Abstract

We study the strangeness production in antiproton-nucleus collisions at the beam momenta from 200 MeV/c to 15 GeV/c and in \(\bar{p}\) annihilation at rest within the Giessen Botzmann-Uehling-Uhlenbeck (GiBUU) transport model. The GiBUU model contains a very detailed description of underlying antinucleon-nucleon cross sections, in-particular, of the strangeness production channels. We compare our calculations with experimental data on \(\Lambda\), \(K^0_S\) and \(\bar{\Lambda}\) production in \(\bar{p}A\) collisions and with earlier intranuclear cascade calculations. The contributions of various partial channels to the hyperon production are reported and systematic differences with the experiment are discussed. The possible formation of bound \(\Lambda\) and \(\Lambda\Lambda\)-nucleus systems is also considered. Finally, results on the \(\Xi\) hyperon production are presented in view of forthcoming experiments with antiproton beams at FAIR.

I. INTRODUCTION

The production of strange particles in antiproton annihilation on nuclei has been a challenge to theory since about two decades when the Λ and \( K^0_S \) yields and spectra were measured in the series of bubble chamber experiments [1–3]. The most intriguing experimental fact is that the yield ratio \( \Lambda / K^0_S \) is very large (> 2) not only for heavy target nuclei (\( \bar{p} + 181 \text{Ta} \) at 4 GeV/c [3]), but even for light ones (\( \bar{p} + ^{20}\text{Ne} \) at 608 MeV/c [2]). The direct mechanism \( \bar{p}p \to \Lambda\Lambda \) can only explain less than 20% of the measured Λ production cross section for \( \bar{p} + ^{181}\text{Ta} \) at 4 GeV/c [4]. Thus, the hyperon production in \( \bar{p} \) annihilation on nuclei is dominated by the interactions of secondary particles produced in \( \bar{p}N \) annihilation with the nuclear medium. Extensive theoretical calculations within the intranuclear cascade (INC) model [5] tend to overestimate the yields of both particle species, Λ and \( K^0_S \), and underestimate the yield ratio \( \Lambda / K^0_S \). The latter might indicate the in-medium enhanced cross sections of the strangeness exchange reactions, \( \bar{K}N \to Y\pi \) (\( Y \) stands for a Λ- or Σ-hyperon). The enhanced hyperon production has been also interpreted in terms of \( \bar{p} \) annihilations on the clusters of nucleons [4, 6] or even the formation of a cold quark-gluon plasma (QGP) [7].

Even more interesting is the double-strange (\( S=-2 \)) hyperon production in antiproton annihilation on nuclei which has not yet been studied experimentally. The calculations of Ref. [8], motivated by the planned Double-Hypernuclei experiment by PANDA@FAIR [9, 10], take into account only the direct mechanism \( \bar{N}N \to \bar{\Xi}\Xi \) which can only account for a few percent of an inclusive \( \Xi \) yield. However, the inclusive production of the \( S=-2 \) hyperons in \( \bar{p} \) annihilation on nuclei is very interesting by itself. This process should be a quite sensitive test for the unusual mechanisms of the \( \bar{p} \) annihilation on nuclei, like the QGP formation, since it requires the simultaneous production of two \( s\bar{s} \) pairs.

In this work, we study strangeness production in \( \bar{p}-\text{nucleus} \) collisions at \( \text{p}_{\text{lab}} = 0.2 - 15 \) GeV/c and in \( \bar{p}-\text{nucleus} \) annihilation at rest within the microscopic GiBUU transport model [11]. We compare our calculations with all available experimental data [1–3, 12] on Λ, \( K^0_S \) and \( \bar{\Lambda} \) production for in-flight annihilation of \( \bar{p} \) on nuclei and with earlier calculations within the INC models [5, 13, 14]. We also analyse the selected data set of ref. [15] on \( \pi^- \), proton and Λ production in \( \bar{p} \) annihilation at rest on \( ^{14}\text{N} \). In contrast to the INC models, the GiBUU model includes selfconsistent relativistic mean fields acting on baryons, antibaryons, kaons and antikaons. The selfconsistency means that the mean fields depend on the actual particle
densities and currents. This has never been done in the previous transport calculations of antiproton-nucleus reactions. The selfconsistent potential fields are very important, for example, for a realistic treatment of annihilation on light nuclei, when a nucleus get almost destroyed by pions produced in annihilation, and the outgoing particles propagate in much weaker potential fields.

We study in detail the mechanisms of strangeness production by decomposing spectra and reaction rates into the partial contributions from various elementary processes. Estimates for the production probabilities of hypernuclei are also given. Finally, we present the predictions of our model for the Ξ hyperon spectra. We argue that the latter can be used to disentangle the hadronic and hypothetic QGP mechanisms of ¯p annihilation on nuclei.

The structure of the paper is as follows. Sec. II contains a brief description of the GiBUU model with an accent on its new and/or improved ingredients, such as, e.g., strangeness production channels in ¯NN collisions. In sec. III we present the results of our calculations for the Λ, K⁰ and ¯Λ production and compare them with experimental data and INC calculations. Then, we give our predictions for the Ξ hyperon production at various ¯p beam momenta. Finally, sec. IV summarizes our work.

II. MODEL

The GiBUU model [11] is a transport-theoretical framework which allows to describe a wide range of photon-, lepton-, hadron-, and nucleus-nucleus reactions. Below we concentrate mostly on the model ingredients which govern strangeness production in antiproton-induced reactions. For other model details relevant for the present study we refer the reader to refs. [11, 16–19].

The GiBUU model solves the coupled system of kinetic equations for the different hadronic species \(i = N, \Delta, Y, Y^*, \Xi, \pi, K\) etc and respective antiparticles:

\[
\frac{1}{p_0} \left[ p^\mu \frac{\partial}{\partial x^\mu} + \left( p_i^\mu F_i^{\mu\nu} + m_i^* \frac{\partial m_i^*}{\partial x^\mu} \right) \frac{\partial}{\partial p^\nu} \right] f_i(x, p^*) = I_i(\{f\}) ,
\]

where \(f_i(x, p^*)\) is the phase-space distribution function, \(p^* = p - V_i\) is the kinetic four-momentum, \(F_i^{\mu\nu} \equiv \partial^\mu V_i^\nu - \partial^\nu V_i^\mu\) is the field tensor, and \(m_i^* = m_i + S_i\) is the effective mass. The scalar potential \(S_i = g_{\sigma} \sigma\) is expressed in terms of the isoscalar \(\sigma\) meson \((J^P = 0^+)\) field. The vector potential \(V_i\) includes the contributions from the isoscalar \(\omega\) meson \((J^P = 1^-)\).
field, isovector $\vec{\rho}$ meson ($J^P = 1^-$) field and the electromagnetic field $A$:

$$V_i = g\omega i + g\rho_3 \tau^3 \rho^3 + qA.$$  \hspace{1cm} (2)

Here, the isovector term $\propto \rho^3$ is included only for nucleons and antinucleons. The collision term $I_i[f]$ in the r.h.s. of Eq. (1) represents the contribution of binary collisions and resonance decays to the partial time derivative $\frac{\partial}{\partial\tau} f_i(x, p^*)$. The term $\frac{p_i^*}{p^*} \nabla f_i(x, p^*)$ in the l.h.s. of Eq. (1) is a usual drift term. The term $\propto \frac{\partial}{\partial p^*} \mu f_i(x, p^*)$ describes the deviation of particle trajectories from straight lines as well as acceleration/deceleration due to the meson mean fields. Without this term, the GiBUU model is basically reduced to a usual cascade model. The meson mean fields $\sigma, \omega, \rho$ and the electromagnetic field $A$ are calculated from the corresponding Lagrange equations of motion neglecting time derivatives \cite{16, 19}. This calculation is selfconsistent in the sense that the fields are induced by actual particle densities and currents which serve as source terms in the Lagrange equations. The full system of transport equations (1) and meson field equations admits the energy-momentum conservation (c.f. ref. \cite{16}).

In order to determine the meson-nucleon coupling constants and the self-interaction parameters of the $\sigma$ field, we use the relativistic mean field (RMF) model in the NL3 version \cite{20}. The coupling constants of mesons with other nonstrange baryonic resonances ($\Delta, N^*$ etc) are set equal to the respective meson-nucleon coupling constants. For the meson-hyperon and meson-kaon coupling constants, we apply a simple light quark counting rule by putting

$$\frac{g_\sigma Y}{2} = g_\sigma z = g_\sigma K = \frac{g_\sigma N}{3},$$  \hspace{1cm} (3)

$$\frac{g_\omega Y}{2} = g_\omega z = g_\omega K = \frac{g_\omega N}{3}.$$  \hspace{1cm} (4)

The coupling constants with the corresponding antiparticles are obtained as follows:

$$\frac{g_\sigma B}{3\xi} = \frac{g_\sigma Y}{2} = g_\sigma z = g_\sigma K = \frac{g_\sigma N}{3},$$ \hspace{1cm} (5)

$$\frac{g_\omega B}{3\xi} = \frac{g_\omega Y}{2} = g_\omega z = g_\omega K = -\frac{g_\omega N}{3},$$ \hspace{1cm} (6)

$$g_\rho N = \xi g_\rho N.$$  \hspace{1cm} (7)

Here, "$B$" denotes any nonstrange baryon, i.e. $B = N, \Delta, N^*$ etc. The relative signs in Eqs. (5)-(7) are obtained from the $G$-parities of the meson fields. The factor $\xi = 0.22$ is introduced in order to obtain the Schrödinger equivalent potential $U_N = -150$ MeV for
an antiproton at the zero kinetic energy and normal nuclear density \( \rho_0 = 0.148 \text{ fm}^{-3} \), in agreement with \( \bar{p} \)-nucleus scattering phenomenology (c.f. \cite{18} and refs. therein). One should keep in mind, however, that in experiment only the nuclear surface is tested due to a large annihilation cross section. Thus, an empirical information at \( \rho_0 \) can only be obtained by model dependent extrapolations.

