Abstract. We study the utility of wavelets for detecting the redshift evolution of the dark energy equation of state \( w(z) \) from the combination of supernovae (SNe), CMB and BAO data. We show that local features in \( w \), such as bumps, can be detected efficiently using wavelets. To demonstrate, we first generate a mock supernovae data sample for a SNAP-like survey with a bump feature in \( w(z) \) hidden in, then successfully discover it by performing a blind wavelet analysis. We also apply our method to analyze the recently released “Constitution” SNe data, combined with WMAP and BAO from SDSS, and find weak hints of dark energy dynamics. Namely, we find that models with \( w(z) < -1 \) for \( 0.2 < z < 0.5 \), and \( w(z) > -1 \) for \( 0.5 < z < 1 \), are mildly favored at 95% confidence level. This is in good agreement with several recent studies using other methods, such as redshift binning with principal component analysis (PCA) (e.g. Zhao and Zhang, arXiv: 0908.1568).

1 Introduction

The observed acceleration of cosmic expansion [1, 2] means that either our understanding of gravity on cosmological scales is incomplete, or that there exists a yet unknown dark energy (DE) component, which is gravitationally repulsive, contributing around 70% of the total energy budget of the universe. The redshift evolution of the DE fraction is determined by its equation of state $w(z)$ via

$$\Omega_{\text{DE}}(z) = \Omega_{\text{DE}} \exp \left\{ -3 \int \ln z'[1 + w(z')] \right\},$$  

where $\Omega_{\text{DE}}$ is the dark energy fraction at $z = 0$. The simplest DE candidate is the cosmological constant $\Lambda$ with $w = -1$. However, in the absence of a convincing theory of DE, one should not disregard the possibility of a more complicated evolution history of $w(z)$.

Much effort has been put in extracting $w(z)$ from data. Even though $\Lambda$ provides a good fit [3], current experimental constraints on $w$ are not accurate enough to rule out the possibility of a time-varying $w$. It is of fundamental importance to know if DE is a constant or dynamical, and future observations will be in a much better position to address this important question [4]. Approaches used so far to estimate $w(z)$ from data can be classified into three types: fitting a model [5–8], binning and principal component analysis (PCA) [9–11], and a direct differentiation of distance data [12]. In the first method, one assumes a functional form for $w(z)$ or the Hubble parameter $H(z)$ and fits the form to data. Many different functions have been considered and the results are generally strongly dependent on the assumed model. In the PCA method, recently adopted by the JDEM figure of Merit Science Working Group [13], $w(z)$ is binned in redshift or scale-factor, and the value in each bin is considered as a parameter of the model. The best measured principal components can be used to reconstruct $w(z)$. In the third method, the Type Ia SNe luminosity distance data is smoothed, and $w(z)$ is calculated from the second derivative of this smoothed function.
All of the three techniques above have their merits, and can be used to address appropriately formulated questions. In this paper we are examining the possibility of using wavelets as a tool to detect possible features in $w(z)$ from a combination of supernovae (SNe), cosmic microwave background (CMB) and baryon acoustic oscillations (BAO) data, in a model-independent way. Local features in $w(z)$ would exist if, for example, dark energy was a quintessence scalar field with a potential that had a step-like bump. Sharp features in $w(z)$ are also predicted in certain types of phantom models of dark energy [14].

An advantage of wavelets is that one does not need to assume a prior knowledge of the position and size of features in $w(z)$. Wavelets search for large and small scale features at the same time and can reconstruct them with only a few parameters.

This paper is organized as follows. In section 2 we describe the wavelet method. In section 3 we demonstrate the method by hiding a feature in a simulated data and then performing a blind analysis to reconstruct it. In section 4 we apply the same method to search for features in the current data and conclude with a summary in section 5.

