Lysosomal storage diseases (LSDs) are individually rare but collectively common; their estimated total prevalence is 1 out of 8,000 live births [6]. As current therapies have limited effect and most LSDs progress relentlessly, therapies that are more efficient are urgently needed. To develop efficient therapies, a more thorough understanding of the pathophysiological development of LSDs at the cellular level is essential. Several LSD disease models have been established in knockout mice for disease modeling and drug tests [7-12]. However, at present, these models are not able to mimic the whole spectrum of LSD conditions. Therefore, lack of appropriate human cells affected by LSDs for drug screening and toxicity testing may be a major obstacle in the development of new therapies for LSDs. Since pluripotency reprogramming technology offers an easy and efficient means to generate patient-specific iPSCs, the iPSCs derived from patients with familiar or sporadic disease offer a valuable methodology through which to study the mechanisms involved in the initiation and progression of LSDs in vitro and further screen remedies for clinical treatment.

This review focuses on the current status of the application of iPSCs in LSD research by summarizing the LSD-iPSC cellular/ultrastructural findings that have been reported in the literature and by presenting useful strategies through which LSD-iPSCs can be exploited to identify novel drugs and improve future clinical treatment of LSDs.
organelle dysfunctions relating to the accumulation of specific substrates (Table 1) [14]. LSDs also encompass two other types of rare disorders caused by either transport defects through the lysosomal membrane [14,15] or defective vesicular trafficking (Table 1) [14,16,17]. The majority of LSDs are clinically progressive and currently have no definite cures. Recent development of enzyme replacement therapy (ERT) has successfully alleviated the symptoms of patients with certain types of LSDs, such as Gaucher's disease, Pompe disease, Fabry disease, and type I, II, and VI mucopolysaccharidosis (MPS) [18], but the benefit of ERT on the neurological manifestations of LSDs is less obvious [19]. Hematopoietic stem cell transplantation [20], substrate reduction therapy [21], and pharmaceutical chaperones [22] have also been developed to treat selected patients with LSDs and showed beneficial effects [23]. Nevertheless, for patients with advanced-stage or late-onset LSDs, the current treatment results are still not satisfactory.

**History and progress of induced pluripotent stem cell technology**

In 2006, Yamanaka and colleagues [1,2] demonstrated that forced expression of only four transcription factors (Oct3/4, Sox2, Klf4, and c-Myc) is sufficient to convert both mouse and human fibroblasts into ESC-like cells. Other researchers reported similar results at almost the same time [24-26]. The cells generated were named iPSCs. Such a breakthrough circumvented the thorny ethical issues surrounding research that employs human embryos and also offered the hope of providing replaceable human cells with less immune rejection for use in clinical applications. A major disadvantage of iPSC technology is its low efficiency. However, an increasing number of modified protocols employing chemicals and small molecules have been forwarded to improve the efficiency of iPSC derivation; these methods have been reviewed extensively elsewhere [27-29]. In addition, alternative strategies have been developed to avoid the problem of integration of viral genes, including piggyBac vectors [30], recombinant proteins [31], modified miRNAs [32], microRNAs [33], and Sendai virus [34]. In general, however, it is accepted that the most efficient method to generate human iPSCs is still through lentiviral and retroviral transduction [35]. While iPSC research in vitro has progressed considerably, the large-scale application of iPSCs in clinical practice in the near future still hangs in the balance, mainly because of the concern of tumorigenicity that is comparable to that of ESCs. In addition, a recent report [36] demonstrated that the teratomas from inbred C57BL/6 fibroblast-derived iPSCs still cannot prevent the occurrence of immune rejection when transplanted back to the syngeneic mice, although Okita and colleagues [37] argued against this conclusion and reasoned that teratoma formation might not be a good approach through which to evaluate immune rejection. Consistent with this viewpoint, transplantations of mutation-corrected iPSC-derived cells into affected mice have been shown to result in the rescue of disease phenotypes in mice with sickle cell anemia [38]. Nevertheless, it should be borne in mind that de novo immunogenicity might be produced during iPSC derivation and maintenance, which could be caused by, for example, the viral antigens generated by viral vectors or the animal antigens contained in the serum or supplements used for cell culture. Despite all of these uncertainties regarding clinical application, it is well recognized that human iPSCs are an unprecedented and powerful tool that is highly promising for modeling numerous human genetic diseases **in vitro**.

**Induced pluripotent stem cells for disease modeling and drug testing**

So far, more than 40 iPSC disease models have been successfully generated from patients with genetic diseases [5], and the length of the list keeps increasing. Notable examples of models developed so far are Duchenne and Becker muscular dystrophy [7], Huntington disease [7], Shwachman-Diamond syndrome [7], Lesch-Nyhan syndrome [7], amyotrophic lateral sclerosis [39], spinal muscular atrophy [40], familial dysautonomia [41], dyskeratosis congenital [42], Friedreich's ataxia [43], fragile X syndrome [44], LEOPARD (lentigines, electrocardiographic conduction abnormalities, ocular hypertelorism, pulmonary stenosis, abnormal genitalia, retarded growth, deafness) syndrome [45], long-QT syndrome [46,47], Rett syndrome [48], and Hutchinson-Gilford progeria [49], although not all of these iPSCs exhibit disease-specific phenotypes. The derivatives of some of these disease-specific iPSCs have been employed as in vitro disease models to test the phenotype-correcting effects of small numbers of promising drugs, such as neurons differentiated from spinal muscular atrophy-specific iPSCs [40] and Rett syndrome-specific iPSCs [48] and cardiomyocytes differentiated from iPSCs for long-QT syndrome [47], suggesting the probability of their use as platforms for performing high-throughput screenings of large chemical libraries to identify novel drug candidates for these diseases.

