Comment: Demystifying Double Robustness: A Comparison of Alternative Strategies for Estimating a Population Mean from Incomplete Data

Anastasios A. Tsiatis and Marie Davidian

INTRODUCTION

We congratulate Drs. Kang and Schafer (KS henceforth) for a careful and thought-provoking contribution to the literature regarding the so-called “double robustness” property, a topic that still engenders some confusion and disagreement. The authors’ approach of focusing on the simplest situation of estimation of the population mean \( \mu \) of a response \( y \) when \( y \) is not observed on all subjects according to a missing at random (MAR) mechanism (equivalently, estimation of the mean of a potential outcome in a causal model under the assumption of no unmeasured confounders) is commendable, as the fundamental issues can be explored without the distractions of the messier notation and considerations required in more complicated settings. Indeed, as the article demonstrates, this simple setting is sufficient to highlight a number of key points.

As noted eloquently by Molenberghs (2005), in regard to how such missing data/causal inference problems are best addressed, two “schools” may be identified: the “likelihood-oriented” school and the “weighting-based” school. As we have emphasized previously (Davidian, Tsiatis and Leon, 2005), we prefer to view inference from the vantage point of semiparametric theory, focusing on the assumptions embedded in the statistical models leading to different “types” of estimators (i.e., “likelihood-oriented” or “weighting-based”) rather than on the forms of the estimators themselves. In this discussion, we hope to complement the presentation of the authors by elaborating on this point of view.

Throughout, we use the same notation as in the paper.

SEMIPARAMETRIC THEORY PERSPECTIVE

As demonstrated by Robins, Rotnitzky and Zhao (1994) and Tsiatis (2006), exploiting the relationship between so-called influence functions and estimators is a fruitful approach to studying and contrasting the (large-sample) properties of estimators for parameters of interest in a statistical model. We remind the reader that a statistical model is a class of densities that could have generated the observed data. Our presentation here is for scalar parameters such as \( \mu \), but generalizes readily to vector-valued parameters. If one restricts attention to estimators that are regular (i.e., not “pathological”; see Davidian, Tsiatis and Leon, 2005, page 263 and Tsiatis 2006, pages 26–27), then, for a parameter \( \mu \) in a parametric or semiparametric statistical model, an estimator \( \hat{\mu} \) for \( \mu \) based on independent and identically distributed observed data \( z_i, i = 1, \ldots, n \), is said to be asymptotically linear if it satisfies

\[
    n^{1/2}(\hat{\mu} - \mu_0) = n^{-1/2} \sum_{i=1}^{n} \varphi(z_i) + o_p(1)
\]

for \( \varphi(z) \) with \( E\{\varphi(z)\} = 0 \) and \( E\{\varphi^2(z)\} < \infty \), where \( \mu_0 \) is the true value of \( \mu \) generating the data, and expectation is with respect to the true distribution of \( z \). The function \( \varphi(z) \) is the influence function of the estimator \( \hat{\mu} \). A regular, asymptotically linear estimator with influence function \( \varphi(z) \) is consistent...
and asymptotically normal with asymptotic variance $E\{\varphi^2(z)\}$. Thus, there is an inextricable connection between estimators and influence functions in that the asymptotic behavior of an estimator is fully determined by its influence function, so that it suffices to focus on the influence function when discussing an estimator’s properties. Many of the estimators discussed by KS are regular and asymptotically linear; in the sequel, we refer to regular and asymptotically linear estimators as simply “estimators.”

We capitalize on this connection by considering the problem of estimating $\mu$ in the setting in KS in terms of statistical models that may be assumed for the observed data, from which influence functions corresponding to estimators valid under the assumed models may be derived. In the situation studied by KS, the “full” data that would ideally be observed are $(t, x, y)$; however, as $y$ is unobserved for some subjects, the observed data available for analysis are $z = (t, x, ty)$. As noted by KS, the MAR assumption states that $y$ and $t$ are conditionally independent given $x$; for example, $P(t = 1 | y, x) = P(t = 1 | x)$. Under this assumption, all joint densities for the observed data have the form

$$p(z) = p(y|x)I(t=1)p(t|x)p(x),$$

where $p(y|x)$ is the density of $y$ given $x$, $p(t|x)$ is the density of $t$ given $x$, and $p(x)$ is the marginal density of $x$. Let $p_0(z)$ be the density in the class of densities of form (2) generating the observed data (the true joint density).