2 Methodology

2.1 The wavelet parametrization

Wavelets, known as “mathematical microscopes”, have the ability to “see” signals on multiple scales, making them a powerful tool for detecting features in noisy data. Examples of their use in cosmology include reconstructing the primordial power spectrum [15, 16], probing the non-Gaussianity of the primordial fluctuations [17], and searching for signals of parity breaking [18]. Wavelets are specially designed functions that have the property of being localized in both frequency and configuration space. Individual wavelets are generated from a “mother” function as

$$\psi_{nm}(x) = \left(\frac{2^n}{L}\right) \psi\left(\frac{2^n x}{L} - m\right)$$

where $\psi(x)$ is the mother function, $L$ is the range on which the function is defined, $0 < m < 2^n - 1$ and $0 < n < N - 1$. Each wavelet function has a localized shape. The index $n$ determines the size of the feature, while $m$ determines its location on $x$. Functions $\psi_{nm}$ are orthogonal by design, hence we can expand any function onto the wavelet basis in the same way as we do for any other orthogonal basis:

$$f(x) = \sum_{n=0}^{N-1} \sum_{m=0}^{2^n-1} a_{nm} \psi_{nm}(x) .$$

By this definition, each wavelet acts as a band-pass filter and an infinite number of wavelets are needed to cover the whole spectrum. This problem is solved by introducing a scaling function. Wavelets coefficients together with the coefficient of the scaling function, $2^N$ in total, can be used to describe $f(x)$ at $2^N$ points. In this work, we consider $w(z)$ to be an unknown function which can, in principle, have local features in $z$. Like any other function, we can expand it into the wavelet basis as

$$1 + w(z_j) = \sum P_i \psi_i(z_j) ,$$

where $z_j$ are the redshift points at which we calculate $w$. $P_i$ are the wavelet expansion coefficients, and $\psi_i$ are the wavelet functions. We chose to simplify our indices so that $P_1$
is the scaling function coefficient, $P_2 = a_{00}$, $P_3 = a_{10}$, etc. We then treat the wavelet expansion coefficients as the parameters of the model to be measured from data. Note that we expand $1 + w(z)$, as opposed to $w(z)$, so that all coefficients are zero if $w = -1$, as in the currently favored $\Lambda$CDM model. We use Daubechies 4 (D4)\cite{19} and Haar\cite{20} wavelets (prototypes shown in figure 1) in this paper. The D4 wavelets are highly localized and suitable for reconstructing sharp features. The Haar wavelets are made of step functions. We should keep in mind that our results using different types of wavelets should converge and be consistent with each other in the limit of large number of data points.

Based on the expected redshift range of a future Type Ia SNe survey like SNAP, we take the redshift range to be $0 < z < 1.7$. We choose to work with up to 16 wavelet parameters, which allows us to calculate $w(z)$ at 16 equally spaced points in $z$ and probe features of up to $1.7/8 \approx 0.2$ size in redshift. The values of the wavelet coefficients are determined by fitting (2.3) to data using Markov-chain Monte Carlo (MCMC) as explained in Subsection 2.2.

| $z$  | 0.1 | 0.2 | 0.3 | 0.4 | 0.5 | 0.6 | 0.7 | 0.8 | 0.9 | 1.0 | 1.1 | 1.2 | 1.3 | 1.4 | 1.5 | 1.6 | 1.7 |

2.2 How many wavelet coefficients?

The main advantage of wavelets is that we do not need to a prior knowledge of the position, the scale and the shape of the possible features in the function $w(z)$. Wavelets search for large and small scale features at the same time and the fact that they are localized in configuration space makes it possible to reconstruct features with only a few nonzero coefficients. In practice, we start with performing an initial MCMC run with all 16 wavelet coefficients as free parameters. We then keep those parameters whose signal-to-noise ratio (SNR) is above

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{figure1}
\caption{The 5th and 15th D4 (upper) and Haar (lower) wavelets. The resolution (16 points) in this illustration is the same as the one used in the numerical calculations in this paper.}
\end{figure}
a certain threshold, and set parameters with low SNR to zero, since they are not sensitive to features in \( w(z) \). From the surviving set of wavelet coefficients, we find the combination that has the lowest reduced \( \chi^2 \). This gives us the optimal number of wavelets we need to detect a feature in \( w(z) \). We then use three model selection criteria, described below, to determine if this wavelet fit is in fact preferred over a constant \( w \).

