Conventional tomographic reconstruction algorithms assume that one has obtained pure projection images, involving no within-specimen diffraction effects nor multiple scattering. Advances in x-ray nanotomography are leading towards the violation of these assumptions, by combining the high penetration power of x-rays which enables thick specimens to be imaged, with improved spatial resolution which decreases the depth of focus of the imaging system. We describe a reconstruction method where multiple scattering and diffraction effects in thick samples are modeled by multislice propagation, and the 3D object function is retrieved through iterative optimization. We show that the same proposed method works for both full-field microscopy, and for coherent scanning techniques like ptychography. Our implementation utilizes the optimization toolbox and the automatic differentiation capability of the open-source deep learning package TensorFlow, which demonstrates a much straightforward way to solve optimization problems in computational imaging, and endows our program great flexibility and portability.
1 Introduction

Depending on the photon energy used, X rays are able to penetrate into samples with a thickness ranging from micrometers to centimeters. At the same time, x-ray microscopes are beginning to be able to deliver images with sub-10 nanometer spatial resolution (1–4). However, combining these characteristics is complicated by the fact that any imaging method with spatial resolution $\delta_r$ has a depth of focus DOF limit (5, 6) of

$$DOF = \frac{2}{0.61^2} \frac{\delta_r^2}{\lambda} \approx 5.4\delta_r \frac{\delta_r}{\lambda}.$$  

This is straightforward to understand in lens-based imaging systems. However, even when lensless imaging methods involving wavefront recovery are employed, the depth of focus limit of Eq. [1] gives the axial distance over which features can be considered to all lie within a common transverse plane before subsequent wavefield propagation effects are taken into account. That is, Eq. [1] represents the limit of validity of the pure projection approximation, within which a depth-extended object can be treated as producing a simple pure projection image when viewed from one illumination direction. For objects thicker than the depth of focus (DOF) limit, one must instead account for wave propagation effects within the specimen. This will be especially important for fully exploiting the dramatic increases in coherent x-ray flux that the next generation of synchrotron light sources will provide (7).

One approach to simulate wave propagation in a complex object is the finite-difference method (8). However, due to the need to solve a series of partial differential equations, the efficiency of this method relies on the availability of distributed differential equation solvers, which are usually sophisticated to implement. On the other hand, Multislice wave propagation (9) is a historic, simple but still powerful method allowing one to account for wave diffraction in an inhomogeneous medium. The multislice simulation method subdivides the propagation problem into a series of elemental modulation and propagation operations, and accounts for the change of the probe wave throughout the object instead of assuming a constant probe. Hence, it can provide accurate numerical results propagation through a complicated object, and remains valid over a much larger object thickness compared to diffraction tomography models assuming single scattering (10, 11). The incorporation of multislice propagation could stand as a novel and reliable strategy for the reconstruction of beyond-DOF objects.

We describe here an approach for imaging objects that extend beyond the DOF limit, and within which multiple scattering might take place. We formulated the 3D object reconstruction problem as a minimization problem which incorporates a data fidelity term (L2-norm of simulated and measured data) and a regularization term (L1-norm of the object and its gradient), where the multislice wave propagation is used to accurately model the exit wave leaving the object. Because the new model better captures the wave-object interactions for any object size, the same model can be applied to reconstruct either near-field imaging with propagation phase contrast or ptychography (Fig. 1) without the need for any modification. We used the Adaptive Moment Estimation (Adam) optimizer that is implemented in TensorFlow, which is Google
Brains open-source software library. The automatic differentiation capability in TensorFlow allows us to implement the optimization problems with minor tweaks. With this approach, we are able to use one computer code for two different types of microscopes to reconstruct 3D objects beyond the DOF limit.

It is worthwhile noticing that while there exist several multislice-based reconstruction method which have proven success in several imaging scenarios (12–14), our method differs from them in a few aspects. Our implementation provides both a ptychography mode and a full-field mode, while the above methods are concerned with ptychography alone. In addition, instead of requiring planes that are axially separated by 1 DOF of more, in our method the spacing between slices can be equal to the lateral pixel width which allows for an isotropic voxel size. Finally, the method for updating the object function is different. In (12), slices are updated sequentially using an update function that resembles the modulus replacement operation in ePIE, a reconstruction engine for 2D ptychography. In (13), the first method described is similarly based on modulus replacement, while the second method involves the minimization of a loss function that has a similar form of ours. However, in our approach to full-field microscopy, the loss equation is constructed also with a sparsity constraint, and non-negative and finite support constraints are applied to the object function throughout the minimization process. This also distinguishes our

Figure 1: Schematic representation of the two different microscope types used in our demonstration. In the full-field mode (a), phase contrast is incorporated by allowing the wavefield leaving the object to undergo Fresnel propagation over a distance \( d \) before that plane is imaged by a lens (with \( 1/f = 1/s + 1/s' \)) onto a detector. In ptychography, a small coherent beam spot (probe) is scanned through the object and the far-field diffraction intensities are recorded for each probe position. The schematic here shows Fresnel zone plates as lenses for quasimonochromatic x-ray beams.
work with (14). Lastly, our employment of automatic differentiation through the widely used software package TensorFlow renders the implementation highly accessible and flexible. On the top of the first reports of using AD in phase retrieval problems (15–17), our work reinforces the vast potential of AD for a large variety of computational imaging tasks.

2 Imaging beyond the depth-of-focus limit

Present-day x-ray nanotomography is usually done within the depth of focus limit of Eq. [1] (18–26), such as with 1 μm resolution at 25 keV (giving λ = 0.050 nm and DOF=110 mm), or 20 nm resolution at 6.2 keV (giving λ = 0.20 nm and DOF=11 μm). In these cases, one can obtain an image that represents a pure projection through the specimen at each rotation angle by using standard phase retrieval methods based on the inversion of the Transport-of-Intensity equation (27); one can then use standard tomographic reconstruction algorithms such as filtered backprojection. For objects that are thicker and/or interact more strongly, the complete solution of the wave function of electromagnetic wave within an inhomogeneous scattering potential field results in a recursive equation. With the first iteration, one arrives at the first Born approximation, which physically accounts for single scattering within the sample. On this basis, one can approximate the imaging of thicker specimens by acknowledging the fact that the far-field diffraction pattern of an object provides information on the surface of the Ewald sphere corresponding to the beam energy and viewing direction (28). This re-mapping of Fourier space information from a plane (pure projection), to the surface of the Ewald sphere, is used in filtered backpropagation algorithms in diffraction tomography (11). It has been widely applied in tomographic diffractive microscopy with visible light (29) and has been demonstrated in x-ray coherent diffraction imaging (30).