One may posit different statistical models by making different assumptions on the components of (2). We focus on three such models:

I. Make no assumptions on the forms of $p(x)$ or $p(t|x)$, leaving these entirely unspecified. Make a specific assumption on $p(y|x)$, namely, that $E(y|x) = m(x, \beta)$ for some given function $m(x, \beta)$ depending on parameters $\beta$ (p × 1). Denote the class of densities satisfying these assumptions as $\mathcal{M}_I$.

II. Make no assumptions on the forms of $p(x)$ or $p(y|x)$. Make a specific assumption on $p(t|x)$ that $P(t = 1|x) = E(t|x) = \pi(x, \alpha)$ for some given function $\pi(x, \alpha)$ depending on parameters $\alpha$ (s × 1). Here, we also require the assumption that $P(t = 1|x) \geq \varepsilon > 0$ for all $x$ and some $\varepsilon$. Denote the class of densities satisfying these assumptions as $\mathcal{M}_{II}$.

III. Make no assumptions on the form of $p(x)$, but make specific assumptions on $p(y|x)$ and $p(t|x)$, namely, that $E(y|x) = m(x, \beta)$ and $P(t = 1|x) = E(t|x) = \pi(x, \alpha) \geq \varepsilon > 0$ for all $x$ and some $\varepsilon$ for given functions $m(x, \beta)$ and $\pi(x, \alpha)$ depending on parameters $\beta$ and $\alpha$. The class of densities satisfying these assumptions is $\mathcal{M}_I \cap \mathcal{M}_{II}$.

All of I–III are semiparametric statistical models in that some aspects of $p(z)$ are left unspecified. Denote by $m_0(x)$ the true function $E(y|x)$ and by $\pi_0(x)$ the true function $P(t = 1|x) = E(t|x)$ corresponding to the true density $p_0(z)$.

Semiparametric theory yields the form of all influence functions corresponding to estimators for $\mu$ under each of the statistical models I–III. As discussed in Tsiatis (2006, page 52), loosely speaking, a consistent and asymptotically normal estimator for $\mu$ in a statistical model has the property that, for all $p(z)$ in the class of densities defined by the model, $n^{1/2}(\hat{\mu} - \mu) \overset{D{(p)}}{\longrightarrow} N\{0, \sigma^2(p)\}$, where $D{(p)}$ means convergence in distribution under the density $p(z)$, and $\sigma^2(p)$ is the asymptotic variance of $\hat{\mu}$ under $p(z)$.

If model I is correct, then $m_0(x) = m(x, \beta)$ for some $\beta$, and it may be shown (e.g., Tsiatis, 2006, Section 4.5) that all estimators for $\mu$ have influence functions of the form

$$m_0(x) - \mu + ta(x)\{y - m_0(x)\}$$

for arbitrary functions $a(x)$ of $x$. If model II is correct, then $\pi_0(x) = \pi(x, \alpha)$ for some $\alpha$, and all estimators for $\mu$ have influence functions of the form

$$\frac{ty}{\pi_0(x)} + \frac{t - \pi_0(x)}{\pi_0(x)}h(x) - \mu$$

for arbitrary $h(x)$, which is well known from Robins, Rotnitzky and Zhao (1994). If model III is correct, then $m_0(x) = m(x, \beta)$ and $\pi_0(x) = \pi(x, \alpha)$ for some $\beta$ and $\alpha$, and influence functions for estimators $\hat{\mu}$ have the form

$$m_0(x) - \mu + ta(x)\{y - m_0(x)\}$$

$$+ \frac{t - \pi_0(x)}{\pi_0(x)}h(x)$$

for arbitrary $a(x)$ and $h(x)$. Depending on forms of $m(x, \beta)$ as a function of $\beta$ and $\pi(x, \alpha)$ as a function of $\alpha$, there will be restrictions on the forms of $a(x)$ and $h(x)$; see below.