To judge whether a model is preferred by data, we use three selection criteria: the improvement in \( \chi^2 \) per extra degree of freedom \( \Delta \chi^2 / \Delta (\text{DoF}) \), the Akaike Information Criterion (AIC) \([21]\), and the Bayesian Information Criterion (BIC) \([22]\). The AIC and BIC are defined as

\[
AIC = -2 \log L + 2N_p + \frac{2N_p(N_p + 1)}{N_d - N_p - 1},
\]

\[
BIC = -2 \log L + \frac{N_p N_d \log(N_d)}{N_d - N_p - 1},
\]

where \( N_p \) is the number of parameters and \( N_d \) is the number of data points. The second terms on the right hand sides of these relations show the penalty for adding new parameters, which is stronger for BIC. Both expressions include second-order corrections, which is important for the case with a small data sample size, i.e. small \( N_d \). The AIC and BIC are widely used in the model selection — the lower the value of AIC(BIC), the more the model is preferred. A model with \( \Delta \text{BIC} < -10 \) is decisively preferred, while models with \(-6 \leq \Delta \text{BIC} < -2 \) and \( \Delta \text{BIC} \geq 2 \) have very strong, strong, positive and weak evidence of model preference, respectively. In the case of the AIC, models with \( \Delta \text{AIC} \leq 2 \) have substantial support, models with \( 4 \leq \Delta \text{AIC} \leq 7 \) have considerably less support and those with \( \Delta \text{AIC} > 10 \) have essentially no support.

### 2.3 Current and future data sets

For our tests we will work with a combination of SNe, CMB and BAO data, considering both the current available data and the simulated future data. The combined likelihood of the model is calculated as

\[
-2 \log L = \chi^2_{\text{total}} = \chi^2_{\text{SNe}} + \chi^2_{\text{CMB}} + \chi^2_{\text{BAO}}
\]

with

\[
\chi^2 = (x - d)^T C^{-1} (x - d)
\]

where \( x \) is theoretical value for an observable, \( d \) is data vector and \( C \) is the data covariance matrix.

#### 2.3.1 SNe data

The observable quantity in SNe data is the redshift-dependent magnitude:

\[
m = M + 5 \log d_L + 25
\]

where \( M \) is the intrinsic supernova magnitude and \( d_L \) the luminosity distance. The luminosity distance is defined as

\[
d_L(z) = (1 + z) \int_0^z \frac{dz'}{H(z')},
\]
where $H(z)$ is the Hubble parameter with a current value of $H_0$. We use the characteristics of a SNAP-like JDEM survey [23] to simulate futuristic SNe data with errors given by

$$\sigma_m(z) = \sqrt{\frac{\sigma^2_{\text{obs}}}{N_{\text{bin}}} + d_m^2}, \quad (2.10)$$

where $\sigma_{\text{obs}} = 0.15$. The systematic error, $d_m$, is assumed to increase linearly with redshift:

$$d_m = \delta m \frac{z}{z_{\text{max}}}, \quad (2.11)$$

$\delta m$ being the expected uncertainty and $z_{\text{max}}$ the maximum redshift. Table 1 shows the redshift distribution of type Ia supernovae expected to be detected by JDEM together with estimated error in magnitude for different redshift bins. In addition, we assume that 300 supernovae at $z < 0.1$ will be measured by the Nearby Supernovae Factory (NSNF) [24]. For current SNe data, we use the recently released “Constitution” sample with 397 data points [25].

### 2.3.2 CMB and BAO data

Rather than working with the full CMB data, we use the procedure suggested in [3] and work with two distance ratios: the shift parameter $R$, and the acoustic scale $\ell_A$, defined as

$$R(z_*) = \sqrt{\Omega_m H_0^2} (1 + z_*) D_A(z_*) \quad (2.12)$$

$$\ell_A \equiv (1 + z_*) \frac{\pi D_A(z_*)}{r_s(z_*)} \quad (2.13)$$

where $z_*$ is the redshift of decoupling, $D_A(z)$ is the proper angular diameter distance to redshift $z$, and $r_s(z)$ is the comoving sound horizon at $z$. It was shown that these two quantities contain almost all of the information required to constrain dark energy with CMB [26–28]. For future CMB data, we used the Planck characteristics for parameters and their errors [29]. For today’s data we used the WMAP-5 values and errors for the parameters [3].