In Table I, we collect the Schrödinger equivalent potentials of different particles evaluated by using the relations (3)-(7) and the nucleon scalar \( (S_N = -380 \text{ MeV}) \) and vector \( (V_0^N = 308 \text{ MeV}) \) potentials in nuclear matter at \( \rho_0 \) \cite{18}. The potential depths for nucleon, \( \Lambda \) hyperon

\begin{table}[h]
\centering
\begin{tabular}{|c|cccccccc|
\hline
\(i\) & \(N\) & \(\Lambda\) & \(\Sigma\) & \(\Xi\) & \(\bar{N}\) & \(\bar{\Lambda}\) & \(\bar{\Sigma}\) & \(\bar{\Xi}\) & \(K\) & \(\bar{K}\) \\
\hline
\(U_i\) & -46 & -38 & -39 & -22 & -150 & -449 & -449 & -227 & -18 & -224 \\
\hline
\end{tabular}
\end{table}

and antikaon are consistent with phenomenology \cite{21}. The \( \Sigma \) potential is attractive, which contradicts the analysis of \( \Sigma^- \) atoms \cite{21}. A weak attraction for kaons is also not supported by the analysis of the kaon flow from heavy ion collisions (c.f. \cite{22} and refs. therein), where a weak repulsion has been found. These drawbacks are the consequences of a simple treatment of particle potentials based on the same RMF model. We do not expect that they sensitively influence our results since the multiplicity of \( \Sigma \) hyperons is considerably smaller than the multiplicity of \( \Lambda \) hyperons while the kaon potential is weak anyway. The potentials of the \( \Xi \) hyperons and antihyperons are still not restricted by any experimental data.

The nucleus is modeled by employing a local density approximation. The momenta of nucleons are sampled uniformly within the spheres of radii

\[ p_{F,i} = (3\pi^2 \rho_i)^{1/3}, \quad i = p, n, \]  

by using a Monte Carlo method. The density profiles of protons and neutrons \( \rho_i(r) \) are obtained from a selfconsistent solution of the relativistic Thomas-Fermi equations \cite{19}. This makes the nucleus stable on the time scale of the order of several 100 fm/c, enough for the most reactions with nuclear targets. The Fermi motion of nucleons results in the smearing of particle production thresholds, which is especially important for the reactions with low-energy projectiles.
For the simulation of an $\bar{p}$-nucleus collision, at $t = 0$ an antiproton is placed at the distance 5 fm + nuclear radius from the nuclear center along the collision axis. Such a distant initialization of the antiproton is needed in order to take into account the change of its momentum and trajectory under the action of attractive nuclear and Coulomb potentials [18].

For the simulation of annihilation at rest, the initial radial position of the antiproton is chosen according to the probability distribution (c.f. [23, 24])

$$dP = C|R_{nl}(r)|^2 \rho(r) r^2 dr . \tag{9}$$

where $R_{nl}(r)$ is the radial wave function of the antiproton in the Coulomb atomic state with quantum numbers $n$ and $l \leq n - 1$, $\rho(r)$ is the nucleus density profile, and $C$ is a normalization constant. Quoting ref. [24], a cascade of electromagnetic deexcitation of the $\bar{p}$-atom, essentially through the $(n, l = n - 1)$ states, emits X-rays, which permits us to trace the $\bar{p}$ down to the level where annihilation takes place.

Once a nucleus and an antiproton are initialized, the system of kinetic equations (1) supplemented by the meson field equations is solved by the test particle method in the parallel ensemble mode [25]. Between the two-body collisions, the test particle centroids $(r, p^*)$ propagate according to the Hamiltonian-like equations (c.f. [18, 19]). The two-body collisions are treated in a geometrical picture: the test particles $a$ and $b$ from the same parallel ensemble are allowed to collide if they pass their minimal distance $d_{\text{min}}$ during a given time step. Here $d_{\text{min}} < \sqrt{\sigma_{\text{tot}}^{ab}/\pi}$, where $\sigma_{\text{tot}}^{ab}$ is the total interaction cross section depending on the types of colliding particles and invariant energy $\sqrt{s}$. In the present work, we use vacuum cross sections neglecting their possible in-medium modifications. The final state of a two-body collision $ab \rightarrow cde...$ is chosen by a Monte Carlo method according to the partial cross sections of various outgoing channels. The final state probability includes the products of Pauli blocking factors $(1 - f)$ for the outgoing nucleons. These factors are calculated from the actual time-dependent neutron and proton phase-space distributions. Collisions between the secondary and primary particles as well as between two secondaries are taken into account. The mean fields are recomputed on every time step according to the modified particle densities and currents.

In the case of an antinucleon-nucleon collision, the annihilation may result in a large number of various mesonic final states. This makes the direct parameterization of all partial
cross sections practically impossible. Thus, we rely on the statistical annihilation model with SU(3) symmetry \[26, 27\]. This model has been successfully applied in the calculations of pion and proton spectra from $\bar{p}$ annihilation on nuclei at 608 MeV/c within the GiBUU framework \[18\]. According to the model \[26, 27\], the probability of the $\bar{N}N$ annihilation to a given final state meson configuration, which may include up to $n = 6$ mesons $\pi, \eta, \omega, \rho, K, \bar{K}, K^*$ and $\bar{K}^*$, is defined as

$$W_n(\sqrt{s}, I_1, ..., I_n, Y_1, ..., Y_n) = w_n(\sqrt{s}, I_1, ..., I_n, Y_1, ..., Y_n) \times a_{\pi}^{n_{\pi}} a_{\eta}^{n_{\eta}} a_{\omega}^{n_{\omega}} a_{\rho}^{n_{\rho}} a_{K}^{n_{K}} a_{\bar{K}}^{n_{\bar{K}}} a_{K^*}^{n_{K^*}} a_{\bar{K}^*}^{n_{\bar{K}^*}},$$

where $I_1, ..., I_n$ and $Y_1, ..., Y_n$ are, respectively, the isospins and hypercharges of outgoing mesons, and $n_i$ are the multiplicities of mesons of each type ($i = \pi, \eta, \omega$ etc). The quantity $w_n$ is proportional to the phase space volume of a given final state and is calculated assuming that the incoming and outgoing hadrons can be exactly classified according to the SU(3) symmetry. The dimensionless parameters $a_{\pi}, a_{\eta}, ..., a_{K^*}$ break the exact SU(3) symmetry. They approximate the unknown parts of matrix elements and depend on the types of the particles and on their internal structure. For the annihilation channels without strangeness, the values $a_{\pi} = 1, a_{\eta} = 0.13, a_{\omega} = 0.18$ and $a_{\rho} = 0.24$ were determined in \[28\] from the best agreement with the data on $\bar{p}p$ annihilation at rest and in flight at $p_{\text{lab}} \leq 10$ GeV/c \[29\].

For the parameters related to the strange mesons, we apply the beam momentum dependent expressions obtained from the fit of the $\bar{p}p \to K_S^0X$ and $\bar{p}n \to K^-K_S^0\pi^+\pi^-$ cross sections (see Fig. 1 for the $\bar{p}p$ case):

$$a_{K(K^*)} = 0.07 (0.05) C(p_{\text{lab}}),$$

where

$$C(p_{\text{lab}}) = \begin{cases} 4.2 \exp(-1.4p_{\text{lab}}) + 0.5 \exp(-0.16p_{\text{lab}}) + 1, & \text{for } \bar{p}p \\ 2.0 \exp(-0.7p_{\text{lab}}) + 0.5 \exp(-0.16p_{\text{lab}}) + 1, & \text{for } \bar{p}n \end{cases}$$

with $p_{\text{lab}}$ being the beam momentum (in GeV/c). The statistical annihilation model works, strictly speaking, only at high beam momenta, when the particle multiplicities are large. At low beam momenta, this model has to be supplemented by the phenomenological branching ratios of the different annihilation channels. For the channels without strange particles, this has been already done in \[26, 27\]. In the present work, we have extended the tables of probabilities for various $\bar{p}p$ and $\bar{p}n$ annihilation channels at rest \[26, 27\] by including the
channels with strange particles $K\bar{K}$, $K^*\bar{K}$ + c.c., and $K^*\bar{K}^*$ (see Appendix A). In order to have a smooth transition from these empirical branching ratios to the description according to the statistical model as the beam energy grows, we determine by a Monte-Carlo method whether the statistical model itself or the empirical branching ratios are used to simulate a given $\bar{N}N$ annihilation event. The probability to choose the tables is

$$P_{\text{at rest}} = \max \left( 0, 1 - \frac{\sqrt{s} - 2m_N}{\sqrt{s_{\text{max}}^2} - 2m_N} \right),$$

where $\sqrt{s_{\text{max}}} = 2.6$ GeV is the maximum invariant energy up to which the annihilation tables at rest still can be selected (respective beam momentum $p_{\text{lab}} = 2.5$ GeV/c). At the invariant energies above $\sqrt{s_{\text{max}}}$, the statistical model is used directly. The momenta of outgoing mesons in an $\bar{N}N$ annihilation event are always sampled microcanonically according to the available phase-space volume, regardless of whether annihilation tables at rest or the statistical model are applied to choose the flavours and charges of the outgoing mesons. This ensures a smooth behavior of the kinematics of produced mesons with increasing beam energy.

Apart from the $\bar{N}N$ annihilation to mesons, we also include elastic (+charge exchange) scattering $\bar{N}N \to \bar{N}N$, $\Delta$ resonance production $\bar{N}N \to \bar{N}\Delta$ (+c.c.), and hyperon production $\bar{N}N \to \bar{\Lambda}\Lambda$, $\Sigma\Lambda$(+c.c.), $\Xi\Xi$ channels. The corresponding total and angular differential cross section parameterizations are obtained from the fits of empirical data. The cross sections are described in detail in Appendix B.