We now consider estimators discussed by KS from the perspective of influence functions. The regression estimator $\hat{\mu}_{OLS}$ in (7) of KS comes about naturally if one assumes model I is correct. In terms
of influence functions, $\hat{\mu}_{OLS}$ may be motivated by considering the influence function (3) with $a(x) = 0$, as this leads to the estimator $n^{-1} \sum_{i=1}^{n} m(x_i, \beta)$. In fact, although KS do not discuss it, the “imputation estimator” $\hat{\mu}_{IMP} = n^{-1} \sum_{i=1}^{n} \{ t_i y_i + (1 - t_i) m(x_i, \beta) \}$ may be motivated by taking $a(x) = 1$ in (3). Of course, in practice, $\beta$ must be estimated. In general, (3) implies that all estimators for $\mu$ that are consistent and asymptotically normal if model I is correct must be asymptotically equivalent to an estimator of the form

$$n^{-1} \sum_{i=1}^{n} \{ m(x_i, \beta) + t_i \tilde{a}(x_i) \{ y_i - m(x_i, \beta) \} \},$$

where $\beta$ is estimated by solving an estimating equation $\sum_{i=1}^{n} t_i A(x_i, \beta) \{ y_i - m(x_i, \beta) \} = 0$ for $A(x, \beta)$ ($p \times 1$). Because $\beta$ is estimated, the influence function of the estimator (6) with a particular $\tilde{a}(x)$ will not be exactly equal to (3) with $a(x) = \tilde{a}(x)$; instead, it may be shown that the influence function of (6) is of form (3) with $a(x)$ in (3) equal to

$$\tilde{a}(x) - E[\{ \pi_0(x) \tilde{a}(x) - 1 \} m_T^T(x, \beta_0)]$$

$$\cdot [E\{ \pi_0(x) A(x, \beta_0) m_T^T(x, \beta_0) \}]^{-1}$$

$$\cdot A(x, \beta_0),$$

where $m_{\beta}(x, \beta)$ is the vector of partial derivatives of elements of $m(x, \beta)$ with respect to $\beta$, and $\beta_0$ is such that $m_0(x) = m(x, \beta_0)$.

The IPW estimator $\hat{\mu}_{IPW-POP}$ in (3) of KS and its variants arise if one assumes model II. In particular, $\hat{\mu}_{IPW-POP}$ can be motivated via the influence function (4) with $h(x) = -\mu$. The estimator $\hat{\mu}_{IPW-NR}$ in (4) of KS follows from (4) with $h(x) = -E[y \{ 1 - \pi(x) \}] / E[\{ 1 - \pi(x) \}]$. In fact, if one restricts $h(x)$ in (4) to be a constant, then, using the fact that the expectation of the square of (4) is the asymptotic variance of the estimator, one may find the “best” such constant minimizing the variance as $h(x) = -E[y \{ 1 - \pi(x) \}] / \pi(x) / E[\{ 1 - \pi(x) \}] / \pi(x)$. An estimator based on this idea was given in (10) of Lunceford and Davidian (2004, page 2943). In general, as for model I, (4) implies that all estimators for $\mu$ that are consistent and asymptotically normal if model II is correct must be asymptotically equivalent to an estimator of the form

$$n^{-1} \sum_{i=1}^{n} \{ t_i y_i / \pi(x_i, \hat{\alpha}) + t_i - \pi(x_i, \hat{\alpha}) \hat{\pi}(x_i) \},$$

where $\hat{\alpha}$ is estimated by solving an equation of the form $\sum_{i=1}^{n} \{ t_i - \pi(x_i, \alpha) \} B(x_i, \alpha) = 0$ for some $(s \times 1)$ $B(x_i, \alpha)$, almost always maximum likelihood for binary regression. As above, because $\alpha$ is estimated, the influence function of (8) is equal to (4) with $h(x)$ equal to

$$h(x) - E[\pi_0^T(x, \alpha_0) \{ m_0(x) + h(x) \} / \pi_0(x)]$$

$$\cdot [E\{ B(x, \alpha_0) \pi_0^T(x, \alpha_0) \}]^{-1}$$

$$\cdot B(x, \alpha_0) \pi_0(x),$$

where $\pi_0(x, \alpha)$ is the vector of partial derivatives of elements of $\pi(x, \alpha)$ with respect to $\alpha$, and $\alpha_0$ satisfies $\pi_0(x) = \pi(x, \alpha_0)$.