We use the BAO data point at $z = 0.35$ from [30] corresponding to $r_s/D_V(z)$, where $D_V(z)$ is given by

$$D_V = \left[ (1 + z)^2 D_A^2(z) \frac{cz}{H(z)} \right]^{1/3}, \quad (2.14)$$

where $c$ is the speed of light.

### 2.4 PCA analysis

A significant departure from zero of any of the wavelet coefficients would indicate a departure from the $\Lambda$CDM model. Although the wavelet functions are orthogonal by construction, and hence their expansion coefficients should be uncorrelated, the error bars on the fitted wavelet coefficients are actually correlated. In the presence of correlation among parameters, one can not determine conclusively at what significance level a deviation from zero has occurred for any one of the coefficients. In order to quantify the detection of a departure from zero we decorrelate the wavelet coefficients. The PCA analysis [31] is designed to do precisely that by diagonalizing the covariance matrix of the original parameters to find their uncorrelated
Figure 2. Comparison of the residuals of the distance modulus for ΛCDM, WCDM and bump (from wavelet fit) models with characteristic error-bars for SNAP.

linear combinations. The original data vector $P_j$ is transformed into a new data vector $q_i$ using the same rotation matrix $\omega_{ij}$ that diagonalizes the covariance matrix. Namely, we have

$$q_i = \sum_j \omega_{ij} P_j$$

so that the new covariance matrix, $C_q = \omega C_P \omega^{-1}$, is diagonal, and $q_i$’s are the uncorrelated principal components of $P$. Like the wavelet coefficients, principal components should also be zero for the ΛCDM model. We will use the PCA to quantify the significance with which the current data sees departures from ΛCDM.

2.5 Features in $w(z)$

Broad features in $w(z)$, such as a single transition from one constant value to another, can be efficiently detected by other methods such as binning. Our aim is to develop a method to detect, if any, local features in $w(z)$ in a model-independent way. In this sense, we found that wavelets can do a good job phenomenologically. Wavelet method is more effective for searching for localized features in $w(z)$ that would likely require a larger number of parameters to describe with other methods. From the theoretical point of view, a local feature in $w(z)$ is not particularly motivated, but can be produced in scalar field models of dark energy with a step-like bump in the potential, or in certain types of phantom models \[14\].

In the next section we will try to recover a feature in $w(z)$, a bump, that we “hide” in a simulated future data. Such a bump is not ruled out by current data \[32\], since the averaged $w(z)$ — the quantity that the current data essentially constrains — does not significantly deviate from $-1$ for this feature. The main rationale for considering this particular choice is that such a bump feature cannot be easily discovered by binning if one does not know the size, the position and the scale of the bump in advance.

3 Reconstructing features with future data

In this section, we use the wavelet method to reconstruct a feature hidden in the simulated mock future data. Our procedure can be summarized as follows:

1. Generate a mock dataset with a feature of $w(z)$ hidden in;
2. Perform the first MCMC fit for 16 wavelet coefficients;

3. Sort the wavelet coefficients according to their signal-to-noise ratio (SNR) and set all except the few with the highest SNR to zero;

4. Perform the second MCMC with all possible combinations of “surviving” wavelet coefficients to find the model with the least $\chi^2$ per degree of freedom (DoF)

5. Quantify the detection using $\Delta \chi^2 / \Delta (\text{DoF})$, $\Delta \text{AIC}$ and $\Delta \text{BIC}$.

To start, we simulate future SN data for a dark energy model with a feature in $w(z)$ given by

$$ w(z) = -1 + A \exp \left[ -\frac{(z - z_0)^2}{\sigma^2} \right], $$

where we choose $A = -0.9$, $z_0 = 0.6$, $\sigma = 0.1$. This $w(z)$ is shown with a black solid line in figure 5. We assume a flat universe, and choose the other cosmological parameters as $\Omega_b = 0.046$, $\Omega_m = 0.279$ and $H_0 = 70$ km/s/Mpc. We also apply the distance priors derived from the CMB and BAO data as described in section 2.3. We assume a SNAP-like JDEM survey with the luminosity data binned into 17 redshift bins in the range of $z \in [0, 1.7]$. Figure 2 shows the comparison of the residuals (defined with respect to the $\Lambda$CDM model) of the distance modulus for the model with a bump-like feature in $w(z)$ and a constant-$w$ model which has the same average value $w$ (i.e. one that gives the same distance to the CMB last scattering surface). Error-bars are plotted according to the characteristics of SNAP. The plot shows that a SNAP-like experiment is capable of differentiating between these models around $z = 0.5$.