At $\sqrt{s} > 2.37$ GeV, the inelastic production in $\bar{N}N$ collisions is simulated with a help of the FRITIOF model [30]. Exception are the processes $\bar{N}N \to \bar{N}N$, $\bar{N}N \to \bar{\Lambda}\Lambda$, $\Sigma\Lambda$(+c.c.), $\Xi\Xi$ which are either not included or not described well in FRITIOF. Thus, we treat these processes separately according to their partial cross sections at any $\sqrt{s}$.

Figure 1 shows the inclusive cross sections of $K^0_S$ and hyperon production in $\bar{p}p$ collisions. The partial cross sections of $K^0_S$ production in the annihilation and nonannihilation events are also shown in the same figure. The experimental data on $K^0_S$ production are described very well, including the nonannihilation channels, which are simulated by the FRITIOF model. The hyperon production cross section is somewhat underestimated at the beam momenta $\sim 4$ GeV/c. This is mainly due to still underestimated cross section of the $\bar{p}p \to \bar{\Lambda}\Lambda X$ inclusive channel above 3 GeV/c, which is practically missed in the FRITIOF model. However, we find that, overall, the FRITIOF model describes the inelastic production in $\bar{p}p$
FIG. 1: Inclusive cross section of $K_S^0$ production (upper left panel), the cross section of $K_S^0$ production in annihilation and nonannihilation channels (lower left and upper right panels, respectively), and the inclusive cross section of the hyperon production (lower right panel) in antiproton-proton collisions as a function of the beam momentum. The experimental data are taken from refs. [31, 32].

collisions better, than, e.g., the Pythia model [33]. Generally, the latter is successfully employed in GiBUU for the description of baryon-baryon and meson-baryon collisions at high invariant energies ($\sqrt{s} > 2.6$ GeV and $\sqrt{s} > 2.2$ GeV, respectively). We have to only admit one problem. The Pythia model does not include $K^0$ and $\bar{K}^0$ in its list of the possible incoming particles. Thus, both of them are replaced by $K_L^0$ in GiBUU every time when Pythia is used. This leads to $\sim 5\%$ violation of the total strangeness conservation in our calculations, which, however, is accurate enough for the present exploratory studies.
The processes of a hyperon scattering, $\Lambda N \to \Lambda N$, $\Lambda N \leftrightarrow \Sigma N$, $\Sigma N \to \Sigma N$, $\Xi N \to \Xi N$, $\Xi N \to \Lambda \Lambda$, $\Xi N \to \Lambda \Sigma$, and of the strangeness exchange on nucleons, $\bar{K}N \to Y\pi$, $\bar{K}N \to \Xi K$, are taken into account in the model. When present, their empirical cross sections have been suitably parameterized or the fits to the existing theoretical calculations have been done [34, 35]. As we will see later on, the strangeness exchange processes are very important for the hyperon production in antiproton-induced reactions on nuclei. In GiBUU, the strangeness exchange reactions $\bar{K}N \to Y\pi$ are partly mediated by the $S = -1$ hyperon resonance formations and decays $\bar{K}N \to Y^* \to Y\pi$ [35].

The associated hyperon production is included in GiBUU via reaction channels $\pi N \to Y K$, $\eta N \to Y K$, $\rho N \to Y K$ and $\omega N \to Y K$. The cross sections $\pi N \to Y K$ have been parameterized according to Ref. [36]. The $\eta$-induced associated hyperon production cross sections on proton have been reconstructed from the respective cross sections of the $\pi^0$-induced processes at the same invariant energy $\sqrt{s}$ by utilizing the detailed balance relations [37] and isospin invariance:

$$\sigma(\eta p \to K^+\Lambda) = \sigma(\pi^0 p \to K^+\Lambda)\frac{p_{\pi N}}{p_{\eta N}}, \quad (14)$$
$$\sigma(\eta p \to K^+\Sigma^0) = \sigma(\pi^0 p \to K^+\Sigma^0)\frac{p_{\pi N}}{p_{\eta N}}, \quad (15)$$
$$\sigma(\eta p \to K^0\Sigma^+) = 2\sigma(\eta p \to K^+\Sigma^0), \quad (16)$$

where $p_{\pi N}$ and $p_{\eta N}$ are the center-of-mass (c.m.) momenta for the corresponding initial channels calculated at the same $\sqrt{s}$. Similar formulas have also been used for the $\omega p$ initial channel. For the $\rho$-induced reactions on proton, we have assumed

$$\sigma(\rho p \to K\Lambda) = \sigma(\pi p \to K\Lambda)\frac{p_{\pi N}}{p_{\rho N}}, \quad (17)$$
$$\sigma(\rho p \to K\Sigma) = \sigma(\pi p \to K\Sigma)\frac{p_{\pi N}}{p_{\rho N}}, \quad (18)$$

where the isospin states of all particles match each other. The cross sections of the $\eta$-, $\omega$- and $\rho$-induced reactions on neutron have been obtained by using the isospin reflection from the corresponding cross sections on proton.

We note, finally, that the bubble chamber data on $\Lambda$ production contain also the admixture of $\Lambda$’s produced by the decays $\Sigma^0 \to \Lambda\gamma$. These decays are not included in GiBUU, since the $\Sigma^0$ life time $\tau = 7.4 \times 10^{-20} \text{ s} \simeq 222000 \text{ fm/c}$ is much longer than the typical hadron-nucleus reaction time scale of $\sim 100 \text{ fm/c}$. Thus, in the present calculations, we simply add the $\Sigma^0$ yield to the $\Lambda$ yield.
III. RESULTS

A. Time evolution of hyperon production

In our calculations, baryons experience the action of attractive mean field potentials. Slow hyperons get captured inside the residual excited nuclear system. This system may evaporate particles and/or decay into fragments, some of which will be single- or double-$\Lambda$ hypernuclei. It is natural to assume that the fragmentation and evaporation will not change much the total yield of hypernuclei; they may, however, affect the production of a given hypernuclear species.

In order to distinguish the hyperons outside and inside the residual nucleus, we have applied a simple criterion based on the relative distance between particles \[ d_c \] : a particle is outside the nucleus if it is separated by the distance larger than some critical distance \( d_c \) from all other particles of the nucleus. Otherwise, the particle is inside the nucleus. Provided the evolution time is long enough, the result should not be much influenced by the choice of \( d_c \), if the latter is larger than the internucleon spacing \( \sim 1 - 2 \text{ fm} \). This is illustrated in Fig. 2 where we show the number of \((\Lambda + \Sigma^0)\) hyperons outside and inside the residual nucleus per one annihilation event as a function of time for \( \bar{p}(225 \text{ MeV/c}) + ^{12}\text{C} \) collisions for various choices of the critical distance. After \( \sim 200 \text{ fm/c} \) the both numbers change very slowly indicating the presence of really captured \( \Lambda \) hyperons inside the attractive potential well. For comparison, we also present the results for the bound and unbound hyperons in the same figure. In this case a hyperon \( Y \) is considered to be bound (unbound) if \( E_Y < m_Y \) \( (E_Y > m_Y) \), where \( E_Y = \sqrt{(p^*)^2 + (m_Y^*)^2 + V_Y^0} \) is its single-particle energy. This criterion allows to identify the captured hyperons somewhat earlier. However, after 200 fm/c it is very close to the criterion according to \( d_c = 3 \text{ fm} \).

Of course, the capture may only happen if a particle experiences the action of an attractive potential. Fig. 3 compares the time dependence of the number of \( \Lambda \)'s inside and outside the nucleus for calculations with and without \( \Lambda \)-potential. As expected, in the calculations without \( \Lambda \)-potential, the number of hyperons inside the nucleus quickly drops with time indicating that there are no captured \( \Lambda \)'s in this case.

In the following, we always fix \( d_c = 3 \text{ fm} \) as in ref. 38 \text{ and calculate the time evolution until 200 fm/c. Our results for the number of free hyperons, i.e. those outside the residual...}
FIG. 2: The number of \((\Lambda + \Sigma^0)\) hyperons outside (out) and inside (in) the residual nucleus per annihilation event as a function of time for \(\bar{p}\) annihilations at 225 MeV/c on \(^{12}\text{C}\). The calculations are done for three different critical distances \(d_c\) and for the criterion according to the hyperon binding energy. The results are weighted with the impact parameter of an incoming \(\bar{p}\).

nucleus, change only by \(\sim 10\%\) if we further increase the evolution time (c.f. Fig. 2). As demonstrated in Fig. 4 this change concerns only slow hyperons, while the yields of fast particles are practically stable. In particular, the kaon yields and spectra are not influenced by any further increase of the evolution time.

B. Annihilation at rest

We selected the ASTERIX@LEAR data \([15]\) on charged pion, proton and \(\Lambda\) production from \(\bar{p}\) annihilation at rest on \(^{14}\text{N}\). According to ref. \([39]\), the last observable transition in light antiprotonic atoms is \(4 \rightarrow 3\). Thus we assumed that the antiproton occupies mainly the \(n = 3, l = 2\) level immediately before annihilation which we used as an input in our calculations (see Eq. \([9]\)). We have checked, however, that our results are changed by only few percent if the quantum numbers \(n = 4, l = 3\) are chosen for the antiproton wave function.
Fig. 3: Same as in Fig. 2 but for calculations with and without Λ-potential at the fixed critical distance $d_c = 3$ fm.

