum field theory, one might be tempted to suggest that physically complete results are obtained after regularization, renormalization and resummation.

ACKNOWLEDGMENTS

It is a pleasure to thank Professor G. Soff and Professor J. Zinn–Justin for many insightful discussions, and G. Soff for continuous encouragement. Helpful discussions with Professor P. J. Mohr, E. Caliceti, E. J. Weniger, J. Sims, I. Nándori and S. Roether are also gratefully acknowledged. The author would also like to acknowledge support from the Deutscher Akademischer Austauschdienst (DAAD) during a post-doctoral fellowship, and he would like to thank the Laboratoire Kastler–Brossel, where major parts of this work were performed, and the National Institute for Standards and Technology for kind hospitality.

APPENDIX A: DIVERGENT PERTURBATION SERIES IN QUANTUM FIELD THEORY

We briefly indicate aspects of certain divergent perturbation series in quantum field theory, in particular the quantum electrodynamic (QED) effective action and the associated pair–production amplitude for electron–positron pairs. We use natural units in which the reduced Planck’s constant, the permittivity of the vacuum and the speed of light (in field-free vacuum) assume the value of unity ($\hbar = c_0 = c = 1$). The one-loop QED effective action for an arbitrary electric and magnetic field per space-time volume reads [this result can be found e.g. in Eq. (4-123) of $\mathcal{A}$, upon inclusion of an additional counterterm; see also $\mathcal{B}$]

\[
S = \lim_{\epsilon, \eta \to 0^+} \int_0^{i\infty + \eta} \frac{ds}{s^3} e^{-(m_0^2 - i\epsilon)s} \times \left[ (es)^2 ab \coth(eas) \cot(ebs) \right. \\
\left. - \frac{1}{3} (es)^2 (a^2 - b^2) - 1 \right]. \tag{A1}
\]

The specification of the infinitesimal quantity $\eta$ is necessary, strictly speaking, in order to avoid the singularities of the coth function along the imaginary axis. By $a$ and $b$ we denote the secular invariants,

\[
a = \sqrt{\mathcal{F}^2 + \mathcal{G}^2 + \mathcal{F}^2},
\]
\[
b = \sqrt{\mathcal{F}^2 + \mathcal{G}^2 - \mathcal{F}^2},
\]
\[
\mathcal{F} = \frac{1}{4} F^{\mu\nu} F_{\mu\nu} = \frac{1}{2}(B^2 - E^2),
\]
\[
\mathcal{G} = \frac{1}{4} F^{\mu\nu} (\ast F)_{\mu\nu} = -E \cdot B.
\]

If the relativistic invariant $\mathcal{G}$ is positive, then it is possible to transform to a Lorentz frame in which $E$ and
\( B \) are antiparallel. In the case \( \mathcal{G} < 0 \), it is possible to choose a Lorentz frame in which \( E \) and \( B \) are parallel. Irrespective of the sign of \( \mathcal{G} \) we have in the specified frame
\[
a = |B| \quad \text{and} \quad b = |E|.
\]

Then, in the special Lorentz frame, the effective action reads [we keep all infinitesimal contributions]
\[
S = \lim_{\epsilon, \eta \to 0^+} -\frac{1}{8\pi^2} \int_0^{\infty+\eta} \frac{ds}{s^3} e^{-(m^2_e - i\epsilon)s} \times \left[ (es)^2 |B| |E| \text{coth}(e|B|s) \cot(e|E|s) \right.
\]
\[
\left. - \frac{1}{3} (es)^2 (B^2 - E^2) - 1 \right]. \quad (A2)
\]