Having produced our mock datasets, we perform a MCMC fit for all the 16 wavelet parameters plus $\Omega_b h^2$, $\Omega_m h^2$ and $h$, assuming a flat universe and flat priors for all the wavelet parameters. Figure 3 shows the marginalized 1-D likelihood distributions for the 16

![Figure 3](image-url)
wavelet parameters, with table 2 listing the corresponding mean values and the 68% CL error bars. As one can see, for many wavelet parameters the standard deviation is much larger than the mean value, indicating that they are not sensitive to the presence of a feature in \( w \). Such poorly constrained parameters are thus redundant, so we keep only the ones with the highest SNR. In order for the D4 wavelets to be able to describe a constant \( w \), one should keep \( P_1 \). In addition, we keep the 2-3 coefficients with the highest SNR. In our example, we keep parameters \( P_1, P_5 \) and \( P_{12} \).

Next, we redo the MCMC using every combination of the selected parameters (with \( P_1 \) always included) and find the one that gives the minimum value of the reduced \( \chi^2 \). In this case, the optimal combination is that of \( P_1 \) and \( P_5 \), while setting \( P_{12} = 0 \). Marginalized likelihood distributions for this model are shown in figure 4 and the plot of \( w(z) \) reconstructed using this model is shown in the left panel of figure 5.

In the above example two wavelet parameters were measured to be non-zero. Their uncorrelated linear combinations, or principal components, have essentially the same values:

\[
PC_1 = 0.9 \pm 0.4, \quad PC_2 = 0.43 \pm 0.08, \quad (3.2)
\]

| Para. | Constraints | SNR | Para. | Constraints | SNR |
|-------|-------------|-----|-------|-------------|-----|
| \( P_1 \) | \(-0.1 \pm 1.2\) | 0.1 | \( P_9 \) | \(-0.5 \pm 3.0\) | 0.2 |
| \( P_2 \) | \(1.1 \pm 4.4\) | 0.3 | \( P_{10} \) | \(-0.7 \pm 4.3\) | 0.2 |
| \( P_3 \) | \(-1.3 \pm 4.3\) | 0.3 | \( P_{11} \) | \(1.5 \pm 4.6\) | 0.3 |
| \( P_4 \) | \(-0.2 \pm 1.4\) | 0.1 | \( P_{12} \) | \(7.4 \pm 9.2\) | 0.8 |
| \( P_5 \) | \(1.7 \pm 2.7\) | 0.6 | \( P_{13} \) | \(-0.1 \pm 5.0\) | 0.0 |
| \( P_6 \) | \(-0.3 \pm 4.7\) | 0.1 | \( P_{14} \) | \(0.1 \pm 5.2\) | 0.0 |
| \( P_7 \) | \(0.2 \pm 5.2\) | 0.0 | \( P_{15} \) | \(1.6 \pm 4.8\) | 0.3 |
| \( P_8 \) | \(-0.3 \pm 1.7\) | 0.2 | \( P_{16} \) | \(-1.6 \pm 4.1\) | 0.4 |

**Table 2.** Marginalized mean values with 68% CL. errors and SNR for all the 16 wavelet parameters. The high SNR parameters are underlined.

