Measuring the Properties of the Higgs Boson with the ATLAS Detector

W. Quayle on behalf of the ATLAS Collaboration

Abstract. If an excess of events is discovered in the Higgs boson searches at LHC, it will be important to establish whether the excess is a Higgs boson or a different particle with similar decay modes. This talk reviews the measurements of the Higgs boson properties that are planned for the ATLAS detector at the LHC.

Keywords: Higgs
PACS: 14.80.Bn, 14.80.Cp

INTRODUCTION

One of the major goals of the LHC is to understand the mechanism of Electroweak symmetry breaking by searching for evidence of the Higgs boson [1, 2, 3]. The strongest such constraints presently come from searches at LEP, which has excluded a Standard Model Higgs boson with a mass below 114.4 GeV [4], and from Tevatron, which has ruled out the existence of a Standard Model Higgs boson with a mass of 170 GeV [5].

The ATLAS detector [6] at the LHC will either find evidence for a Higgs boson or place strong constraints on its production cross-section that will contradict the prediction of the Standard Model [7]. If a Higgs-like particle is found, its properties must be measured to establish that it is indeed a Higgs boson and not a different particle.

MASS, SPIN, AND CP PROPERTIES OF THE HIGGS BOSON

Observables such as the Higgs boson’s branching ratios vary considerably as a function of mass; in order to interpret the other property measurements, one must measure the Higgs boson mass precisely. The Higgs boson mass determination at ATLAS is dominated by the $H \to \gamma\gamma$ and $H \to ZZ \to 4\ell$ channels.

The $H \to \gamma\gamma$ channel is sensitive in the mass range below about 150 GeV, and its mass resolution is 1.36 GeV for a Higgs boson with a mass of 120 GeV. The $H \to ZZ \to 4\ell$ channel is sensitive for a broad range of Higgs boson masses. Its resolution in the region below the ZZ threshold ranges from 1.8 GeV at $M_H = 120$ GeV to 2.7 GeV at $M_H = 180$ GeV. The resolution degrades slightly at higher mass, but for very heavy Higgs bosons the natural width is larger than the experimental resolution. The expected precision of a measurement of the natural width of the Higgs boson after collecting 300 fb$^{-1}$ of integrated luminosity is better than 8% for masses above 270 GeV [8]. It is worth noting that the mass resolutions quoted here are taken from very recent studies, but other
FIGURE 1. Left: the expected significance for the exclusion of several alternative spin/CP scenarios as a function of the Higgs boson mass, after 100 fb$^{-1}$ of integrated luminosity. Right: the transverse opening angle between the two tag jets in the Weak Boson Fusion $H \rightarrow WW \rightarrow \ell\nu\ell\nu$ signal, for the Standard Model case (SM, black), a CP-odd scenario (CPO, red), and a CP-even scenario (CPE, green).

measurements, such as spin, CP, and coupling determinations, are based on older studies that have not yet been updated with the latest understanding of the detector.

A spin-1 boson cannot be produced by gluon fusion or decay to a photon pair [9], so if the decay $H \rightarrow \gamma\gamma$ is observed, then the spin of the Higgs boson cannot be 1. If the decay $H \rightarrow \gamma\gamma$ is not observed, it is still possible to extract information about the spin of the Higgs boson from angular correlations in the $H \rightarrow ZZ \rightarrow 4\ell$ channel and the angular distributions of the struck quarks in Higgs production by Weak Boson Fusion.

The Higgs boson spin and CP are extracted from $H \rightarrow 4\ell$ decays using three main observables: $\alpha$, $\beta$, and $R$ [10]. $\alpha$ and $\beta$ are obtained by fitting $F(\phi) = 1 + \alpha \cos(\phi) + \beta \cos(2\phi)$ to the distribution of $\phi$, the angle between the decay planes of the two $Z$ bosons in the rest frame of the Higgs boson. $R$ is given by $R = (L - T)/(L + T)$, where $L$ and $T$ are obtained by fitting $G(\theta) = T(1 + \cos^2(\theta)) + L \sin^2(\theta)$ to the distribution of the angle $\theta$ between the $Z$ boson decay products and the receding Higgs boson in the rest frame of the $Z$ boson. The left plot in Figure 1 shows the significance with which several alternative models can be ruled out with 100 fb$^{-1}$ of integrated luminosity. The analysis of $\phi$ can rule out a non-Standard-Model Higgs boson with a mass larger than about 250 GeV; the analysis of $\phi$ through the coefficients $\alpha$ and $\beta$ yields the strongest discriminating power for Higgs bosons with a mass around 200 GeV.