Fig. 5 shows the $\pi^-$, $p$ and Λ kinetic energy spectra in comparison with our calculations. In ref. [15], the measured spectra were fitted by the relativistic Maxwell-Boltzmann distribution

$$E \frac{dN}{p^2 dp} = A \exp(-E/E_0)$$

with the normalization $A$ and the temperature $E_0$ being fit parameters. We observe that the high energy parts of calculated spectra — except for very high energy ($E_{\text{kin}} > 0.6$ GeV) pion spectrum — agree with the data and with the Maxwell-Boltzmann formula (19) reasonably well. A slight underprediction of the high-energy pion spectrum can be traced back to the case of $\bar{p}p$ annihilation at rest (c.f. Fig. B.52 in ref. [11]). More significant is the deviation from the data at small kinetic energies. We predict the strongly enhanced evaporative emission of the low-energetic particles, in-particular, $p$ and Λ, in contrast with the ASTERIX data. The enhanced emission of low-energy nucleons is also present in the INC calculations of ref. [24] for the $\bar{p}$ annihilations at rest on $^{98}$Mo.

The calculated pion spectrum also has a clear two-component structure, which seems to be absent in the pion spectra measured by ASTERIX. The high energy pions ($E_{\text{kin}} > 300$ MeV or $p_{\text{lab}} > 400$ MeV/c) originate directly from $\bar{N}N$ annihilation almost without rescattering.
FIG. 4: Kinetic energy spectra of \((\Lambda + \Sigma^0)\) hyperons (left panels) and \(K_S^0\) mesons (right panels). The spectra of free particles selected according to the two different criteria, \(E_i > m_i\) \((i = Y, K, \) upper panels) and \(d_c = 3\) fm (middle panels), are plotted at different times. Also the comparison of the spectra obtained with these two criteria with the spectrum of all particles, i.e., without any restrictions is shown at 200 fm/c (lower panels). The number of \(K_S^0\) mesons has been determined from the numbers of \(K^0\) and \(\bar{K}^0\) as \(N_{K_S^0} = \frac{1}{2}(N_K + N_{\bar{K}})\).
FIG. 5: Kinetic energy spectra of negative pions, protons and ($\Lambda + \Sigma^0$) hyperons for the $\bar{p}$ annihilation at rest on $^{14}$N. The GiBUU calculations are performed for the n=3, l=2 and n=4, l=3 states of the antiproton. Experimental data and their fits according to the relativistic Maxwell-Boltzmann distribution of Eq. (19) are from ref. [15]. The slope temperatures $E_0$ for the experimental spectra are also given on the plots.
FIG. 6: The probability of a free \( \Lambda \) as well as one and two captured \( \Lambda \)'s production per annihilation event vs the target mass number for annihilations of \( \bar{p} \) at \( p_{\text{lab}} = 225 \text{ MeV/c} \) on \( ^{12}\text{C}, ^{48}\text{Ti}, ^{181}\text{Ta} \) and \( ^{208}\text{Pb} \). The experimental data for free \( \Lambda \) are from [1].

on nucleons. The low energy pions are mostly the products of the \( \pi N \rightarrow \Delta \rightarrow \pi N \) processes. This structure is present in the CALLIOPE@LEAR data [40] for the pion momentum spectra from 608 MeV/c antiproton annihilation on \( ^{12}\text{C} \) and \( ^{238}\text{U} \) which agree with the GiBUU calculations very well [18].

Although the radial distributions of annihilation points are somewhat different for annihilation at rest and low-energy annihilation in-flight, the angle-integrated momentum spectra of emitted particles are expected to change only a little [24]. Therefore, we attribute the above discrepancies to the reduced acceptance of the ASTERIX spectrometer for the low-momentum particles, as also mentioned by the authors themselves in ref. [15].
C. Annihilation in-flight

We start from the lowest beam momenta and consider the reactions \( \bar{p}(0-450 \text{ MeV/c}) + ^{12}\text{C}, ^{48}\text{Ti}, ^{181}\text{Ta} \) and \(^{208}\text{Pb}\) measured at BNL [1]. Figure 6 shows the calculated target mass dependence of the free \( \Lambda \) production probability per annihilation event together with the data. Note, that the \( \bar{p} \)-annihilation cross section \( \sigma_{\text{ann}} \propto A^{2/3} \), i.e., it grows with the target mass number. However, we got rid of this enhancement by dividing out \( \sigma_{\text{ann}} \) from the \( \Lambda \) production cross sections. We also present the calculated production probabilities of nuclear systems with one and two captured \( \Lambda \) hyperons in the same reactions. In calculations, the beam momentum was fixed at 225 MeV/c. The free \( \Lambda \) production probability is weakly sensitive to the target mass number and agrees with experiment. However, the probabilities of one and two captured \( \Lambda \) production grow with the target mass number by almost one order of magnitude from the lightest \((^{12}\text{C})\) to the heaviest \((^{208}\text{Pb})\) target. This is expected since, in heavier targets, the produced hyperons are more efficiently decelerated by rescattering on nucleons. The detailed calculations of hyperfragment production in \( \bar{p} \) annihilation on nuclei within the coupled GiBUU + statistical multifragmentation models are presented in Ref. [34].

Figure 7 shows the rapidity distributions of \( \Lambda \) hyperons and \( K_S^0 \) mesons from \( \bar{p} + ^{20}\text{Ne} \) collisions at 608 MeV/c in comparison to the data and to the INC calculations from [5]. As we observe, both models agree within \( \sim 30\% \). The experimental \( \Lambda \) rapidity distribution is rather well described, while the calculated \( K_S^0 \) spectra are clearly above the data. Since the direct channel of hyperon production, \( \bar{p}p \rightarrow \bar{\Lambda}\Lambda \) \((p_{\text{lab}}^{\text{thr}} = 1.439 \text{ GeV/c})\), is closed at \( p_{\text{lab}} = 608 \text{ MeV/c} \), the hyperons can only be produced in strangeness exchange processes \( \bar{K}(\bar{K}^*)N \rightarrow Y(Y^*)\pi \), in hyperon resonance formation reactions \( \bar{K}N \rightarrow Y^* \), or in meson-nucleon collisions \((\omega N \rightarrow YK \text{ mostly})\). Our calculation produces somewhat more \( K_S^0 \)'s than the INC calculation [5] does. This is partly due to taking into account the target destruction by \( \bar{p} \) annihilation in our calculations, which reduces the chances for an \( \bar{K} \) to be absorbed. There is also another possible reason for the different results. Both models contain the \( \bar{K}N \) elementary cross sections fitted to the experimental data. However, the important difference is that in GiBUU the \( Y^* \) resonances have finite life times \( \sim 1/\Gamma \) and, therefore, can escape out of the nucleus. This effectively reduces the \( \bar{K} \) absorption since a \( Y^* \) excited as the intermediate state of \( \bar{K}N \) scattering, \( \bar{K}N \rightarrow Y^* \rightarrow \bar{K}N \), “hides” an \( \bar{K} \) from interactions.
FIG. 7: The summed rapidity distributions of Λ and Σ⁰ hyperons (upper panel) and the rapidity distribution of K⁰_S mesons (lower panel) produced in $\bar{p}$ annihilations on ²⁰Ne at 607 MeV/c — thin solid lines. The integrated distributions give the number of particles per annihilation event. The partial contributions to the hyperon rapidity spectrum ("M" means any nonstrange meson $\pi, \eta, \rho, \omega$) are depicted by lines with open symbols. The INC calculations from ref. [5] are shown by dashed lines. The experimental data (histograms) are taken from ref. [2]. The c.m. rapidity of an antiproton and a nucleon $y_{\bar{p}N} = 0.305$ is shown by arrows.
with other nucleons.

The \((\Lambda + \Sigma^0)\) rapidity spectrum shown in Fig. 7 is decomposed to its partial components according to various elementary production channels of \(\Lambda\) or \(\Sigma^0\). We see that the largest contribution is given by the hyperon rescattering on nucleons with flavour and/or charge exchange, in-particular, by the exothermic processes \(\Sigma^+ n \rightarrow \Lambda p\) and \(\Sigma^- p \rightarrow \Lambda n\). The main channel of the hyperon production, however, is the strangeness exchange processes \(\bar{K}(\bar{K}^*)N \rightarrow Y(Y^*)\pi\). The rescattering \(\Lambda(\Sigma_0)N \rightarrow \Lambda(\Sigma_0)N\) somewhat distorts the shapes of these partial contributions by shifting the produced \(\Lambda\)'s(\(\Sigma^0\)'s) towards smaller absolute values of rapidity (see also Fig. 9 below).

A more detailed information on the relative importance of various hyperon production channels is given in Table II. As one can see by inspecting Table II, \(\sim 80\%\) of the total \(Y\) and \(Y^*\) production rate (without \(Y\) and \(Y^*\) absorption contributions) is caused by the \(\bar{K}B \rightarrow YX\), \(\bar{K}B \rightarrow Y^*\) and \(\bar{K}B \rightarrow Y^*\pi\) secondary processes. Nevertheless, the associated production \(MB \rightarrow YK\) constitutes the remaining 20\% and, therefore, is quite important as well. In contrast, 80\% of the kaon and antikaon production rate is caused by the direct mechanism \(\bar{B}B \rightarrow K\bar{K}X\). The INC calculation gives larger contributions of the antikaon absorption \(\bar{K}B \rightarrow YX\) and associated production \(MB \rightarrow YK\). At the same time, the hyperonic decays of \(Y^*\) resonances present in GiBUU counterbalance the smaller \(\Lambda\) and \(\Sigma\) hyperon production by other channels. This leads to rather similar final results for the both models.

It is quite interesting to observe from Table II that the \(\pi B \rightarrow YK\) channels make relatively small contributions to the \(\Lambda\) and \(\Sigma\) production rates with respect to the \(\omega B \rightarrow YK\) channels even though there is an abundant pion production in \(\bar{p}\) annihilation on nuclei. The reason is that in \(\bar{p}\) annihilation at rest or at low \(\bar{p}\) beam momentum most of pions are produced with momenta \(\sim 0.2 - 0.4\) GeV/c (c.f. Fig. 2 in ref. [18], where the \(\pi^+\) momentum spectrum is shown for \(\bar{p}+^{12}\text{C}\) collisions at 608 MeV/c). This is well below the threshold pion momentum of 0.895 GeV/c for the \(\pi N \rightarrow \Lambda K\) reaction on a nucleon at rest. On the other hand, an \(\omega\) meson is produced in a rather large fraction (\(\sim 20\%\)) of \(\bar{NN}\) annihilation events at rest (c.f. ref. [27]). This favors the exothermic \(\omega N \rightarrow YK\) reactions, which have a large cross section at low \(\omega\) momentum. The situation is, however, different for the energetic \(\bar{p}\)-nucleus collisions (see Table III below).