**Figure 4.** 1-D posterior distributions of the 1st and the 5th wavelet coefficients, and the other four cosmological parameters.
Figure 5. The hidden feature (black solid), and the reconstruction using D4 (red dashed, left panel) and Haar (red dashed, right panel) wavelets. The horizontal dashed line and the shaded band illustrate the fit with the constant $w$ model and the 68%CL errors.

| Model            | $\Delta \chi^2/\Delta \text{(DoF)}$ | $\Delta \text{AIC}$ | $\Delta \text{BIC}$ |
|------------------|-------------------------------------|----------------------|----------------------|
| WCDM($w = -0.9$) | 0                                   | 0                    | 0                    |
| CDM-D4-P1,5      | -8.8                                | -6.3                 | -3.7                 |
| CDM-Haar-P2,4    | -8.3                                | -6.8                 | -3.2                 |

Table 3. The differences in the model selection criteria for the simulated data with a bump feature in $w(z)$. Indicating evidence for $\sim 6\sigma$ and $\sim 2\sigma$ departures from zero respectively. The correlation between the two wavelet parameters is negligible, which need not happen in general, but is somewhat expected. Namely, this combination is the one most favored by the reduced $\chi^2$, which means that both parameters are likely needed to describe the data — one of them cannot compensate for the other. This implies a small correlation between these two parameters.

Detecting a departure from $w = -1$, which is all we have discussed so far, does not in itself amount to detecting the bump feature. The value of $w(z)$ in figure 5 averaged over redshift is less than $-1$, so we would detect a departure from $-1$ by simply fitting a constant $w$. Hence, the more relevant question is not to what extent wavelets are able to detect a departure from $-1$, but to what extent the wavelet fit is preferred to a fit by a simpler model with one constant $w$ parameter.

To answer this question, we fit the model with a constant $w$ (WCDM) in a flat universe and apply the model selection criteria to determine the degree to which the wavelet model is preferred in comparison. In particular, we calculate the change in $\chi^2$ per additional degree of freedom, the difference in the BIC and AIC. As one see from the numbers in table 3, the wavelet fit is strongly preferred according to all three criteria.

In addition to using D4 wavelets, we have followed the same procedure and tried to recover the bump feature using the Haar wavelets. We find again that a model with two wavelet parameters is optimal and is preferred to WCDM at a similar significance level as in the D4 case. The plot of $w(z)$ reconstructed using two Haar wavelets is plotted in the right panel of figure 5.

As a test, we have repeated the same procedure using data simulated according to parameters of existing data sets. We confirmed that the bump feature cannot be detected today at any significance. We have also checked if we can accurately recover $w(z)$ if $\Lambda$CDM was the true model for the universe. In this case all the wavelet coefficients should be zero.
Figure 6. Reconstruction of $w(z)$ from current data using D4 (black solid line), Haar (red dashed line) wavelets, binning (error bars) and CPL parametrization (shaded regions). The inner blue error bars (inner shaded dark grey band) and outer green error bars (outer shaded light grey band) show the 68 and 95% CL. constraints respectively.

Table 4. Differences in the model selection criteria for the analysis of the current data.

| Model            | $\Delta \chi^2/\Delta (\text{DoF})$ | $\Delta \text{AIC}$ | $\Delta \text{BIC}$ |
|------------------|------------------------------------|----------------------|---------------------|
| $\Lambda \text{CDM}$ | 0                                  | 0                    | 0                   |
| CDM-D4-16Ps      | -0.3                                | 32.7                 | 91                  |
| CDM-Haar-16Ps    | -0.4                                | 31.1                 | 89                  |
| CDM-D4-1,4,8     | -1.6                                | 0.9                  | 13                  |
| CDM-Haar-2,4,5   | -1.9                                | 0.2                  | 12.3                |

or the difference from zero should not be statistically significant. To test that, we consider simulated data for $\Lambda \text{CDM}$ model and followed the same procedure of selecting the first few coefficients with the highest signal to noise, and then trying all different combinations of the these selected wavelets. Our MCMC results in this case show no evidence of detection of departure from zero for any of the wavelet coefficients, and $\Lambda \text{CDM}$ is correctly recovered as the best model.

4 Searching for features in current data

In this section, we apply our method to the current SNe, CMB and BAO data to search for the deviation of $w(z)$ from $-1$. We use the recently released “Constitution” SNe data sample with 397 data points [25], apply the distance priors measured by the WMAP5 team [3], and assume a flat universe.