The particular cases of a pure magnetic and a pure electric field follow from the above integral representation by considering appropriate limits (\( |E| \to 0 \) and \( |B| \to 0 \), respectively). These particular cases are of some interest, because they can be used as model series for divergent alternating and nonalternating asymptotic perturbation series \([44–46, 58]\). In the case of a pure magnetic field \( B = |B| \), the result reads [see e.g. Eq. (5) in \([46]\)]
\[
S_B = -\frac{e^2 B^2}{8\pi^2} \int_0^{\infty} \frac{ds}{s^2} \left\{ \text{coth} s - \frac{1}{s} - \frac{s}{3} \right\} \exp\left( -\frac{m^2_e B}{e} s \right), \quad (A3)
\]

where \( m_e \) is the mass of the electron. This result can be expressed as a divergent asymptotic perturbation series in the coupling parameter \( g_B = e^2 B^2/m^4_e \). For the pure electric field, the result reads
\[
S_E = \frac{e^2 E^2}{8\pi^2} \int_0^{\infty} \frac{ds}{s^2} \left\{ \text{coth} s - \frac{1}{s} - \frac{s}{3} \right\} 
\]
\[
\times \exp\left[ -i \left( \frac{m^2_e}{e} \frac{1}{E} \right) s \right] 
\]
\[
= -\frac{e^2 E^2}{8\pi^2} \int_{0+ie}^{\infty+ie} \frac{ds}{s^2} \left\{ \text{cot} s - \frac{1}{s} + \frac{s}{3} \right\} \exp\left[ -\frac{m^2_e E}{e} s \right], \quad (A4)
\]

[Eq. (7) of \([46]\) and the expression before Eq. (10) of \([45]\) contain typographical errors]. We take the opportunity to supplement the proportionality factor for the expression in Eq. (7) of \([46]\) to yield the effective action per space-time volume element; it reads \( e^2 E^2/(8\pi^2) \). As evident from the Eq. (A4), the integration of the Borel–Padé transform for the electric field case should be carried out along the contour \( C_{+1} \) shown here in Fig. 1. When this contour is used, then a sign change results for the imaginary contributions in Table 1 of \([46]\) (the sign change of the imaginary part according to the choice of the integration contour has been discussed at length in \([46]\)). The magnitude of the imaginary part yields the pair-production amplitude. The contour \( C_{+1} \) is used in the current investigation (and in the context of the related brief discussion in \([44]\) for the calculation of nonperturbative imaginary effects, i.e. the autoionization decay width of atomic states (LoSurdo–Stark effect).

The divergent asymptotic perturbation series for the cases of the magnetic and electric field, generated by expansion of the results in Eqs. (A3) and (A4), can be found in Eqs. (6) and (7) of \([46]\) \((B\text{-field, alternating series, coupling parameter } g_B = e^2 B^2/m^4_e \) and in Eqs. (8) and (9) of \([46]\) \((E\text{-field, nonalternating series, coupling parameter } g_E = e^2 E^2/m^4_e \)). The singularity structure of the Borel transform of the series for the magnetic field case has been determined in \([58]\) as a sequence of singularities corresponding to alternating, factorially divergent components (these correspond in their mathematical structure to the so-called ultraviolet renormalons in quantum chromodynamics). The perturbation series for the LoSurdo–Stark effect contains both nonalternating and alternating components so that its resummation represents a comparatively more interesting task. The same applies to the more complex perturbation series calculated in \([58]\) for the renormalization group \( \gamma \) function, whose resummation – at strong coupling – has been discussed in \([53, 52]\) (in this case, there is no imaginary part involved). We are not aware of any \textit{a priori} reasoning to determine the absence or presence of imaginary contributions in a particular physical problem (see also the discussion in \([53]\)).

**APPENDIX B: BOREL SUMMABILITY IN PROBLEMATIC CASES**

Consider the one-dimensional double-well Hamiltonian
\[
H(g) = p^2 + x^2 \left( 1 - g x \right)^2.
\]

For \( g = 0 \), the Hamiltonian describes harmonic oscillations. For \( g > 0 \), we have degenerate minima of the potential at \( x = 0 \) and at \( x = 1/g \), and to each eigenvalue of the unperturbed harmonic oscillator, we have to associate two eigenvalues belonging to opposite-parity wavefunctions with respect to \( x = 1/(2g) \). The difference of the two eigenvalues is nonanalytic in \( g \). Two different approaches have been developed to circumvent this problem and to allow for a treatment based on the resummation of perturbation series.