At 4 GeV/c, the agreement of our calculations with the experimental \(K^0_S\) spectrum be-
FIG. 8: The summed rapidity distributions of Λ and Σ⁰ (upper panel) and the rapidity distribution of K⁰_S (lower panel) for the collisions \( \bar{p}(4 \text{ GeV/c}) + {^{181}}\text{Ta} \rightarrow (\Lambda + \Sigma^0)X \) are shown by solid lines. The partial contributions to the hyperon rapidity spectrum ("M" means any nonstrange meson \( \pi, \eta, \rho, \omega \), "B" — any nonstrange baryon \( N, \Delta, N^* \) etc.) are shown by various lines with open symbols. The INC calculations (dashed lines) are taken from ref. [5]. The experimental data (solid circles) are from ref. [3]. The antiproton-nucleon c.m. rapidity \( y_{\bar{p}N} = 1.078 \) is shown by vertical arrows.
TABLE II: Partial contributions of the different reactions to the multiplicities of $\Lambda$, $\Sigma$, $\bar{K}$ and $K$ per 1000 $\bar{p}$ absorption events on $^{20}$Ne at 608 MeV/c. In the calculation of reaction rates we did not distinguish kaons from $K^*$'s and antikaons from $\bar{K}^*$'s. The negative numbers correspond to the absorption reaction channels for a given particle. Results of the INC calculations [5] are given in brackets.

Sum $\Lambda$ 26.5 (27.0) Sum $\Sigma$ 14.5 (12.3) Sum $\bar{K}$ 29.9 (24.0) Sum $K$ 70.6 (63.3)

The disagreement with the experimental rapidity spectrum of $(\Lambda + \Sigma^0)$ hyperons at $y \simeq 0.5$ comes better, as one can see from Fig. 8. However, the $(\Lambda + \Sigma^0)$ yield is now underpredicted at intermediate rapidities $y \simeq 0.5 y_{\bar{p}N}$, where $y_{\bar{p}N}$ is the rapidity of an antiproton-nucleon c.m. system. From the spectrum decomposition into partial channels, which is also given in Fig. 8 we observe qualitatively the same picture as at lower beam momentum 607 MeV/c (Fig. 7 above). Some changes with respect to the lower beam momentum are, however, visible: The hyperon resonance $Y^*$ decays grow to the second place in importance. The relative contribution of nonstrange meson-baryon collisions is increased and becomes as important as that of strangeness-exchange reactions. Also a nonnegligible contribution of direct $\bar{B}B$ channels appears now.
might be due to still underpredicted contribution of the $Y^* \rightarrow Y\pi$ decays. Indeed, this contribution has a broad maximum at $y \approx 0.3$, i.e., close to the maximum of the measured rapidity spectrum. Since our calculations tend to overestimate the $K_S^0$ production, we can assume that the $KN \rightarrow Y^*$ cross sections should be larger. In particular, the total cross section $K^-n \rightarrow X$ (or the same cross section of the isospin-reflected channel $\bar{K}^0p \rightarrow X$) is underestimated at $\sqrt{s} < 1.7$ GeV (see Fig. 2.15 in ref. [35]).

Another reason for the deviation with the experimental rapidity spectrum of $(\Lambda + \Sigma^0)$ hyperons is related to rather uncertain $YN \rightarrow YN$ cross sections. Especially the $\Lambda N \rightarrow \Lambda N$ cross section is important, as has been noticed, first, by Gibbs and Kruk in ref. [14]. These authors have applied their INC code [13, 14] to the reaction $\bar{p}(4 \text{ GeV/c})+^{181}\text{Ta}$ and reproduced the measured $(\Lambda + \Sigma^0)$ and $K_S^0$ rapidity spectra very well. They assigned a constant elastic hyperon-nucleon cross section of 14 mb, which is about two times less than the $\Lambda p$ elastic cross section at $p_{\text{lab}} \approx 0.5$ GeV/c (corresponding to the peak position $y \approx 0.4$ of the measured $\Lambda$ rapidity spectrum, c.f. Fig. 8) in the parameterization of Cugnon et al. [5]. Since we have also applied the latter parameterization in the present calculations, this largely explains the shift of our $(\Lambda + \Sigma^0)$ rapidity spectrum to smaller rapidities with respect to the measured spectrum. Fig. 9 demonstrates the sensitivity of our calculations to the hyperon-nucleon cross sections. The calculation without hyperon-nucleon rescattering produces the peak position of the calculated $(\Lambda + \Sigma^0)$ rapidity spectrum close to the experimental one. However, the spectrum at large forward rapidities is now overestimated.

The stopping power of the nuclear medium with respect to the moving hyperon depends not only on the integrated elastic hyperon-nucleon cross section, but also on its angular dependence. For simplicity, we have chosen the hyperon-nucleon cross sections to be isotropic in the c.m. frame. This also contributes to the somewhat too large deceleration of the hyperons. On the other hand, the total yield of $(\Lambda + \Sigma^0)$ hyperons can be enhanced with increased charge exchange $\Sigma^-p \rightarrow \Lambda n$ and $\Sigma^+n \rightarrow \Lambda p$ cross sections which are rather poorly known from experiment.

Detailed information on the various production rates at 4 GeV/c is collected in Table III. One can see from Table III that with a relative contribution of $\sim 72\%$ the kaon absorption reactions $\bar{K}B \rightarrow YX$, $\bar{K}B \rightarrow Y^*$ and $\bar{K}B \rightarrow Y^*\pi$ are still dominating in the total $Y$ and $Y^*$ production rate, which is somewhat smaller relative contribution than in the case of $\bar{p}(607$ MeV/c)$^{20}\text{Ne}$. This is expected, since at higher $\bar{p}$ beam momenta more
strangeness production channels open. The nonstrange meson-baryon collisions provide the second largest contribution of $\sim 23\%$ to the $Y$ and $Y^*$ production rate. The hyperon production in antibaryon-baryon collisions (including direct channel) and in baryon-baryon collisions contributes only $\sim 3\%$ and $2\%$, respectively, to the same rate. On the other hand, as before, in the case of $\bar{p}(607\text{ MeV/c})^{20}\text{Ne}$, the antibaryon-baryon collisions dominate in the total $K(\bar{K})$ production rate contributing $\sim 60\%$. It is interesting, that the meson-meson reactions $MM \rightarrow KK$ are rather important and contribute $\sim 20\%$ to the $K$ and $\bar{K}$ production rates. This means that the $K\bar{K}$ pair production processes in mesonic cloud created after $\bar{p}$ annihilation should also be taken into account on equal footing with other secondary production channels. Note, however, that in GiBUU the two particles produced in the same two-body collision or resonance decay event are allowed to collide only after at least one of them collided with another particle not involved in this event. This is done in order to avoid multiple chain reactions between the correlated products of the same elementary event, which would otherwise lead to double counting in the production processes and, moreover, violate the molecular chaos assumption.
FIG. 10: Inclusive transverse momentum spectra of $(\Lambda + \Sigma^0)$, $K_S^0$ and $(\bar{\Lambda} + \bar{\Sigma}^0)$ from collisions $\bar{p}^{+181}\text{Ta}$ at 4 GeV/c. The INC calculations from [5] are also presented for comparison. The experimental data are taken from ref. [3].
There is a remarkable agreement for the absolute values of $\Lambda + \Sigma$ the yield of strange quark production and underestimate the ratio calculations and with experimental data at 0.6 and 4 GeV/c. Both models overestimate the by slow antikaons. Moreover, the produced hyperons are decelerated by rescattering on large cross sections of the exothermic strangeness exchange processes $\bar{K}N \rightarrow Y\pi$ induced by slow antikaons. The $(\Lambda + \Sigma)$ production at low $p_t$ is clearly enhanced due to large cross sections of the exothermic strangeness exchange processes $\bar{K}N \rightarrow Y\pi$ induced by slow antikaons. Moreover, the produced hyperons are decelerated by rescattering on nucleons. Our calculations reproduce the shapes of the experimental $p_t^2$-spectra rather well. There is a remarkable agreement for the absolute values of a $(\Lambda + \Sigma)$ yield at high $p_t$. Again, the yield of $K_0^0$ is somewhat overestimated, while the yield of antihyperons is underestimated by our calculations.

Figure 10 shows the inclusive transverse momentum spectra of $(\Lambda + \Sigma)$, $K_0^0$ and $(\bar{\Lambda} + \bar{\Sigma})$ from $\bar{p}(4 \text{ GeV/c}) + ^{181}\text{Ta}$ collisions. The $(\Lambda + \Sigma)$ production at low $p_t$ is clearly enhanced due to large cross sections of the exothermic strangeness exchange processes $\bar{K}N \rightarrow Y\pi$ induced by slow antikaons. Moreover, the produced hyperons are decelerated by rescattering on nucleons. Our calculations reproduce the shapes of the experimental $p_t^2$-spectra rather well. There is a remarkable agreement for the absolute values of a $(\Lambda + \Sigma)$ yield at high $p_t$. Again, the yield of $K_0^0$ is somewhat overestimated, while the yield of antihyperons is underestimated by our calculations.

In Table IV we summarize the results of comparison of our calculations with INC calculations and with experimental data at 0.6 and 4 GeV/c. Both models overestimate the strange quark production and underestimate the ratio $\sigma_{\Lambda+\Sigma}/\sigma_{K_0^0}$.