Searches for Higgs bosons via Weak Boson Fusion use several cuts on the two highest-$P_T$ jets in the event (“tag” jets) to achieve a strong rejection against backgrounds [11]. The most sensitive search channels for this production mechanism are $H \rightarrow \tau\tau$ in the region around $M_H = 120$ GeV and $H \rightarrow WW \rightarrow \ell\nu\ell\nu$ in the region around $M_H = 160$ GeV. One can extract information about the tensor structure of the $HVV$ vertex by analyzing the transverse angle $\Delta\phi_{jj}$ between the two leading jets [12]; the right plot in Figure 1 shows the $\Delta\phi_{jj}$ distribution for $H \rightarrow WW$ signal in the Standard Model and two alternate models. A $\chi^2$ test is used to determine the dominant couplings. With
10 fb$^{-1}$ of integrated luminosity, one would expect to exclude the CP-even (CP-odd) hypothesis with a confidence level corresponding to 5.4σ (4.6σ) using the $H \rightarrow WW$ channel if the Higgs boson mass is 160 GeV. Similarly, with 30 fb$^{-1}$ of data, one would expect to exclude the CP-even (CP-odd) hypothesis with a confidence level corresponding to 2.5σ (2.0σ) using the $H \rightarrow \tau\tau$ channel if the Higgs boson mass is 120 GeV. After establishing that the dominant coupling is Standard Model-like, one can still test for a small CP-even anomalous coupling, since interference terms modify the $\Delta \phi_{jj}$ distribution. With 30 fb$^{-1}$ of data, the expected error on the anomalous CP-even coupling is $\sigma(\mathcal{g}_{HZZ}^e) = 0.11$ if $M_H$ is 160 GeV, or $\sigma(\mathcal{g}_{HZZ}^e) = 0.24$ if it is 120 GeV. These figures neglect systematic uncertainty in the background; adding a 10% background uncertainty leads to an additional error of about 0.02 in the measured coupling.

COUPLINGS TO GAUGE BOSONS AND FERMIONS

The most model-independent observable sensitive to the Higgs couplings is the total rate, $\sigma \times BR$, for each final state. In the case of $H \rightarrow WW$, the event selection assumes that the Higgs boson is CP-even and spin 0; the cut on the dilepton angle in the transverse plane exploits spin correlations to suppress the background. As shown in the last section, it is possible to verify this assumption through an analysis of $\Delta \phi_{jj}$ in Weak Boson Fusion events. Figure 2 shows the expected uncertainty on $\sigma \times BR$ for several channels [13]. For $M_H < 150$ GeV (left), the error in the rate ranges from 30% to 100%. For channels that can be seen in the mass range $110 < M_H < 190$ GeV, the error is smaller.

By assuming that there is only one Higgs boson, it is possible to extract a measurement of relative branching ratios such as $\Gamma_Z/\Gamma_W$. The $H \rightarrow WW$ channel is used as the normalization since it is measured with the smallest error. With 30 fb$^{-1}$ of integrated luminosity, these ratios of partial widths can be measured with an accuracy better than 60% for $M_H > 120$ GeV, with a precision better than 35% for some masses.

Assuming that there are no extra particles or strong couplings to light fermions, it is possible to obtain estimates of the ratios of Higgs couplings. The cross-sections and
FIGURE 3. The expected error on the measurement of the relative (left) and absolute (right) couplings of the Higgs to gauge bosons and fermions after collecting 30 fb$^{-1}$ of integrated luminosity. The discontinuity at $M_H = 150$ GeV is due to a change in the assumption about the sum of all branching ratios. For $M_H < 150$ GeV, decays to $b$ and $\tau$ are included in the sum; for $M_H > 150$ GeV, they are not.

branching ratios are proportional to the squares of the couplings, and the proportionality constants are taken from a theoretical calculation. The left plot of Figure 3 shows the expected relative error on the ratios of Higgs boson couplings after 30 fb$^{-1}$ of integrated luminosity. The uncertainties range from about 20% up to 100%.

Finally, with the additional assumption that the sum of visible branching ratios is the same as in the Standard Model up to an error equal to the sum of undetected Standard Model branching ratios, the absolute couplings of the Higgs boson to the $Z$, the $W$, and the $\tau$ can be measured. The error is less than 100% for $120 < M_H < 200$ GeV, as shown in the right plot of Figure 3.