Doubly robust (DR) estimators are estimators that are consistent and asymptotically normal for models in $M_I \cup M_{II}$, that is, under the assumptions of model I or model II. When the true density $p_0(z) \in M_I \cap M_{II}$, then the influence function of any such DR estimator must be equal to (3) with $a(x) = 1 / \pi_0(x)$ or, equivalently, equal to (4) with $h(x) = -m_0(x)$. Accordingly, when $p_0(z) \in M_I \cap M_{II}$, that is, both models have been specified correctly, all such DR estimators will have the same asymptotic variance. This also implies that, if both models are correctly specified, the asymptotic properties of the estimator do not depend on the methods used to estimate $\beta$ and $\alpha$.

KS discuss strategies for constructing DR estimators, and they present several specific examples: $\hat{\mu}_{BC-OLS}$ in their equation (8); the estimators below (8) using POP or NR weights, which we denote as $\hat{\mu}_{BC-POP}$ and $\hat{\mu}_{BC-NR}$, respectively; the estimator $\hat{\mu}_{WLS}$ in their equation (10); $\hat{\mu}_{\pi-cov}$ in their equation (12); and a version of $\hat{\mu}_{\pi-cov}$ equal to the estimator proposed by Scharstein, Rotnitzky and Robins (1999) and Bang and Robins (2005), which we denote as $\hat{\mu}_{SRR}$. The results for these estimators under the “Correct-Correct” scenarios ($M_I \cap M_{II}$) in Tables 5–8 of KS are consistent with the asymptotic properties above. We note that $\hat{\mu}_{\pi-cov}$ is not DR under $M_I \cup M_{II}$ because of the additional assumption that the mean of $y$ given $\pi$ must be equal to a linear combination of basis functions in $\pi$. Making this additional assumption may not be unreasonable in practice; however, strictly speaking, it takes $\hat{\mu}_{\pi-cov}$ outside the class of DR estimators discussed here, and hence we do not consider it in the remainder of this section. However, $\hat{\mu}_{SRR}$ is still in this class.

KS suggest that a characteristic distinguishing the performance of DR estimators is whether or not the estimator is within or outside the augmented inverse-probability weighted (AIPW) class. We find
this distinction artificial, as all of the above estimators $\hat{\mu}_{BC-OLS}, \hat{\mu}_{BC-POP}, \hat{\mu}_{BC-NR}, \hat{\mu}_{WLS}$ and $\hat{\mu}_{SRR}$ can be expressed in an AIPW form. Namely, all of these estimators are algebraically exactly of the form (8) with $h(x_i)$ replaced by a term $-\hat{\gamma} - m(x_i, \beta)$, where $\hat{\gamma}_{BC-OLS} = \hat{\gamma}_{WLS} = \hat{\gamma}_{SRR} = 0$,

$$\hat{\gamma}_{BC-POP} = \frac{n^{-1} \sum_{i=1}^{n} (t_i/\hat{\pi}_i)(y_i - \hat{m}_i)}{n^{-1} \sum_{i=1}^{n} t_i/\hat{\pi}_i}$$

(10) $$\hat{\gamma}_{BC-NR} = \frac{n^{-1} \sum_{i=1}^{n} (t_i(1 - \hat{\pi}_i)/\hat{\pi}_i)(y_i - \hat{m}_i)}{n^{-1} \sum_{i=1}^{n} t_i(1 - \hat{\pi}_i)/\hat{\pi}_i},$$