To our knowledge, the latest measurement of neutral strange particle production from high-energy antiproton interactions with nuclei was performed at BNL using the Multipar-
TABLE IV: The cross sections of the $\Lambda + \Sigma^0$ hyperon, $K^0_S$ meson and strange quark production (mb) in comparison with the INC results from $[5]$ and experimental data from $[2, 3]$ for reactions $\bar{p}(607 \text{ MeV/c}) + ^{20}\text{Ne}$ and $\bar{p}(4 \text{ GeV/c}) + ^{181}\text{Ta}$. The “experimental” cross sections of the $s$-quark production are, actually, evaluated in $[5]$ based on some simple relations to the really measured cross sections.

The particle Spectrometer (MPS) facility $[12]$. Fig. 11 shows the inclusive cross sections for $\Lambda$, $K^0_S$, $\bar{\Lambda}$ and strange quark production in collisions of antiprotons at 5, 7 and 9 GeV/c with carbon, copper and lead targets in comparison to the MPS data from $[12]$. Also the INC model $[13, 14]$ results given in ref. $[12]$ are shown in Fig. 11. The strange quark (or $s\bar{s}$ pair) production cross section has been calculated consistently with ref. $[12]$, i.e. according to the approximate formula

$$\sigma_s = \frac{1}{2}(4\sigma_{K^0_S} + \sigma_{\Lambda} + \sigma_{\Sigma^0} + \sigma_{\bar{\Lambda}} + \sigma_{\bar{\Sigma^0}}),$$

(20)

where $\sigma_{K^0_S} = (\sigma_{K^0} + \sigma_{\bar{K}^0})/2$. There is a fair overall agreement of GiBUU calculations with data. In particular, $\Lambda$ and $\bar{\Lambda}$ production on the carbon target is described very well by GiBUU, while for the heavier targets we somewhat underpredict $\Lambda$ and $\bar{\Lambda}$ production. The $K^0_S$ production cross section on the carbon target is two times overpredicted by GiBUU. On heavier targets, the agreement with experiment on $K^0_S$ production becomes better, but the slope of the beam momentum dependence of the $K^0_S$-production cross section seems to be overpredicted. We note, that the data on the inclusive cross sections have been obtained by integration over rapidity region with good acceptance and extrapolated to the $4\pi$ solid angle using the INC calculations. This is partly responsible for a better agreement of the INC results with this experiment. Fig. 12 shows the rapidity distributions of $\Lambda$, $K^0_S$ and
FIG. 11: Inclusive cross section of $\Lambda$, $K^0_S$, $\bar{\Lambda}$ and strange quark (s) production for antiproton interactions at $p_{\text{lab}} = 5.2, 7.0$ and 8.8 GeV/c with $^{12}\text{C}$, $^{64}\text{Cu}$ and $^{208}\text{Pb}$ targets. The INC calculations and experimental data are from ref. [12].
FIG. 12: Rapidity distributions of Λ, $K_0^0$ and $\bar{\Lambda}$ from $\bar{p}$ interactions with $^{64}$Cu at 8.8 GeV/c. The INC calculations and experimental data are from ref. [12].
\( \bar{\Lambda} \) from antiproton collisions with copper target at 9 GeV/c. As one observes, the GiBUU calculations agree with the data quite well, except the underprediction of \( \bar{\Lambda} \) yield at \( y \simeq 0.5 \). We also observe a rather close agreement of GiBUU and INC results, which means that the selected observables are, actually, not very sensitive to the model details, once the elementary cross sections are adjusted to the experimental input.

D. \( S = -2 \) hyperon production

Figure 13 shows the inclusive momentum spectrum of \( \Xi \) hyperons from \( \bar{p} + ^{197}\text{Au} \) collisions at 3 GeV/c together with the partial contributions from various \( \Xi \) production channels. In performing this decomposition, we did not distinguish kaons from antikaons. As one can see from Fig. 13, the (anti)kaon-baryon collisions deliver the main contribution \( \sim 35\% \) to the \( \Xi \) production, mainly due to the double strangeness exchange channel \( \bar{K}N \to K\Xi \). The decays \( \Xi^* \to \Xi\pi \) — especially important at low transverse momenta of \( \Xi \) — make the second largest contribution \( \sim 26\% \) to the \( \Xi \) production. It is interesting, that the (anti)kaon-hyperon collisions, which are collisions between the secondary particles, contribute also quite appreciably, \( \sim 17\% \). Other reaction channels are of relatively minor importance for the inclusive \( \Xi \) production. For example, the direct channel \( \bar{N}N \to \bar{\Xi}\Xi \) contributes \( \sim 6\% \) only; this channel is of primary importance for the planned PANDA experiment on the double-\( \Lambda \) hypernuclei production at FAIR [8, 9].

Figure 14 shows the rapidity spectra of \( \Xi^- \) hyperons together with the \((\Lambda + \Sigma^0)\) and \( K_0^S \) rapidity spectra from \( \bar{p} + ^{197}\text{Au} \) collisions at 3, 9 and 15 GeV/c. The \( \Xi^- \) spectra are about two orders of magnitude below those for the \((\Lambda + \Sigma^0)\) and \( K_0^S \) production. They are peaked at \( y \simeq 0.5, 0.9 \) and 1.2 for the beam momenta of 3, 9 and 15 GeV/c, respectively. However, the \((\Lambda + \Sigma^0)\) spectra are always peaked near the target rapidity, \( y = 0 \), even at the largest beam momentum. This is because the hyperon production is dominated by the \( \bar{K}N \to Y\pi \) processes with slow antikaons. Moreover, at 3 GeV/c, also the \( K_0^S \) spectrum has a broad maximum at the target rapidity.

The experimental fact that the \((\Lambda + \Sigma^0)\) and \( K_0^S \) rapidity spectra from \( \bar{p} + ^{181}\text{Ta} \) collisions at 4 GeV/c are peaked at nearly the same rapidities (c.f. Fig. 8) has been interpreted by Rafelski [7] as the manifestation of a common production source for strange particles, i.e. of an annihilation fireball with the baryon number \( \simeq 10 \). The large baryon number is...
FIG. 13: Inclusive momentum spectrum of Ξ hyperons from \( \bar{p}(3 \text{ GeV/c}) + ^{197}\text{Au} \rightarrow \Xi X \) collisions (the solid line). The partial contributions according to the parent particles of a Ξ hyperon are depicted by various lines with symbols. In key notations, “M” denotes any nonstrange meson \( \pi, \eta, \rho, \omega \), “B” — any nonstrange baryon \( N, \Delta, N^* \) etc.. The symbol “\( K(K^\star) \)” denotes both kaon (\( K^* \)) and antikaon (\( \bar{K}^* \)).

due to absorbing nucleons by the propagating fireball. Rafelski assumed that the fireball undergoes the transition to the supercooled QGP state and then hadronizes. The rapidity spectra of Ξ hyperons would also be peaked at the fireball rapidity if the fireball mechanism would dominate. In our model, a purely hadronic picture emerges instead, where the Ξ production is dominated by the double strangeness exchange processes of \( \bar{K}N \rightarrow K\Xi \) type. The latter are endothermic and require the momentum of incoming antikaon in the rest
FIG. 14: Inclusive rapidity spectra of $\Xi^-$, $(\Lambda + \Sigma^0)$ and $K_S^0$ from $\bar{p} + ^{197}\text{Au}$ collisions at 3, 9 and 15 GeV/c. The spectra of $\Xi^-$ are multiplied by a factor of 10. The $\bar{p}N$ c.m. rapidity $y_{\bar{p}N} = 0.940, 1.479$ and 1.733 for $p_{\text{lab}} = 3, 9$ and 15 GeV/c, respectively, is shown by vertical arrows.
frame of a nucleon placed above the threshold value $p_{\text{thr}} \simeq 1.05$ GeV/c corresponding to the $KN$ c.m. rapidity of 0.55. This makes the $\Xi$ rapidity spectra shift to higher rapidities. In contrast, the $S = -1$ hyperon production is dominated by the exothermic strangeness exchange $\bar{K}N \rightarrow \pi Y$. The cross section of this process grows with decreasing antikaon momentum in the nucleon rest frame. This favors the isotropic production of slow hyperons in the target nucleus rest frame.

Finally, Fig. 15 presents the laboratory momentum spectra of the different strange particles in the forward ($\Theta = 0^\circ - 60^\circ$) and transverse ($\Theta = 60^\circ - 120^\circ$) directions for $\bar{p}+^{197}$Au collisions at 3, 9 and 15 GeV/c. The spectra of $(\Lambda + \Sigma^0)$ hyperons and $K^0_S$ are rather close to each other both in forward and transverse directions. It is, moreover, interesting that the high-momentum slopes are similar for all considered particles. However, the production of the low-momentum $\Xi^-$ hyperons is suppressed due to the dominating $\Xi$ production via the double strangeness exchange in $\bar{K}N \rightarrow K\Xi X$ processes.

IV. SUMMARY AND CONCLUSIONS

To summarize, we have studied the strange particle production in $\bar{p}$-induced reactions on nuclei by applying the GiBUU model. We have considered both at-rest and in-flight reactions and confronted our results with experimental data [1–3, 12, 15] on neutral strange particle yields and spectra. We have also compared our calculations with the earlier INC calculations of Cugnon-Deneye-Vandermeulen [9] and Gibbs-Kruk [14]. Finally, the model predictions for the $\Xi$ hyperon production are given.

So far the main motivation for the experimental studies of strangeness production in antiproton-nucleus reactions has been to find the signatures of QGP production, which can be complementary to similar studies in high-energy heavy-ion collisions. Overall, our results are in a fair agreement with existing experimental data on $K^0_S$, $(\Lambda + \Sigma^0)$ and $(\bar{\Lambda} + \Sigma^0)$ production for $\bar{p}$ annihilation on nuclei and with INC models. There seems to be, indeed, no striking disagreements with data on inclusive $\Lambda$, $K^0_S$ and $\bar{\Lambda}$ production at high beam momenta, which could point to the exotic mechanisms, as it has been already concluded in refs. [12, 14].