The first approach \([53]\) is based essentially on generalized Bohr–Sommerfeld quantization formulas and leads to an expansion of the ground-state energy eigenvalue in terms of
\[
E(g) = \sum_{n=0}^{\infty} E_n^{(0)} g^n + \sum_{n=1}^{\infty} \frac{1}{\sqrt{n}} g^{-1/6} e^{-1/6g}
\]
where the upper index of the $E$-coefficients labels the multi-instanton contributions (the zero-instanton contribution corresponds to the “usual” perturbative expansion). The odd-instanton contributions lead to a separation of the ground state and the first excited state which have opposite parity but the same naive perturbation series $\sum_{n=0}^{\infty} E^{(0)}_n g^l$. The series $\sum_{n=0}^{\infty} E^{(0)}_n g^l$ is non-alternating and therefore not Borel-summable; however, possible imaginary contributions must be suppressed for physical reasons because the ground-state energy is real. The suppression can be enforced explicitly by defining the sum as the arithmetic mean of the values obtained above and below the real axis, or it can be motivated by the following observation \[\square\]: We define the sum of $\sum_{n=0}^{\infty} E^{(0)}_n g^l$ for negative $g$ and carry out an analytic continuation to positive $g$; this leads to an imaginary part which in this case cancels with the imaginary part generated by the $\ln(-2/g)$ coming from the two-instanton contribution ($n = 2$, $k = 1$). Note that for the model example discussed in Sec. \[\square\], only one alternative is feasible—the explicit cancellation, because no additional terms are present which could lead to cancellations.

The second approach \[\square, \square\] involves contour integrations and makes use of projection operators in order to “select” states of specified parity (this approach has been shown to be applicable as well to the problematic Herbst–Simon hamiltonian \[\square\] which involves a vanishing perturbation series). Specifically, we can write the perturbed energy eigenvalue as

$$E(g) = \frac{\text{Re} F_1(g,g)}{\text{Re} F_0(g,g)}$$  \tag{B3}

where

$$F_j(g, \gamma) = \frac{1}{2\pi i} \oint_{\Gamma} dz \frac{1}{H(\gamma) - z} \langle \psi^\pm (g) | \psi^\pm (g) \rangle.$$  \tag{B4}

where $\psi^\pm (g)$ are test functions with a definite parity with respect to $1/(2g)$. The closed contour $\Gamma$ has radius unity; it is chosen to encircle one and only one shifted resonance of the perturbed oscillator, while the test functions select the state with the desired parity. Specifically, we have $\psi^\pm (g) = P^\pm (g) \psi$ where $\psi$ is the eigenvector of the unperturbed hamiltonian, and the projection operators are

$$(P^\pm (g) \psi) (x) = \frac{1}{2} (\psi(x) \pm \psi(1/g - x)).$$  \tag{B5}

The functions $F_j(g, \gamma)$ may be expressed as asymptotic series,

$$F_j(g, \gamma) = \sum_{N=0}^{M} [a_{j,N} + i b_{j,N}(g)] \gamma^N + O(\gamma^{M+1}).$$  \tag{B6}

The authors of \[\square, \square\] define $\Phi_j^R(g, \gamma)$ to be the Borel sum of $\sum_{N=0}^{\infty} b_{j,N} \gamma^N$ for $g, |\gamma|$ and $\arg \gamma$ small and positive, and they establish a corresponding relation for $\Phi_j^R(g, \gamma)$ and $\sum_{N=0}^{\infty} b_{j,N} \gamma^N$. According to (unnumbered) equations on p. 626 of \[\square\], the final result in this case is given in terms of the mean values—each obtained above and below the real axis—of the two Borel sums $\Phi_j^R$ and $\Phi_j^R$.

$$\text{Re} F_j(g, \gamma) = \frac{1}{2} \left[ \Phi_j^R(g, \gamma) + \Phi_j^R(g, \gamma) \right]$$

$$+ \frac{i}{2} \left[ \Phi_j^R(g, \gamma) - \Phi_j^R(g, \gamma) \right],$$  \tag{B7}

where $\gamma$ denotes the complex conjugate of $z$. The value $\text{Re} F_j(g, \gamma)$ is then determined by (unique) analytic continuation $\gamma \rightarrow g$ from $\text{Re} F_j(g, \gamma)$. In our simplified model example, we have $b_{j,N}(g) = 0$ (all perturbative coefficients are real). The need to evaluate the arithmetic mean of Borel sums above and below the real axis appears to arise naturally in the context of double-well problems.