where we write $\hat{\pi}_i = \pi(x_i, \hat{\alpha})$ and $\hat{m}_i = m(x_i, \hat{\beta})$ for brevity. For $\hat{\mu}_{WLS}$ and $\hat{\mu}_{SRR}$, this identity follows from the fact that $\sum_{i=1}^{n} \hat{t}_i(y_i - \hat{m}_i) = 0$, which for $\hat{\mu}_{WLS}$ holds because KS restrict to $m(x, \beta) = x^T \beta$, with $x$ including a constant term. Thus, we contend that issues of performance under $\mathcal{M}_I \cup \mathcal{M}_H$ are not linked to whether or not a DR estimator is AIPW, but, rather, are a consequence of forms of the influence functions of estimators under $\mathcal{M}_I$ or $\mathcal{M}_H$. In particular, under model II, it follows that the above estimators have influence functions of the form (4) with $h(x)$ equal to (9) with $h(x) = -\{\gamma^* + m(x, \beta^*)\}$, where $\gamma^*$ and $\beta^*$ are the limits in probability of $\hat{\gamma}$ and $\hat{\beta}$, respectively. Thus, features determining performance of these estimators when model II is correct are how close $\gamma^* + m(x, \beta^*)$ is to $m_0(x)$ and how $\alpha$ is estimated, where maximum likelihood is the optimal choice. In fact, this perspective reveals that, for fixed $m(x, \beta)$, using ideas similar to those in Tan (2006), the optimal choice of $\hat{\gamma}$ is as in $\hat{\gamma}_{BC-NR}$ with $t_i(1 - \hat{\pi}_i)/\hat{\pi}_i$ replaced by $t_i(1 - \hat{\pi}_i)/\hat{\pi}_i^2$.

Similarly, under model I, the influence functions of these estimators are of the form (3) with $a(x)$ equal to (7) with $\tilde{a}(x) = \psi_1/\pi(x, \alpha^*) + \psi_2$, where $\alpha^*$ is the limit in probability of $\alpha$ and $\psi_1 = 1$ and $\psi_2 = 0$ for $\hat{\mu}_{BC-OLS}, \hat{\mu}_{WLS}$ and $\hat{\mu}_{SRR}$; $\psi_1 = 1/E\{\pi_0(x)/\pi(x, \alpha^*)\}$ and $\psi_2 = 0$ for $\hat{\mu}_{BC-POP}$; and $\psi_1$ and $\psi_2$ for $\hat{\mu}_{BC-NR}$ are more complicated expectations involving $\pi_0(x)$ and $\pi(x, \alpha^*)$. Thus, under model I, features determining performance of these estimators are the form of $\tilde{a}(x)$ and how $\beta$ is estimated through the choice of $A(x, \beta)$.

We may interpret some of the results in Tables 5, 6 and 8 of KS in light of these observations. Under the “$\pi$-model Correct–$y$-model Incorrect” scenario ($\mathcal{M}_H \cap \mathcal{M}_I$), $\hat{\mu}_{BC-OLS}, \hat{\mu}_{WLS}$ and $\hat{\mu}_{SRR}$ show some nontrivial differences in performance, which, from above, are likely attributable to differences in $m(x, \beta^*)$. Under the “$\pi$-model Incorrect–$y$-model Correct” ($\mathcal{M}_I \cap \mathcal{M}_I^c$), all three estimators share the same $\tilde{a}(x)$ but use different methods to estimate $\beta$, so that any differences are dictated entirely by the choice of $A(x, \beta)$. The poor performance of $\hat{\mu}_{SRR}$ can be understood from this perspective: “$\beta$” for this estimator is actually $\beta$ in the model $m(x, \beta)$ used by the other two estimators concatenated by an additional element, the coefficient of $\hat{\pi}_i^{-1}$. The $A(x, \beta)$ for $\hat{\mu}_{SRR}$ thus involves a design matrix that is unstable for small $\hat{\pi}_i$, consistent with the comment of KS at the end of their Section 3.

In summary, we believe that studying the performance of estimators via their influence functions can provide useful insights. Our preceding remarks refer to large-sample performance, which depends directly on the influence function. Estimators with the same influence function can exhibit different finite-sample properties. It may be possible via higher-order expansions to gain an understanding of some of this behavior; to the best of our knowledge, this is an open question.

**BOTH MODELS INCORRECT**

The developments in the previous section are relevant in $\mathcal{M}_I \cup \mathcal{M}_H$. Key themes of KS are performance of DR and other estimators outside this class; that is, when both the models $\pi(x, \alpha)$ and $m(x, \beta)$ are incorrectly specified, and choice of estimator under these circumstances.