There are, however, some systematic deviations the origins of which remain to be better understood. The GiBUU and INC models are based on the same hadronic cascade picture.
FIG. 15: Inclusive laboratory momentum spectra of $\Xi^-$, $(\Lambda + \Sigma^0)$ and $K^0_S$ from $\bar{p}(3, 9, 15 \text{ GeV/c})+^{197}\text{Au}$ collisions in the two ranges of the polar angle: $\Theta = 0^\circ - 60^\circ$ and $\Theta = 60^\circ - 120^\circ$. The spectra of $\Xi^-$ are multiplied by a factor of 10.
but differ in several details like, e.g. the mean field potentials and the treatment of $Y^*$ resonances. There is a clear tendency to underestimate the $\Lambda/K_S^0$ ratio in our calculations. This tendency is present also in the results of INC calculations, although somewhat less pronounced. This problem might be caused by possible in-medium effects on the $\bar{K}N \to YX$ cross section. Poorly known hyperon-nucleon cross sections also strongly influence the observed hyperon spectra. The latter cross sections are also of more general interest, since they are related to the hyperon-nucleon interaction relevant in hypernuclear studies. To disentangle various possibilities, it would be very useful to measure the rapidity spectra of not only neutral strange particles, $(\Lambda + \Sigma^0)$ and $K_S^0$, but also of the charged ones, $\Sigma^\pm$ and $K^\pm$.

The exotic mechanisms of strangeness production may, in-principle, manifest themselves more clearly in the $S = -2$ hyperon production. We have calculated the inclusive production of $\Xi$ hyperons from collisions $\bar{p} + ^{197}$Au at 3-15 GeV/c. The $\Xi^-$ rapidity spectra are strongly shifted to forward rapidities in the laboratory system, since the $\Xi$ production via the dominating endothermic $\bar{K}N \to K\Xi$ channel requires a high-momentum initial antikaon. This is in a contrast to the strangeness production mechanism from a moving annihilation fireball proposed by Rafelski [7]. Thus a simultaneous measurement of the single- and double-strange hyperon rapidity spectra may serve as a sensitive test for the hadronic and QGP scenarios of strangeness production in $\bar{p}$ annihilation on nuclei. The possibility for such measurements opens up in the planned PANDA experiment at FAIR [10].

Acknowledgments

We thank H. Lenske, I.N. Mishustin, J. Pochodzalla, and I.A. Pshenichnov for their interest in our work and for stimulating discussions. We are especially grateful to I.A. Pshenichnov for explanations on the application of his statistical annihilation code to the annihilation final states with strangeness. This work was financially supported by the Bundesministerium für Bildung und Forschung, by the Helmholtz International Center for FAIR within the framework of the LOEWE program, by DFG and by the Grant NSH-7235.2010.2 (Russia). The support by the Frankfurt Center for Scientific Computing is gratefully acknowledged.
Appendix A: Strangeness production in $\bar{N}N$ annihilation at rest

In this Appendix we list the probabilities for the various channels with strangeness for $\bar{p}p$ and $\bar{p}n$ annihilation at rest (Tables V and VI, respectively). We also provide references on source papers. Footnotes explain how some of the probabilities have been obtained from experimental data. Many of the partial probabilities for the $\bar{p}p$ annihilation at rest can be also found in the data compilation [41].
TABLE V: Probabilities of the different channels with strange mesons for $\bar{p}p$ annihilation at rest (in %).

1) Nonresonance contribution obtained as $B_{K^0K^0\pi^0}^{\text{nonres}} = B_{K^0K^0\pi^0}^{\text{res}} + B_{K^0K^0\pi^0} = 1.46 \cdot 10^{-3}$.

2) Nonresonance contributions obtained as

$$B_{K^0K^+\pi^0}^{\text{nonres}} = 0.5 \cdot (B_{K^0K^+\pi^0} - B_{K^0K^+\pi^0} = 0.5 \cdot (B_{K^0K^+\pi^0} - B_{K^0K^+\pi^0} = 1.42 \cdot 10^{-3}.$$
3) Obtained as \( B_{K^0 K^0 M} = B_{K_S K_S M} + B_{K_L K_L M} \), where \( M = \eta, \omega \).

4) Obtained as

\[
B_{K^0 K^0 \rho^0} = B_{K^0 K^0 \rho^0} - B_{K^+ K^0 \rho^0} - B_{K^+ K^0 \rho^0} - B_{K^+ K^0 \rho^0} - B_{K^+ K^0 \rho^0} - B_{K^+ K^0 \rho^0} - B_{K^+ K^0 \rho^0} - B_{K^+ K^0 \rho^0} - B_{K^+ K^0 \rho^0} \\
-0.34 \cdot (B_{\phi + \pi^-} + B_{\phi + \rho}) = (7.45 - 3.63 - 0.57 - 0.34 \cdot (0.54 + 0.34)) \cdot 10^{-3} = 2.96 \cdot 10^{-3}
\]

\[
B_{K^+ K^- \rho^0} = B_{K^+ K^- \rho^0} - B_{K^+ K^- \rho^0} - B_{K^+ K^- \rho^0} - B_{K^+ K^- \rho^0} - B_{K^+ K^- \rho^0} - B_{K^+ K^- \rho^0} - B_{K^+ K^- \rho^0} - B_{K^+ K^- \rho^0} - B_{K^+ K^- \rho^0} \\
= (3.6 - 1.0 - \frac{2}{3} \cdot 1.7 - 0.49 \cdot (0.54 + 0.34)) \cdot 10^{-3} = 1.07 \cdot 10^{-3}
\]

5) Obtained as

\[
B_{K^0 K^+ \rho^0} = B_{K^0 K^+ \rho^0} - B_{K^0 K^+ \rho^0} - B_{K^0 K^+ \rho^0} - B_{K^0 K^+ \rho^0} - B_{K^0 K^+ \rho^0} - B_{K^0 K^+ \rho^0} - B_{K^0 K^+ \rho^0} - B_{K^0 K^+ \rho^0} - B_{K^0 K^+ \rho^0} \\
-0.34 \cdot (B_{\phi + \pi^-} + B_{\phi + \rho}) = (10.38 - 0.57 - 0.97 - 1.04 - 0.77 - 1.43 - \frac{2}{3} \cdot 1.4) \cdot 10^{-3} = 4.67 \cdot 10^{-3}
\]

6) Non-resonance contribution obtained as

\[
B_{K^0 K^0 \rho^0}^{\text{nonres}} = B_{K^0 K^0 \rho^0} - \frac{1}{3} (B_{K^0 K^0 \rho^0} + B_{K^0 K^0 \rho^0}) - \frac{1}{9} B_{K^0 K^0 \rho^0} - 0.34 B_{\phi + \rho} \\
= (1.1 - \frac{1}{3} \cdot 1.4 - \frac{1}{9} \cdot 2.25 - 0.34 \cdot 0.11) \cdot 10^{-3} = 0.35 \cdot 10^{-3}
\]

assuming that \( B_{K^0 K^0 \rho^0} = B_{K_L K_S \rho^0} \) according to [47].

7) Non-resonance contribution obtained as

\[
B_{K^0 K^0 \rho^0}^{\text{nonres}} = B_{K^0 K^0 \rho^0} - 0.28 \cdot B_{K^0 K^0 \rho^0} - 0.89 \cdot B_{K^0 K^0 \rho^0} - 0.34 \cdot (0.28 \cdot B_{\phi + \rho} + 0.89 \cdot B_{\phi + \rho}) \\
= (2.98 - 0.28 \cdot 0.50 - 0.89 - 2.32 - 0.34 \cdot (0.28 \cdot 0.036 + 0.89 \cdot 0.30)) \cdot 10^{-3} = 0.68 \cdot 10^{-3}
\]

8) Obtained as \( B_{K^0 K^+ \pi^+ \pi^-} = B_{K^0 K^- \pi^- \pi^+} = B_{K_L K_S \pi^+ \pi^- \pi^+} \).

a) Averaged with respect to the charged and neutral \( K \) or \( K^* \) production channels.

b) Obtained by isospin relations from the branching ratio of another channel.
TABLE VI: Probabilities of the different channels with strange mesons for $\bar{p}n$ annihilation at rest (in %).

| Channel | Prob. | Ref. | Channel | Prob. | Ref. |

1) Obtained by averaging the transition rates into $K^*\bar{K} + \bar{K}^*K$ from $^1S_0 \ I = 1$ and $^3S_1 \ I = 1$ states as

$$B_{K^*\bar{K} + \bar{K}^*K} = 0.5 \cdot (2.0 + 24.6) \cdot 10^{-4} = 13.3 \cdot 10^{-4},$$

$$B_{K^{*0}K^{*-}} = B_{K^-K^{*0}} = 0.5 \cdot B_{K^*\bar{K} + \bar{K}^*K} = 6.7 \cdot 10^{-4}.$$

2) Reconstructed from the partial contribution into the $\bar{K}^0K^+\pi^-\pi^-$ channel.