One approach that has been developed for imaging beyond the DOF limit is multislice ptychography (12). In standard ptychography (31, 32), one scans a finite sized coherent beam with overlap across a planar sample and separates or factorizes the probe from the optical modulation at each scan position. Multislice ptychography is based on utilization of the multislice method (9) (also known as the beam propagation method (33)) to propagate a beam through a thick object, where the refractive effect of the first thin slab of the object is applied to the incident wavefield, the wavefield is free-space-propagated to the next slab position, and the process is repeated until one obtains the exit wave leaving the object (which can then be free-space propagated to a far-field detector, for example). If the object is in fact comprised of a series of discrete planes separated axially by 1 DOF or more, one can factorize the probe from both transverse positions, and axial planes as well. One can also account for violation of the Born approximation, in that the object-modulated exit wave from the upstream plane is propagated to the next axial plane in a recursive manner through all planes. This approach has been used with success in ptychography using visible light (34), X rays (13, 35, 36), and electrons (37). It has also been used for tomographic imaging of more continuous specimens by assuming that the object could be represented by discrete axial planes separated by the DOF (38). However,
this assumption is only approximately true, since one can often see image contrast variations with defocus settings of less than 1 DOF (or the separation of the slices), especially in phase contrast which is the dominant contrast mechanism in transmission x-ray microscopy (39). In that case, variation of features along the beam axis between each two adjacent slices will not be captured. In addition, multislice ptychographic tomography as implemented above requires phase-unwrapping of individual (40) or the summation (38) of phase contrast images obtained prior to their use in tomographic reconstruction, and this phase unwrapping process can sometimes present difficulties or inaccuracies.

Therefore it can be advantageous to use reconstruction methods that use a forward model of multislice propagation in a continuous object and retrieve directly the refractive indices of the objects instead of the phase of the exiting waves, so that multiple scattering effects are included and no phase unwrapping is required. Calculations for x-ray imaging of biological specimens show that one must begin to account for multiple scattering effects at a specimen thickness of a few $\mu$m in soft x-ray imaging at 0.5 keV, and a few tens of $\mu$m in hard x-ray imaging at 15 keV (41). The need for the inclusion of multiple scattering effects is well known in optical diffraction microscopy (29), and we have shown that this approach can be used for x-ray microscopy as well (14). What we describe below is a new approach that is different than the above: it uses the method of automatic differentiation to carry out the reconstruction, which offers greater flexibility on imaging method and for incorporating various constraints on the object as numerical optimization regularizers.

### 3 Formulation of the image reconstruction problem

Our approach is to treat image reconstruction of objects beyond the DOF limit as a numerical optimization problem. That is, we wish to find the optimal parameter set $n_0$ of the forward model $f$ by minimizing an objective function $L$, leading to a solution of

$$n_0 = \arg\min_n L[f(n), y], \text{ subject to } n \in \Phi$$

(2)

where the observable $y$ is the set of experimental measurements (near-field images or far-field diffraction patterns), and $\Phi$ is the manifold of contraints that $n$ is subject to. The parameter set $n$ will be defined in Eq.5 below to be proportional to the x-ray refractive index (RI) distribution within the object’s voxel grid positions $r$. This refractive index is written as

$$n(r) = 1 - \delta(r) - i\beta(r).$$

(3)

where the values of $\delta$ and $\beta$ for various materials are readily obtained from tabulations (42). Except at photon energies right near x-ray absorption edges where anomalous dispersion effects can appear, $\delta$ and $\beta$ have small positive values (typically $\delta \approx 10^{-4}$ and $\beta \approx 10^{-5}$ to $10^{-6}$) so a positivity constraint can be applied to their solution. One can also apply a sparsity constraint for objects that are relatively discrete in space (43), and in most cases tomography experiments
are designed so that the object fits within the field of view so one can also apply a finite support constraint on the solution of \( n(r) \).

Because the size of the optimization problem is high, efficient mechanisms must be used to find gradients for each iteration of the first-order solver used in optimizing Eq. [2]. If one is always considering one type of imaging experiment, one can calculate derivatives of the cost function and indeed this approach has been used with success for simulations of x-ray ptychographic reconstruction of objects beyond the DOF limit (14). However, if one wishes to be able to treat multiple imaging methods (so as to compare or benchmark their properties and performances, for example) and include a variety of regularizers, other approaches that place the burden of finding minimization strategies on a computer rather than a scientist can have advantages. One approach is to represent multislice propagation with a computational architecture resembling a convolutional neural network and use mathematical formulations that are common in machine learning to solve for the object that matches the observations, as has been demonstrated for diffraction microscopy using visible light (44). Automatic differentiation (AD) (45) provides another approach which was suggested for use in phase retrieval problems (46), and then successfully implemented for x-ray ptychography (15, 16). More recently, the adaptability of automatic differentiation to a variety of coherent diffraction imaging methods has been demonstrated (17), and a variety of software toolkits are now available to utilize this method (spurred on by their use for constructing the trainer module in supervised machine learning programs). We use this AD approach to reconstruct beyond-depth-of-field imaging in two successful imaging methods, and thus gain insight on their relative advantages and complications.