One way to study performance in this situation is through simulation. KS have devised a very interesting and instructive specific simulation scenario that highlights some important features of various estimators. In particular, the KS scenario emphasizes the difficulties encountered with some of the DR estimators when $\pi(x_i, \hat{\alpha})$ is small for some $x_i$. Indeed, in our experience, poor performance of DR and IPW estimators in practice can result from few small $\pi(x_i, \hat{\alpha})$. When there are small $\pi(x_i, \hat{\alpha})$, as noted KS, responses are not observed for some portion of the $x$ space. Consequently, estimators like $\hat{\mu}_{OLS}$ rely on extrapolation into that part of the $x$ space. KS have constructed a scenario where failure to observe $y$ in a portion of the $x$ space can wreak havoc on some estimators that make use of the $\pi(x_i, \hat{\alpha})$ but has minimal impact on the quality of extrapolations for these $x$ based on $m(x, \hat{\beta})$. 
One could equally well build a scenario where the
\( x \) for which \( y \) is unobserved are highly influential
for the regression \( m(x, \beta) \) and hence could result in
deleterious performance of \( \hat{\mu}_{\text{OLS}} \). We thus reiterate
the remark of KS that, although simulations can be
illuminating, they cannot yield broadly applicable
conclusions.

Given this, we offer some thoughts on other stra-
tegies for deriving estimators that may have some ro-
bustness properties under the foregoing conditions,
that is, offer good performance outside \( M_I \cup M_{II} \).
One approach may be to search outside the class
of DR estimators valid under \( M_I \cup M_{II} \). For
example, as suggested by the simulations of KS, esti-
mators in the spirit of \( \hat{\mu}_{\text{OLS}} \), which impose addi-
tional assumptions rendering them DR in the strict
sense only in a subset of \( M_I \cup M_{II} \), may compensate
for this restriction by yielding more robust perfor-
mance outside \( M_I \cup M_{II} \); further study along these
lines would be interesting. An alternative tactic for
searching outside \( M_I \cup M_{II} \) may be to consider the
form of influence functions (5) for estimators valid
under \( M_I \cap M_{II} \). For instance, a “hybrid” estimator
of the form
\[
\frac{1}{n} \sum_{i=1}^{n} \left\{ m(x_i, \hat{\beta}) I\{\pi(x_i, \hat{\alpha}) < \delta\} + \left\{ \frac{t_i y_i}{\pi(x_i, \hat{\alpha})} + \frac{t_i - \pi(x_i, \hat{\alpha})}{\pi(x_i, \hat{\alpha})} \tilde{h}(x_i) \right\} \cdot I\{\pi(x_i, \hat{\alpha}) \geq \delta\} \right\},
\]
for \( \delta \) small, may take advantage of the desirable
properties of both \( \hat{\mu}_{\text{OLS}} \) and DR estimators.

A second possible strategy for identifying robust
estimators arises from the following observation. Con-
sider the estimator
\[
(11) \quad \frac{1}{n} \sum_{i=1}^{n} \left\{ \frac{t_i y_i}{\pi(x_i)} - \frac{t_i - \pi(x_i)}{\pi(x_i)} m(x_i, \hat{\beta}) \right\}.
\]
If \( \pi(x_i) = \pi(x_i, \hat{\alpha}) \), then (11) yields one form of a DR
estimator. If \( \pi(x_i) \equiv 1 \), then (11) results in the impu-
tation estimator. If \( \pi(x_i) = \infty \), (11) reduces to \( \hat{\mu}_{\text{OLS}} \).
This suggests that it may be possible to develop es-
timators based on alternative choices of \( \pi(x_i) \) that
may have good robustness properties. For exam-
ple, a method for obtaining estimators \( \pi(x_i, \hat{\alpha}) \) that
shrinks these toward a common value may prove
fruitful. The suggestion of KS to move away from
logistic regression models for \( \pi(x_i, \alpha) \) is in a similar
spirit.

Finally, we note that yet another approach to
developing estimators would be to start with the
premise that one make no parametric assumption on
the forms of \( E(y|x) \) and \( E(t|x) \) beyond some mild
smoothness conditions. Here, it is likely that first-
order asymptotic theory, as in the previous section,
may no longer be applicable. It may be necessary to
use higher-order asymptotic theory to make progress
in this direction; see, for example, Robins and van
der Vaart (2006).

**CONCLUDING REMARKS**

We again compliment the authors for their thought-
ful and insightful article, and we appreciate the op-
portunity to offer our perspectives on this important
problem. We look forward to new methodological
developments that may overcome some of the chal-
 lenges brought into focus by KS in their article.