3) Nonresonance contribution calculated as

$$B_{K^{*0}K^-\pi^0} = B_{K^{*0}K^-\pi^0} - B_{K^{*0}K^{*-},K^{*-}\rightarrow K^-\pi^0} - B_{K^-K^{*0},K^{*0}\rightarrow K^0\pi^0}$$

$$= B_{K^{*0}K^-\pi^0} - \frac{1}{3} \cdot B_{K^{*0}K^{*-}K^-\pi^0} = (36.0 - \frac{1}{3} \cdot 13.3) \cdot 10^{-4} = 31.6 \cdot 10^{-4}.$$

4) Nonresonance contribution evaluated as

$$B_{K^{*0}K^0\pi^-} = B_{K^0K^0\pi^-} - B_{K^{*0}K^{*0},K^{*0}\rightarrow K^0\pi^-} - B_{\phi\pi^-}\phi\rightarrow K^0L_K^3.$$
\[
= (50.6 - \frac{2}{3} \cdot 6.7 - 0.34 \cdot 8.8) \cdot 10^{-4} = 43.2 \cdot 10^{-4} .
\]

5) Nonresonance contribution evaluated as
\[
B_{K+K^-\pi^-}^{\text{nonres}} = B_{K+K^-\pi^-} - B_{K+K^0\pi^0, K^+\pi^- K^-\pi^-} - B_{\phi\pi^-\phi K + K^-}
\]
\[
= (60.0 - \frac{2}{3} \cdot 6.7 - 0.49 \cdot 8.8) \cdot 10^{-4} = 51.3 \cdot 10^{-4} .
\]

6) Reconstructed from the partial contribution to the \(K^0K^-\pi^-\pi^+\) channel.

7) Reconstructed from the partial contribution to the \(K^0S\bar{K}^0\pi^-\pi^0\) channel.

8) Reconstructed from the partial contribution to the \(K^0K^-\pi^-\pi^+\pi^-\) and \(\bar{K}^0K^+\pi^-\pi^-\) channels.

9) Nonresonance contribution evaluated as
\[
B_{K^0K^-\pi^-\pi^0}^{\text{nonres}} = B_{K^0K^-\pi^-\pi^0} - B_{K^0K^-\omega, \omega\rightarrow\pi^+\pi^-\pi^0}
\]
\[
= (33.6 - 0.89 \cdot 35.0) \cdot 10^{-4} = 2.5 \cdot 10^{-4} .
\]

a) Obtained by isospin relations from the branching ratio of another channel.
Appendix B: Elementary cross sections

In this Appendix we describe the cross sections of the hyperon production in $\bar{N}N$ collisions. Other partial cross sections of the $\bar{N}N$ collisions are described in Appendix B.2 of ref. [11].

The $\bar{p}p \rightarrow \bar{\Lambda}\Lambda$ and $\bar{p}p \rightarrow \bar{\Lambda}\Sigma^0 + (c.c.)$ cross sections (in mb) are parameterized as a function of the invariant energy $\sqrt{s}$ (in GeV) by the following expressions:

$$
\sigma_{\bar{p}p \rightarrow \bar{\Lambda}\Lambda} = \begin{cases} 
0, & \sqrt{s} < 2.232 \\
0.0357(\sqrt{s} - 2.232)^{0.5} + 9.005(\sqrt{s} - 2.232)^{1.5}, & 2.232 < \sqrt{s} < 2.252 \\
\max(0.01, 0.726(s/4.982 - 1)^{0.774}(4.982/s)^{3.350}), & 2.252 < \sqrt{s} 
\end{cases}
$$

(B1)

$$
\sigma_{\bar{p}p \rightarrow \bar{\Lambda}\Sigma^0 + c.c.} = \begin{cases} 
0, & \sqrt{s} < 2.308 \\
0.184(s/5.327 - 1)^{0.437}(5.327/s)^{1.850}, & 2.308 < \sqrt{s} 
\end{cases}
$$

(B2)

The functional form in (B1) at lower energies is adopted from ref. [55], however, with slightly different numerical parameters. The parameterization used in (B1) at higher energies and in (B2) is taken from ref. [56]. The numerical parameters in (B1) and (B2) are obtained by the fit to the world data on the cross sections $\bar{p}p \rightarrow \bar{\Lambda}\Lambda$ and $\bar{p}p \rightarrow \bar{\Lambda}\Sigma^0 + c.c.$ from [32].

For the $\bar{p}p \rightarrow \bar{\Xi}^+\Xi^-$ cross section only the value of 2 $\mu$b at 3 GeV/c is known experimentally [32]. Thus, we simply assume the constant cross section above threshold:

$$
\sigma_{\bar{p}p \rightarrow \bar{\Xi}^+\Xi^-} = \sigma_{\bar{p}p \rightarrow \bar{\Xi}^0\Xi^0} = \begin{cases} 
0 \mu b, & \sqrt{s} < 2.630 \text{ GeV} \\
2 \mu b, & 2.630 \text{ GeV} < \sqrt{s} 
\end{cases}
$$

(B3)

The cross sections involving $n$, $\bar{n}$, $\Delta$ and $\bar{\Delta}$ in the initial state are obtained from the isospin relations as

$$
\sigma_{nn \rightarrow \bar{\Lambda}\Lambda} = \sigma_{\bar{p}p \rightarrow \bar{\Lambda}\Lambda},
$$

(B4)

$$
\sigma_{BB \rightarrow \bar{\Lambda}\Sigma^0 + c.c.} = 2\sigma_0 \left( I^B I^\bar{B} I^\bar{B} I^B | I I^\Sigma \right)^2,
$$

(B5)

$$
\sigma_{BB \rightarrow \bar{\Xi}\Xi} = \sigma_1 \sum_{I=0,1} \left( I^B I^\bar{B} I^\bar{B} I^B | I (I^\bar{B} + I^B) \right)^2 \left( I^\bar{B} I^\bar{B} I^\bar{B} I^B | I (I^\bar{B} + I^B) \right)^2
$$

(B6)

where $\sigma_0 = \sigma_{\bar{p}p \rightarrow \bar{\Lambda}\Sigma^0 + c.c.}$, $\sigma_1 = 2\sigma_{\bar{p}p \rightarrow \bar{\Xi}^+\Xi^-}$, $B$ stands for $N$ or $\Delta$, and only the combinations $\bar{N}N$, $\bar{\Delta}N$ and $\bar{N}\Delta$ of incoming particles are taken into account. Equations (B5) and (B6) can be simplified, which gives the following:

$$
\sigma_{nn \rightarrow \bar{\Lambda}\Sigma^0 + c.c.} = \sigma_0,
$$

(B7)
\[ \sigma_{\bar{p}n \to \Lambda \Sigma^- + \Lambda \Sigma^-} = 2\sigma_0, \quad (B8) \]
\[ \sigma_{\Delta^- p \to \Lambda \Sigma^0 + c.c.} = \sigma_{\Delta^0 n \to \Lambda \Sigma^0 + c.c.} = \sigma_0, \quad (B9) \]
\[ \sigma_{\Delta^- n \to \Lambda \Sigma^- + \Lambda \Sigma^-} = \sigma_{\Delta^0 p \to \Lambda \Sigma^+ + \Lambda \Sigma^+} = \frac{1}{2}\sigma_0, \quad (B10) \]
\[ \sigma_{\Delta^- p \to \Lambda \Sigma^+ + \Lambda \Sigma^-} = \sigma_{\Delta^0 n \to \Lambda \Sigma^0 + \Lambda \Sigma^-} = \frac{3}{2}\sigma_0, \quad (B11) \]
\[ \sigma_{\bar{n}n \to \Xi^- \Xi^+ + \Xi^0 \Xi^0} = \sigma_{\bar{p}n \to \Xi^- \Xi^0} = \sigma_1, \quad (B12) \]
\[ \sigma_{\bar{n} \Xi^- \Xi^+ + \Xi^0 \Xi^0} = \sigma_{\bar{p} \Xi^0} = \frac{1}{2}\sigma_1, \quad (B13) \]
\[ \sigma_{\Delta^- n \to \Xi^- \Xi^0} = \sigma_{\Delta^0 p \to \Xi^0} = \frac{1}{4}\sigma_1, \quad (B14) \]
\[ \sigma_{\Delta^- p \to \Xi^- \Xi^0} = \sigma_{\Delta^+ n \to \Xi^0} = \frac{3}{4}\sigma_1 \quad (B15) \]

The partial cross sections for the different outgoing channels shown with a “+” sign in (B7) - (B13) are equal to each other. The expressions for the charged conjugated reaction channels are obtained by replacing all particles by the corresponding antiparticles.

The angular differential cross sections for the \( \bar{N}N \to \bar{\Lambda} \Lambda \) process at \( \sqrt{s} > 2.37 \text{ GeV} \) (\( p_{\text{lab}} > 1.830 \text{ GeV/c} \)) and for \( \bar{N}N \to \bar{\Lambda} \Sigma, \Lambda \Sigma \) processes are chosen according to the phenomenological Regge-like fit of ref. [57]. At \( \sqrt{s} < 2.37 \text{ GeV} \), we fitted the experimental angular distributions for the \( \bar{N}N \to \bar{\Lambda} \Lambda \) scattering of refs. [55, 58–61] by the following expression:
\[ \frac{d\sigma_{\bar{N}N \to \bar{\Lambda} \Lambda}}{dt} = \left[a_0 + a_1 \exp(a_2(t_{\text{min}} - t))\right] \mu b/\text{GeV}^2, \quad (B16) \]
where \( t_{\text{min}} = -(p_{\bar{N}N} - p_{\bar{\Lambda} \Lambda})^2 \) (in \( \text{GeV}^2 \)),
\[ a_0 = (19.1946 + 132202\epsilon^{2.5})/(1 + 42592\epsilon^{3.5}), \quad (B17) \]
\[ a_1 = (277.044\epsilon^{0.25} - 3145.39\epsilon + 4993140\epsilon^{2.8})/(1 + 19075.7\epsilon^3), \quad (B18) \]
\[ a_2 = \begin{cases} 67357.8\epsilon - 257.692, & \epsilon \leq 0.0033 \\ 4.66944 \ln(1.49962\epsilon), & 0.0033 < \epsilon \end{cases} \quad (B19) \]
where \( \epsilon = \sqrt{s} - 2m_\Lambda \) (in GeV). For the \( \bar{B}B \to \bar{Y}Y \) processes involving \( \Delta \) or \( \bar{\Delta} \) in the initial state and for the \( \bar{B}B \to \Xi^- \Xi^0 \) processes we assume the isotropic angular differential cross sections in the c.m. frame.