As noted above, in x-ray ptychography one scans a finite sized coherent beam through a series \( k \) of overlapping probe positions across the specimen, and collects the far-field diffraction pattern from each. Because the extent of the far-field diffraction pattern is determined by the scattering properties of the object rather than the spatial resolution of the probe, one can obtain reconstructed x-ray images with a spatial resolution far finer than the size of the probe (47, 48). In contrast, point projection x-ray microscopy (49), where an object is placed downstream of a point source of radiation, provides geometric magnification of the object with a penumbral blur limit given by the source size, plus diffraction blurring that can be compensated for by near-field wave backpropagation (23, 50). Because near-field diffraction blurring is localized to a region given by the finest reconstructed feature size times the propagation distance divided by the wavelength, one can make use of illumination with a coherence width equal to this region rather than the entire illumination field as required for ptychography, and thus make more complete use of partially coherent sources. Since the advancing of x-ray imaging instruments has granted considerable potential to both techniques in their imaging applications for thick samples with high resolution, it is of interest to understand the beyond-DOF imaging properties of both of these approaches.
4 Algorithm implementation

4.1 The forward model

We use the multislice method (9) to calculate the wave exiting the object, since it incorporates multiple scattering while also accounting for effects such as waveguide phenomena (51) (with the sole limitation of ignoring backscattering which is negligible for all cases except Bragg diffraction from perfect crystals or synthetic multilayers). As illustrated in Fig. 2 in multislice propagation, the object is divided into J slices along the beam axis. The wavefield $\psi_{j,k}(x, y, z_j)$ from probe position $k$ (for full-field, $k = 0$ for the first and only probe position) entering the $j^{th}$ slice with thickness $\Delta z$ is modulated by the slice to yield a wavefield $\psi'_{j,k}(x, y, z_j)$ of

$$
\psi'_{j,k}(x, y, z_j) = \psi_{j,k}(x, y, z_i) \exp\left[-\frac{2\pi \Delta z}{\lambda} i[1 - \delta(x, y, z_j) - i\beta(x, y, z_j)]\right]
$$

(4)

with

$$
n_j = \frac{2\pi(\Delta z)}{\lambda}[i\delta(x, y, z_j) - \beta(x, y, z_j)].
$$

(5)

We will denote the RI distribution of the entire object by vector $n$ in the following text.

The wavefront is then free-space propagated to the next slice according to the Fresnel diffraction integral given by

$$
\psi_{j+1,k}(x, y, z_{j+1}) = \psi'_{j,k}(x, y, z_j) * h_{\Delta z}(x, y)
$$

(6)
where * denotes the convolution operator, and \( h_{\Delta z}(x, y) \) is the Fresnel propagator given by

\[
h_{\Delta z}(x, y) = \exp \left[ -i \frac{\pi}{\lambda \Delta z} (x^2 + y^2) \right].
\]  
(7)

This process is repeated for all \( J \) slices until one obtains the exit wave leaving the object. Here the slice thickness \( \Delta z \) can be equal to the transverse pixel size \( \Delta x \), or for computational speed one can combine multiple slices from the 3D volume together provided one satisfies the condition of

\[
\Delta z \leq \frac{2 \tilde{n} Q (\Delta x)^2}{\pi \lambda}
\]  
(8)

where \( \tilde{n} \) is the mean RI, \( \Delta x \) is the pixel size, and \( Q \) is the Klein-Cook parameter for which values of \( Q \lesssim 1 \) represent the case of plane grating rather than volume grating diffraction (52).

In fact, multislice propagation is only one of several steps that must be combined in the forward model of tomography beyond the DOF limit. Tomography acquisition requires the illumination of the object from multiple rotation angles \( \theta \). Our approach to account for the rotation is to rotate the object onto a constant wave propagation direction, rather than to rotate the illumination; this is done with a rotation operator \( R_\theta \). After carrying out the sequence of \( J \) multislice propagation steps through the rotated object, we then need to apply the operator \( P_d \) to take the exit wave \( \psi_{J,k} \) from the object to the plane of the detector, either using free space propagation as described by \( \psi_{J,k} \ast h(x, y, d) \) for near-field propagation of distance \( d \), or a simple Fourier transform for far-field propagation (in the Fraunhofer approximation). This leads us to a combined forward operation of

\[
f(n, \theta, k, \Delta z, d) = P_d M_{n,\theta,\Delta z} \psi_{0,k}.
\]  
(9)

In Eq. \( \text{9} \) \( M_{n,\theta,\Delta z} \) is the multislice propagation operator which is a function of the 3D object and the incident probe. \( M_{n,\theta,\Delta z} \) describes the exit wave that leaves the depth-extended specimen. It can be compactly written as

\[
M_{n,\theta,\Delta z} = \prod_j P_{\Delta z} A_{n,\theta,j}
\]  
(10)

with

\[
A_{n,\theta,j} = \exp[\text{diag}(S_j R_\theta n)]
\]  
(11)

where \( S_j \) is a matrix that samples the \( j \)-th slice of column vector \( R_\theta n \). If the total number of voxels of the object function is \( N_v \), and the number of pixels in the detector is \( N_p \), then \( n \) is a \( N_v \times 1 \) column vector, \( R_\theta \) is a \( N_v \times N_v \) square matrix, and \( S_j \) is in the shape of \( N_p \times N_v \), so that it yields an \( N_p \times 1 \) column vector, which is of the same size as the wavefront \( \psi_{0,k} \). Multiplying diagonal matrix \( A_{n,\theta,j} \) with the wavefront vector \( \psi_{0,k} \) is exactly the wavefront modulation given in Eq. \( \text{4} \).
4.2 Constrained loss function minimization

It has been pointed out for conventional 2D coherent diffraction imaging that since only magnitude information is available in the detected far-field diffraction pattern, a reconstructable object should be spatially isolated, with prior knowledge about the geometry of the object incorporated into the reconstruction through zeroing out pixels out of the object boundaries. This is known as a “finite support” constraint \((53)\). Ptychography does not require a finite support constraint applied in object space because the bounded probe itself is already a form of finite support constraint, and furthermore the overlap between adjacent probe positions supplies sufficient information to solve for all object unknowns.

In our work where a 3D object is retrieved, the same criteria are followed. As will be shown in the results section, the ptychography reconstruction of the object using our algorithm does not need prior knowledge about the spatial extent of the sample. However, a finite support constraint was found to be necessary for the full-field case. The initial finite support mask is determined following the procedures below. First, single-distance near-field phase retrieval \((54)\) is applied to all projection images to obtain a first guess of the weak phase contrast projection through the object. We then use the tomographic set of these projections to obtain a rough guess of the object support using the standard filtered backprojection tomographic reconstruction algorithm. The reconstructed volume is then Gaussian filtered to remove noise and local discontinuities. A Boolean mask is subsequently obtained by thresholding the filtered object, which yields a support mask denoted by set \(\Theta\). During the iterative reconstruction process, the finite support is contracted to exclude low-value pixels for every epoch, a technique known as “shrink-wrap” in conventional CDI processing \((55)\).