Table 4 shows the main results. We find that using 16 D4 or Haar wavelet coefficients reduces the $\chi^2$ and gives a hint that $w$ may have deviations from $\Lambda \text{CDM}$. However, a model with 16 parameters is not preferred by any of the information criteria. With D4 wavelets, parameters $P_1$, $P_4$, and $P_8$ give the optimal model with a $\Delta \chi^2/\Delta (\text{DoF})$ of $-1.6$. With Haar wavelets, this number is $-1.9$ with the three wavelet parameters being $P_2$, $P_4$ and $P_5$. We also find that none of the wavelet fits are favored by the AIC and BIC.
Table 5. Principal Components for wavelet coefficients of optimum \( w \) models with current cosmological data.

| Model   | PC1      | PC2      | PC3      |
|---------|----------|----------|----------|
| D4-1,4,8 | 0.25±1.04 | 0.36±0.39 | 0.07±0.13 |
| Haar-2,4,5 | -4.03±1.81 | -0.26±0.46 | 0.10±0.15 |

Plots of \( w(z) \) reconstructed using the wavelet method with D4 and Haar are shown in figure 6. We also plot the results obtained using the binning method and the CPL parametrization taken from [33]. As one can see, the best fit wavelet models show weak hints of dark energy dynamics. In particular, \( w(z) < -1 \) for \( z \in [0.25, 0.5] \) and \( w > -1 \) for \( z \in [0.5, 1] \), implying that \( w \) crosses \(-1\) during its evolution. This is consistent with the analysis of the “Constitution” data set in [33], which reported weak evidence for a similar evolution history. Regardless of whether such evolution is real or not, the CPL parametrization would not be able to see it.

A significant deviation from 0 for any of the wavelet parameters shows deviation from \( \Lambda \)CDM. Table 5 shows the eigen-values of principal components for each model together with their errors, separately. There is a 1\( \sigma \) and 2\( \sigma \) detection from D4 and Haar respectively, which can be interpreted as weak hints that \( w \) may have a departure from \(-1\).

We note that although ref. [33] obtained similar results, they used a 5 \( w \) bin model. They found this optimal 5-bin model after performing a model-selection on 10 different binning models, which is computationally expensive. With the wavelet approach, we recover the same feature in \( w(z) \) with only 3 wavelet parameters after running MCMC just a few times. This is possible because of the multi-resolution nature of the wavelets. We should also note that systematic effects like Malmquist bias [34] can mimic the same behavior as dynamical \( w \). Therefore, we need to be cautious about making any strong conclusions about the equation of state parameter \( w \).

5 Summary

We investigated the utility of the wavelet expansion method for recovering a local redshift-dependence in the dark energy equation of state \( w(z) \) with future cosmological data. The advantage of wavelets over other methods is that there is no need to assume a scale or a position for a feature in \( w(z) \). With wavelets, one is able to search for small scale features, while looking at the large scale picture at the same time. Our results show that a bump-like feature in \( w(z) \), which is not ruled out by today’s data, can be recovered using wavelets at a high significance with future data.

We have tried relaxing the flatness assumption and considered curvature as an additional parameter. In this case, we find that the bump feature we put in becomes undetectable, even with the wavelet technique, due to the degeneracy between \( w \) and the curvature \( \Omega_K \). There is sufficient freedom for \( \Omega_K \) and \( \Omega_m \) to adjust themselves to mimic the effect of a featured \( w(z) \) in the luminosity distance observations. More specifically, we find that a model with \( w = -1.2 \), \( \Omega_m h^2 = 0.137 \), \( \Omega_b h^2 = 0.0227 \), \( \Omega_\Lambda = 0.6 \), \( \Omega_K = 0.1 \) and \( h = 0.68 \) has nearly the same goodness-of-fit as the bump model.

Applying the wavelet method to current cosmological data we find a hint of departure from \( \Lambda \)CDM at a 2\( \sigma \) level. The same behavior has been found independently using the binning method [33] at the same significance level. We have shown that such local features can be found more efficiently by using wavelets. The feature we found in current data will require further investigation as the SNe and other cosmological data improves.