We then wish to compare the present guess of the detected amplitude of \(|f(n, \theta, k, \Delta z, d)|\) against the amplitude \(\sqrt{y_{\theta, k}}\) measured in the experiment, and minimize the difference between the two as expressed in a cost function of

\[
L = \frac{1}{N_\theta N_p N_k} \sum_{\theta, k} \left( \left| |f(n, \theta, k, \Delta z, d)| - \sqrt{y_{\theta, k}} \right|^2 + \alpha_\delta |n_\delta|_1 + \alpha_\beta |n_\beta|_1 + \gamma \text{TV}(n_\delta) \right) \quad (12)
\]

That is, the solution of the object function should be given by

\[
n_0 = \arg \min_n L \quad \text{subject to } n_w = 0 \text{ for } n_w \notin \Theta \text{ and } n_w \geq 0 \text{ for } n_w \in \Theta.
\]

Here, \(n_w\) is the \(w\)-th element in \(n\), \(y_{\theta, k}\) is the measured intensity at orientation angle \(\theta\), \(N_\theta\) is the number of projection angles, \(N_p\) is the number of pixels in each \(y_{\theta, k}\), \(N_k\) is the number of probe positions for each projection angle (equals 1 for full-field), and \(\alpha_\delta\) and \(\alpha_\beta\) are the scalar normalizing coefficients added to the L1-norm regularization terms for the \(\delta\)-part and \(\beta\)-part of \(n\) respectively. The separated regularization for the two parts of the object is necessary since \(\delta(r)\) and \(\beta(r)\) of the same material typically differ by a few orders of magnitudes. Together, these two L1-norm terms enhance the sparsity of the object function, which is useful when
the object is spatially discrete or contains a lot of empty space (such as a dispersion of cells, or a hollow structure). Finally, the anisotropic total variation $TV(n)$, weighted by coefficient $\gamma$, enhances the sparsity of the gradient of the object function, which suppresses noises and unwanted heterogeneities (56). This regularizer is expressed as

$$TV(n) = \sum_{l,m,n} \left[ |x_{l+1,m,n} - x_{l,m,n}| + |x_{l,m+1,n} - x_{l,m,n}| + |x_{l,m,n+1} - x_{l,m,n}| \right]$$ (14)

where $l$, $m$, and $n$ are indices along the three axes of $n$. The TV regularizer is only applied to $n_\delta$ because it usually carries higher contrast and better structural information than $n_\beta$ when hard X rays are used.

The successful retrieval of $n$ requires the simultaneous pixel-wise update of it, guided by $\nabla_n L$, which is the gradient of loss function $L$ in the parameter space of $n$. We use TensorFlow (57), a deep learning package first initiated by Google but now available as an open-source toolkit, for carrying out our AD reconstruction. It provides a user-friendly Python application programming interface (API), and the ability to write a reconstruction code of relative simplicity and with easy implementation on a variety of computing platforms. The AD algorithm uses the so-called “back-propagation” method to derive the partial derivatives in a semi-analytical fashion (45). Here, the loss function $L$ is first evaluated in the forward direction using Eq. 14, during which the intermediate variables produced by every algebraic operation are computed and stored. After that, the algorithm calculates the derivative of $L$ with regards to the intermediate variables immediately before $L$ using the values saved in memory. This is repeated back through the entire computation model, and the gradient of $L$ with regards to $n$, $\nabla_n L$, is then found based on the chain rule of differentiation. Compared to symbolic differentiation which attempts to acquire the closed-form expression of $\nabla_n L$ before doing any numerical calculation, AD is free from the problem of expression swell when the forward model is complicated. On the other hand, AD is also more accurate than the finite difference method, which approximates $\nabla_n L = \left( \partial f / \partial x_1, ..., \partial f / \partial x_n \right)$ with $\partial f / \partial x_i \approx [f(n + h e_i) - f(n)] / h$ for a small $h$ (58).

We use the well-established optimization algorithm ADAM (ADAptive Moment estimation) to update $n$ (59). A brief description of the algorithm is provided in the supplementary material.

### 4.3 Computational performance enhancements

Like conventional tomography, the dataset acquired for reconstruction would generally involve a large number of rotation angles $N_\theta$ (though in multislice reconstruction methods one can reduce $N_\theta$ from below the number one would have expected from the Crowther criterion (60)). The large value of $N_\theta$ can lead to the use of considerable computation power in the iterative update of $n$. To reduce this, we note that the first term in Eq. 14 is essentially an expectation value of error per pixel, and it can be adequately approximated by calculating the error over a subset of $N_\theta$. This technique, known as “minibatching” (or “ordered-subsets” in tomography literature (61)), can speed up the convergence of the algorithm by several times. For each
minibatch, the subset of $N_\theta$ to be processed is chosen randomly without replacement, so that the entire collection of $N_\theta$ will be fully gone through after a certain number of minibatches are completed. We hereafter refer to this process as an “epoch,” using terminology drawn from the machine learning community.

In an actual experiment, the presence of noise typically induces uncertainty in the “sub-loss function” obtained from each minibatch. In this case, a true global minimum is ill-defined, which causes $n$ to dangle at the late stage of the optimization and thus prevents a stable convergence. For this reason, users of TensorFlow have the option to aggregate the gradients calculated from several minibatches, and apply them to the optimizer after the completion of all of these minibatches. The larger sample amount for gradient calculation reduces the statistical fluctuation induced by noise and guarantees a more stable solution.

A multiscale technique is also used in this work to further improve reconstruction speed and accuracy. While the algorithm requires that $n$ has the same number of lateral pixels as the measured data, instead of directly reconstructing the object with the same pixel size as the acquired projections, both $n$ and $y_{\theta,k}$ are downsampled by a factor of $2^m$, where $m$ is an integer so that the lateral dimension of $n$ is not larger than 64 pixels. The voxel size of the object is thus accordingly enlarged by $2^m$ times. A first pass reconstruction of $n$ is therefore computed rapidly. The result is upsampled by a factor of 2, and then used as the initial guess for the next pass, where the scale of the object and projections are doubled. This process is repeated until the object is reconstructed with the acquired voxel size. By initializing $n$ with the result from a coarse pass for a higher-resolution pass, the optimization begins at a location closer to the global minimum in the parameter space of $L$, so that fewer iterations are required to converge. This may also reduce the chance for the optimizer to get trapped in a remote local minimum.

4.4 Parallelization

In view of the huge number of unknowns ($3.4 \times 10^7$ for a $256^3$ object because of the presence of both the $\delta$ and $\beta$ parts of the RI) to be solved in our algorithm, parallelized computation is necessary to guarantee a reasonable computational walltime (within a few hours for a $256^3$ object). We use a TensorFlow add-on called Horovod to implement distributed parallelization using the message passing interface (MPI) standard for inter-rank (or inter-process) communication, rather than the TCP/IP protocol used by native TensorFlow (MPI is faster on tightly bound high performance computer clusters). Each thread (or worker) initializes and keeps its own object function, and process a minibatch simultaneously with other threads. When a rank finishes its minibatch, it waits for other threads to finish theirs, after which the gradients obtained by all threads are averaged. The averaged gradient is then used to update the object functions in all threads. Since the volume of samples used for gradient calculation is effectively enlarged by a factor that equals the number of threads $n_{thrd}$, this means that the actual learning rate (59) for the ADAM optimizer is multiplied by $n_{thrd}$.

The code used in this work has been made publicly available on GitHub in the repository...
named “Adorym”\(^1\) which is an acronym for “Automatic Differentiation-based Object Retrieval with dYnamic Modeling.”

### 4.5 Reference reconstructions

In order to compare the outcomes of the proposed algorithm with methods that are conventionally used for phase retrieval, the full-field data demonstrated in this work are also processed and reconstructed by first performing an iterative 2D phase retrieval method termed error reduction (ER; widely used in coherent diffraction imaging (53)) for every projection image. The workflow of ER can be summarized as follows:

1. Propagate the initial guess of the exit wavefront \(\psi_0\) to the detector plane as
   \[
   \psi'_0 = P_d \psi_0;
   \]

2. Replace the magnitude of the wavefront with the modulus of the measured intensity \(I_\theta\) as
   \[
   \psi''_0 = \frac{\psi'_0}{|\psi'_0|} \sqrt{I_\theta};
   \]

3. Backpropagate the wavefront to the exiting plane as
   \[
   \psi'''_0 = P_{-d} \psi''_0;
   \]

4. Mask out the pixels of the wavefront that do not belong to the finite support \(\Theta_2\) by doing
   \[
   \psi_1 = \begin{cases} 
   \psi'''_0(r), & r \in \Theta_2 \\
   0, & r \notin \Theta_2 
   \end{cases}
   \]

5. The above processes are then repeated until the mean square error between the calculated intensity and the measured intensity converges.

The filtered backprojection or FBP tomographic reconstruction method is then applied to phase-retrieved images to obtain a 3D reconstruction result. This ER+FBP approach will be subsequently referred to as “pure projection tomography.”

### 5 Computational experiment

Our Adorym approach was tested in simulations of thick objects that would normally involve multiple scattering along the beam path. Two virtual samples were investigated: one that is

\(^1\)https://github.com/mdw771/adorym.
described below, and a protein sample that is presented in Supplementary Material. The reconstructions of the silicon cone sample shown here were performed on the computing cluster Cooley at the Argonne Leadership Computing Facility. Each node of this cluster is equipped with two 2.4 GHz Intel Haswell E5-2620 v3 CPUs (12 cores total) and 384 GB RAM. Due to the limit of memory, we did not use GPU acceleration on this machine. TensorFlow version 1.4.0 was used as the computational engine for our routine. For the ADAM optimizer built with TensorFlow, we used a step size of $\lambda = 10^{-7}$, and first and second moment exponential decay rates of $\beta_1 = 0.9$ and $\beta_2 = 0.999$, respectively.

We carried out computational experiments on a cone object created using the optical simulation package XDesign (63). In order to exceed the depth of focus limit within a moderate array size, we chose to create a $\text{(256)}^3$ voxel grid with 1 nm voxel size, and to use 5 keV x-ray beam energy. As a result, the x-ray wavelength was 0.248 nm and the depth of focus given by Eq. 1 was $\text{DOF}=21.8$ nm. (Present-day x-ray microscopes achieve a spatial resolution of more typically 15–30 nm as noted in the introduction, but 1 nm represents a goal for the future). Therefore the reconstruction grid was almost 12 times larger than the depth of focus, so the object significantly exceeds the depth-of-focus limit. Within this grid, a hollow cone of silicon was computationally created so as to resemble a thin-walled capillary heated and then pulled. The tube has a top diameter of 80 nm and a bottom diameter of 200 nm, so that neither end fits within the DOF limit. To examine the algorithm’s capability to restore fine details, we also placed 50 TiO$_2$ nanospheres with radii ranging from 2 to 4 nm on the outer wall of the tube, as well as 10 larger spheres (5–13 nm in radius) inside the tube. The refractive indices of both materials were generated using the open-source database package Xraylib (64). In addition, we added spherical bubbles, or “grains,” whose refractive indices fluctuate within 30% of the original material, into the cone’s body as a means to test the ability of the algorithm to retrieve internal structure. These grains also served as marks in assessing the influence of photon noise on ptychography results as will be discussed below. The phase shifting part $\delta$ of the x-ray RI for this computationally-created object is shown in the top row of Fig. 3.

In x-ray full-field imaging, a variety of methods are available to obtain a phase contrast image from detected intensities (66), but propagation-based phase contrast is the simplest to achieve experimentally. We therefore assumed that the x-ray wavefield exiting the object propagated downstream by a sample-detector distance $d$ of 1 µm before the resulting wavefield was imaged without loss by a 1 nm resolution lens onto a detector, as shown in Fig. 1. This is beyond the state of the art with present-day x-ray optics, but as noted above we chose parameters so as to significantly exceed the depth of focus limit within a small array size. Within this optical configuration, we simulated the recording of 500 images over a single-axis rotation range of $360^\circ$ in one case, and $180^\circ$ in another case. The purpose of distinguishing $360^\circ$- and $180^\circ$-rotation is that when diffraction is present in the sample, the image obtained from $\theta$ and $\theta + 180^\circ$ can be different, unlike conventional tomography. In order to acquire high-quality results, we conducted a series of experiments to determine that the optimal values for the regularizer weights in Eq. 14 were $\alpha_\delta = 1.5 \times 10^{-8}$ for the stronger phase-shifting part of the x-ray RI, and $\alpha_\beta = 1.5 \times 10^{-9}$ for the weaker absorptive part. The total variation minimization
Figure 3: Cone object used for computational experiments in beyond depth-of-focus x-ray imaging. The inset between column 2 and 3 shows a near-field diffraction image used in full-field reconstruction. The object (top row) and various reconstructed images (subsequent rows) are shown, displaying only the phase-shifting part $\delta$ of the x-ray RI since it provides higher contrast than the absorptive part $\beta$. In keeping with the convention of most synchrotron tomography experiments, the object is assumed to be rotated around the vertical or $y$ axis. The first column shows a single-plane section of the object in the $yz$ plane, with the location of the section shown by the green dashed line in the third column. The second column shows a projection or summation through the 3D grid in that same direction, while the third column shows a projection or summation through the 3D grid viewed from above. The fourth column shows the surface of the object, as rendered using Vaa3D (65). Both the full-field (b) and the ptychography (d) reconstructions of data acquired over a $360^\circ$ rotation angle range reproduce the object with high fidelity. In the full-field reconstruction from $180^\circ$ rotation data (c), voids appear where there is supposed to be material within the cone (in this case the illumination was incident from top, to right, to bottom in the perspective of the third and fourth columns, though the same type of behavior was observed with different $180^\circ$ illumination ranges). In the pure projection tomographic reconstruction shown in the bottom row (e), one obtains an image with lower resolution and greater differences from the true object: the fine TiO$_2$ spheres on the outside of the cone object are blurred out, and the reconstruction shows spurious material inside the cone. These images are all of a $256\times256$ nm$^2$ field of view.
regularizer term of Eq. 14 was made small by setting $\gamma = 1 \times 10^{-11}$. The x-ray RI grid was initialized to a Gaussian distribution with a mean of $\delta = 8.7 \times 10^{-7}$ and $\beta = 5.1 \times 10^{-8}$ with standard deviations of about a tenth of the mean. These values are lower than the expected values but gave better reconstruction starts than values of zero; the reconstructions were not sensitive to the exact non-zero initialization values. In TensorFlow, we used a minibatch size of 10, and set the iterator to stop automatically once the incremental decrease of the total loss function of Eq. 14 fell below 3%. Parallelized with 4 threads, using 3 levels of multiscaling, and running on CPUs, the full-field reconstruction finished with 10, 10, and 6 epochs for the three passes with $4 \times$, $2 \times$, and $1 \times$ (original resolution) downsampling. The entire computation took approximately 5.0 hours of wall clock time, and 120 core hours.

For ptychography, we assumed that an x-ray optic was used to focus a beam on the entrance of the object volume with a Gaussian profile beam profile with $\sigma_x = \sigma_y = 6$ nm, and a maximum probe phase of 0.5 radians. A total of $23 \times 23 = 529$ probe positions were used to illuminate the specimen from each viewing angle, as shown in Fig. 1. The sparsity and smoothing constraints in ptychography are relaxed by probe overlap, so that a different set of regularizer values for Eq. 14 were used, with $\alpha_\delta = 1 \times 10^{-9}$, $\alpha_\beta = 1 \times 10^{-10}$, and $\gamma = 1 \times 10^{-9}$. The x-ray RI grid was initialized in the same way as the full-field case. The minibatch size was set to 1 rather than 10 so as to allow all data from one projection angle to fit in computer memory. For this larger data set with far-field diffraction intensity recordings, the reconstruction was parallelized with 20 threads, and required 4 epochs to yield a high quality result over a wall clock time of 46 hours, or 16,500 core hours.

Figure 3 shows the true object in row (a), and the reconstruction results for these various approaches in rows (b) through (e). In the 360° full-field reconstruction shown in row (b), and the 360° ptychographic reconstruction shown in row (d), the object boundaries are sharp, and features within the object are nicely reproduced. This is decidedly not the case for the ER+FBP or conventional tomographic reconstruction shown in row (e), where the small spheres on the outside of the object are poorly reproduced in the surface view of the fourth column, and the projection images of columns two and three do not accurately reproduce the true object. In visual appearance, one can argue that the ptychography reconstruction shown in row (d) is slightly sharper and has least “ghost” structure present in what are supposed to be empty voids inside the cone compared to the full-field reconstruction shown in row (b). This may be due to the fact that the large number of spatially separate illumination patterns used in ptychography help limit the regions that contribute scattering signal to each of the 529 individual data recordings acquired per rotation angle. On the other hand, the ptychographic reconstruction shows some slight fringe artifacts at the bottom of the cone, which might arise from the fact that the data are recorded in the far rather than the near field. More quantitative comparisons will be presented below, using the Fourier shell correlation (FSC) method (67, 68) which measures the consistency between images as a function of spatial frequency (resolution in the Fourier transform).

In conventional tomography within the pure projection approximation, projections obtained 180° apart are identical after projection reversal, so that data collected over a 180° range are sufficient for an accurate reconstruction. This is not the case when diffractive effects come
Figure 4: Fourier shell correlation (FSC) measurement of the resolution of full-field reconstructions using 500 rotation angles distributed over 360° [Fig. 3(b)] versus only 180° [Fig. 3(c)]. The FSC measurement shows a considerable loss in spatial resolution over a wide range of spatial frequencies, but especially at the highest spatial frequencies corresponding to the finest features. The FSC was calculated by comparing the phase shifting part of the x-ray RI $\delta$ between two separate iterative reconstructions of the same full-field recording dataset.

into play, as has long been known in diffraction tomography (11) and as was observed in our previous study of ptychographic reconstructions of an object with depth-of-focus effects included (14). Modulations on the wavefield can be produced both by Fresnel diffraction from upstream features, and refractive modulation from features at downstream planes; one cannot unambiguously distinguish between these two effects using a single viewing angle. To illustrate this, we have carried out a simulation of full-field imaging where the same 500 rotation angles used in the 360° case were instead distributed over a 180° angular range, giving the results shown in row (c). This leads to the presence of a number of voids in the reconstructed refractive index distribution, presumably because of the ambiguity noted above; the voids remained in the same position even if the 180° illumination angles were shifted to a different range, and is not related to the shrink-wrap of the finite support. By removing the positivity constraint on the RI distribution and examining the intermediate object function as it was updated after each minibatch, we noticed that the values in the void regions became negative and kept decreasing. We therefore speculate that the voids might arise as the optimizer attempts to compensate for the loss function under information deficiency. The resolution of the 180° and 360° full-field reconstructions was evaluated using the FSC between two independent reconstructions with the same parameter settings, and the result shown in Fig. 4 clearly shows the loss of resolution that results from using the same number of projection angles distributed over 180° only.

In order to understand the robustness of our reconstruction method in the presence of noise
due to limited exposure, we carried out full-field reconstructions where the recorded diffraction intensities were modified to incorporate noise. (Other studies have considered the noise robustness of simple coherent diffraction imaging against zone plate imaging \((69)\) or against near-field imaging \((70)\) with somewhat differing conclusions; we leave a comparison of full-field imaging and ptychography for future work). This was done by setting a quantity \(n_{\text{ph}}\) to be the total number of incident photons that intersect the object support with the object at each of the 500 projection angles. The object support is characterized by an area overdetermination ratio (AOR) of \(\sigma_{\text{AOR}}\)

\[
\sigma_{\text{AOR}} = \frac{N^2_{\text{support}}}{\sigma AOR}\]

where \(N_{\text{support}}\) represents the total number of pixels within the finite support \((71)\). The Gaussian-blurred “shrink-wrap” procedure described above led to \(\sigma_{\text{AOR}} \approx 57\%\) for the simulated cone object. With these factors considered, the number of photons \(N_{\text{pix},\theta}\) incident on each of the \(N^2 = 256^2\) pixels is given by

\[
N_{\text{pix},\theta} = \frac{n_{\text{ph}}}{\sigma_{\text{AOR}} \times N^2}\]

for each of the \(N_{\theta}\) viewing directions such that \(n_{\text{ph}} = 1 \times 10^9\) corresponds to \(N_{\text{pix},\theta} = 2.7 \times 10^4\). The detected intensity images at each of the \(N_{\theta}\) angles, generated by a normalized plane incident wave with unity magnitude, were scaled by \(N_{\text{pix},\theta}\) before Poisson noise was applied to them. We then obtained reconstructions from the Poisson-degraded datasets, and compared them using the Fourier shell correlation (FSC) method \((68)\).

Given the normalized image intensity one would expect from a feature-present versus a feature-absent voxel, one can estimate the exposure required to see that object with a specified signal-to-noise ratio (SNR). Using the phase contrast imaging expression of Eq. 39 of \((41)\) for \(t = 1\) nm thick Si at 5 keV, we obtain an exposure estimate of \(N_{\text{pix},\theta} = 5.0 \times 10^7\) for SNR=5 imaging. Dose fractionation \((72)\) tells us that this dose can be distributed over all \(N_{\theta}\) viewing angles as 3D object statistics are built up from tomographic projections, so one would expect that to achieve full resolution at SNR=5 one would require \(N_{\text{pix},\theta}/N_{\theta} = 1.0 \times 10^5\), which from Eq. [16] translates to \(n_{\text{ph}} = 3.7 \times 10^9\) per viewing angle. Because this exposure scales as SNR\(^2\), reducing \(n_{\text{ph}}\) from \(3.7 \times 10^9\) to \(1.0 \times 10^9\) corresponds to a decrease of SNR from 5 to \(5/\sqrt{3.7/1.0} = 2.6\). Alternatively, because the radiation dose that must be necessarily imparted to a specimen for imaging at a specified SNR scales as the inverse fourth power of spatial resolution \((41,73)\), a decrease of \(n_{\text{ph}}\) from \(3.7 \times 10^9\) to \(\{1 \times 10^7, 1 \times 10^8, 1 \times 10^9\}\) would be expected to correspond to a reduction in spatial resolution from \(1\) to \(\{4.4, 2.5, 1.4\}\) nm. If one translates this into a fraction of the Nyquist sampling limit, the corresponding fractions are \(\{0.23, 0.41, 0.72\}\). These fractions of the Nyquist sampling limit are shown via dashed lines in Fig. [6] and they are consistent with a FSC in the 0.5–0.6 range as a measure of the spatial resolution limit.
Figure 5: Near-field propagation images as would be recorded by the camera in Fig. 1(a) (top row), and reconstructed images (middle and bottom rows) in the presence of simulated Poisson noise with a total number of photons $n_{\text{ph}}$ used in data recording. The middle row projection images correspond to the second column image of row (b) in Fig. 3, while the bottom row slice images correspond to the first column image of row (b) in Fig. 3. As can be seen, reducing the number of photons $n_{\text{ph}}$ within the object (and thus the incident number of photons per pixel per viewing angle $N_{\text{pix,} \theta}$ as given by Eq. (16)) leads to a decrease in image fidelity and signal to noise ratio at the single pixel level. One can also evaluate this as a loss of spatial resolution with decreasing exposure, as shown in Fig. 6.
Figure 6: The Fourier shell correlation (FSC) for the fullfield results with varying photon exposure $n_{ph}$ as shown in Fig. [5]. For each exposure, two different datasets were generated with different Poisson-distributed random noise, after which the same reconstruction algorithm with the same parameters was applied to each noisy dataset before performing the Fourier shell correlation. As discussed in the text, one would expect the SNR to decline at normalized spatial frequencies of $\{0.23, 0.41, 0.72\}$ times the normalized spatial frequency for photon exposures of $n_{ph} = \{1 \times 10^7, 1 \times 10^8, 1 \times 10^9\}$. The dashed lines at these normalized spatial frequencies are all at roughly consistent decreases of the FSC to about 0.5–0.6 for the respective exposures, corresponding to a spatial resolution estimate of $\{4.4, 2.5, 1.4\}$ nm.
6 Discussion

We have shown here an approach (which we call Adorym, as noted above) whereby one can use automatic differentiation and a multislice propagation forward model to reconstruct 3D objects in two different microscope types, with only minor branchpoints in one computer code base. Our approach has the following characteristics which are shared with another related non-automatic-differentiation approach (14), as well as with other multislice learning (44) and optimization-based (43) approaches:

- In standard diffraction tomography approaches, one assumes that the 3D object can be decomposed into volume gratings so that data from one viewing angle is projected not onto a flat plane in Fourier space (as would be the case for a pure projection image), but the surface of the Ewald sphere. These assumptions are valid for the case where there is no multiple scattering in the specimen, but it can be shown (see for example Figs. 2 and 3 in (41)) that multiple scattering can play a role in x-ray imaging of thick specimens. In other words, the illumination of downstream planes can be affected by the presence of strong features in upstream planes. Because our approach involves a full multislice forward calculation along each viewing angle, it can incorporate these effects correctly.

- In previous multislice ptychography approaches (12), it has been assumed that the object can be decomposed into a set $N_a$ of planes along the illumination direction with those planes separated by a depth of focus distance or more. This separation is required for allowing the combination of propagated probe, and discrete object plane, to be decomposed into sufficiently different results along the propagation direction. By allowing for an isotropic forward model where the plane separation distance can be the same as the transverse resolution distance, our approach is better able to represent the subtle contrast variations that occur in imaging over distances that are a reasonable fraction of the depth of focus. It should also be noted that the use of multislice methods to reconstruct $N_a$ planes along the illumination direction means one can reduce the number of illumination angles used (60) from what one might have expected based on the Crowther criterion (74).

- In previous ptychographic tomography (40) and multislice ptychographic tomography approaches (38), phase unwrapping methods have been used to generate a pure projection image with a linear response. No phase unwrapping is required in our approach, eliminating any potential errors and ambiguities that can sometimes occur with phase unwrapping.

One would expect these characteristics to allow for the reconstruction of beyond-depth-of-focus 3D objects with greater fidelity than one would have with multislice ptychographic tomography approaches; exploration of this hypothesis could be the topic of future work.

Our use of automatic differentiation in a numerical optimization approach has several features:
• For ptychography, it lets one phase the far-field Fourier magnitudes as was first suggested (46) and then demonstrated (15) in prior work. For near-field imaging, it avoids the approximations of uniform material type implicit in one commonly-employed approach (54).

• It allows one to easily switch between different imaging modes (in this example, both near-field imaging and ptychography) within the same code framework, and it lets one explore different types of loss functions and regularizers without needing to rebuild the optimizer. This can be very useful for benchmarking different imaging and reconstruction techniques.

• Several software packages that provide automatic differentiation capabilities (such as TensorFlow and Autograd) are already built for parallelized operation on large compute clusters. As an example, an automated differentiation based ptychography reconstruction code was demonstrated in (15). We carried out a direct test of our TensorFlow based AD approach for ptychography against our previous result (14) using manual differentiation of the cost function, and implementation in C++. The approach used here took 8.25 core hours/iteration/angle, compared to 6.48 core hours/iteration/angle. One pays a modest penalty in computer time in this example, but arguably uses less researcher time because automatic differentiation does not require one to re-calculate derivatives as the cost function is modified.

• It also allows one to trivially compare and switch between synchronous and asynchronous schemes of optimization. In the synchronous scheme, object functions are broadcasted and synchronized among all threads for each several iterations. In the asynchronous scheme, each threads does the optimization own its own, and the object functions contained by them are only combined at the end. In the example discussed in (15), the synchronous approach took slightly longer to complete but gave more accurate results. The default scheme that we used to generate the above demonstrative data is a variant of the synchronous approach. Here, each thread keeps its own object function, but the gradient obtained by a thread is broadcasted and averaged along with the results of all other threads before being used to update the object function.

The above stated characteristics have led to increasing attention to automatic differentiation in the optics community, and other work has explored the use of automatic differentiation for several other coherent diffraction imaging modalities (17).

Another point needing attention is that while the full-field mode and the ptychography mode are different in terms of acquisition method and processing wall time, the results they give are sometimes not equivalent as well. This is most obvious for diffusive features without clear boundaries, as in the case demonstrated in Fig. S1 in the supplementary material. In this test case, a protein molecule (originally acquired using electron microscopy tomography) was numerically reconstructed by our algorithm using both full-field mode and ptychography mode.
The result shows that the full-field reconstruction “throws away” the diffusive halo around the molecule, which on the other hand is correctly restored by ptychography reconstruction.

While the proposed method has been implemented for both full-field microscopy and for ptychography, a special note should be given to the former. In the absence of the oversampling constraint in ptychography, we explored the use of finite support constraint and sparsity constraint in 3D space, which would provide more insights to the iterative retrieval of a bounded 3D object by solving an underdetermined system. The algorithm, when combined with non-scanning high-resolution imaging techniques, can potentially become the launchpad for a high-throughput imaging pipeline for measuring thick samples with sub-100-nm resolution. One of such possible paths is to apply the algorithm to point-projection microscopy (75, 76). While far-field diffraction patterns suffer a loss of speckle contrast as one goes from fully coherent to decreasingly partially coherent illumination (with the best results obtained when the coherence width of the beam equals the size of the object array (77)), with near-field wave propagation one only needs to have the spatial coherence match the distance $\lambda z/(\Delta x)$ over which one has the ability to record near-field fringes. Thus point-projection near-field imaging is able to make use of a greater fraction of partially coherent sources, such as today’s synchrotron light sources. At the same time, if one does have full spatial coherence, the separation of subregions of the object into separate experimental recordings (diffraction patterns from limited-size illumination spots) gives reconstructions with better fidelity even with a more relaxed imposition of regularizers. Moreover, application of the proposed method to detection methods beyond X rays – for example, broadband radiation used for atmospheric transmission (78) and seismology (79), might also be exploited to better model the dynamic diffraction of waves propagating in complicated media over long distances.

7 Conclusion

We have developed and demonstrated a novel 3D reconstruction algorithm for objects beyond the depth-of-focus limit. The algorithm uses multislice propagation as the forward model, and retrieve the RI map of the object by minimizing a loss function containing the squared difference between the amplitudes of the forward-propagated wavefront and the measured signals at all viewing angles. We implemented the algorithm for both full-field and ptychography imaging, and compared them in terms of computation walltime and reconstruction fidelity. Investigation on the full-field version allowed us to explore the constraint requirements for reconstructing of bounded 3D objects with non-scanning imaging techniques, where sparsity and finite-support constraints are used to ensure a successful reconstruction. Another novelty of our method lies on the use of automatic differentiation, which not only prevents the laborious manual differentiation involved in numerical optimization, but also makes the computational model extremely adaptable and flexible. Numerical studies of the algorithm using simulated objects indicate that the proposed method is capable of recovering a thick object with high spatial resolution and good accuracy. Further validation of the approach with experimental data will be our subse-
quent step, which would examine the capability of the method in handling noises and help us identify practical challenges such as probe alignment (80). The ultimate goal is to combine the algorithm with high-resolution imaging techniques, which, for full-field imaging, could be the point-projection microscopy. The combination of the two could potentially lead to the development of a high-throughput pipeline for imaging thick samples.