**Lysosomal storage disease-specific iPSCs and their cellular pathology**

**Gaucher disease: the initial proof-of-principle lysosomal storage disease-iPSCs**

Since there is no cure for most LSDs in current medicine, LSD-specific iPSCs may provide a unique opportunity for dissecting unexplored disease pathogeneses and identifying new drugs. Several disease-specific iPSCs have
## Table 1. Clinical profiles of common lysosomal storage diseases

| Disease                          | Gene/defective protein | Function                                         | Clinical symptoms (in vivo phenotypes)                                          | Biochemical/cellular pathology                                      | Available therapies* |
|----------------------------------|------------------------|--------------------------------------------------|----------------------------------------------------------------------------------|----------------------------------------------------------------------|----------------------|
| Pompe disease                    | GAA/acid alpha-glucosidase | Degrading glycogen in cellular vacuoles          | Cardiac and respiratory failure; muscle weakness                                 | Glycogen storage; autophagic build-up                                | Myozyme; Lumizyme; DNJ (trial) |
| Sphingolipidoses                 |                        |                                                  |                                                                                  |                                                                      |                      |
| Fabry disease                    | GLA/alpha-galactosidase A | Hydrolyzing the terminal alpha-galactosyl moieties from glycolipids and glycoproteins | Cardiovascular problems; renal failure; pain and paresthesia in the extremities | Increase levels of GB3; laminated alternate electron-dense and lucent layers (Zebra bodies) in the cytoplasm | Fabrazyme; Replagal; DGJ (trial) |
| Gaucher disease                  | GBA/acid beta-glucocerebrosidase | Cleavage of the glucosylceramide to ceramide and glucose | Hepatosplenomegaly; pancytopenia; skeletal (type 1 and 3) or neurological problems (type 2 and 3) | Tubular structures in arrays inside dilated lysosomes under EM | Cerezyme; Zavesca (miglustat; NB-DNJ); isofagomine (trial) |
| Niemann-Pick disease, type A and B | SMPD1/acid sphingomyelinase | Converting sphingomyelin to ceramide              | Hepatosplenomegaly; cherry-red maculae; pneumonia                              | Abnormal lipid profiles; lamellar inclusions under EM                | rhASM (for type B, trial, not published) |
| Metachromatic leukodystrophy     | ARSA/arylsulfatase A     | Hydrolyzing cerebroside sulfate to cerebroside and sulfate | Progressive neurological dysfunction; demyelination                             | Metachromatic deposits in the nervous system                          | BMT (may delay progress); rhARSA (for those who have received HSCT, trial, not published) |
| Krabbe disease (Globoid cell leukodystrophy) | GALC/beta-galactocerebrosidase | Hydrolyzing the galactose ester bonds of galactosylceramide | Diffuse neurological dysfunction; sensorimotor peripheral neuropathy            | Accumulation of galactosylphosphoglycerol in all tissues, filamentous and curvilinear inclusions | HSCT; BMT |
| Mucopolysaccharidoses (MPS): representative types |                          |                                                 |                                                                                  |                                                                      |                      |
| Hurler syndrome (MPS IH)         | IDUA/alpha-L-iduronidase | Hydrolyzes the terminal alpha-L-iduronic acid residues of the glycosaminoglycans | Hepatosplenomegaly; heart diseases; dysostosis multiplex; mental retardation    | Accumulation of dermatan sulfate and heparan sulfate                  | HSCT; Aldurazyme |
| Hunter syndrome (MPS II)         | IDS/iduronate sulfatase | Lysosomal degradation of heparan sulfate and dermatan sulfate | Growth deficiency; coarse face; stiff joints; mental retardation                 | Accumulation of dermatan sulfate and heparan sulfate                  | BMT; Elaprase |
| Sanfilippo syndrome B (MPS IIIB) | NAGLU/alpha-N-acetylgalcosaminidase | Lysosomal degradation of heparan sulfate          | Severe neurodegeneration; coarse face; mild organomegaly                        | Accumulation of heparan sulfate; abnormal Ca^{2+} homeostasis; Golgi abnormalities; abnormal neurite outgrowth | Miglustat (NB-DNJ, trial) |
| Sly syndrome (MPS VII)           | GUSB/beta-glucuronidase | Lysosomal degradation of glucuronic acid-containing glycosaminoglycans | Heart disease; dysostosis multiplex; hepatosplenomegaly; hydrops fetalis; mental retardation | Progressive lysosomal storage in many tissues because of accumulation of dermatan sulfate and heparan sulfate | BMT |

*Continued overleaf*
been successfully generated from either mouse models for LSDs or patients with LSDs (Table 2). The iPSCs derived from a patient with Gaucher disease type III accounted for perhaps the first reported human LSD-iPSC line established [7], although few Gaucher disease-specific phenotypes have been described in detail.

### Mouse lysosomal storage disease-specific iPSCs

Using tail-tip fibroblasts from mouse models of Fabry disease [8], Krabbe disease [8], MPS VII [8], and Pompe disease [9], Eto and colleagues have generated corresponding disease-specific iPSCs and characterized them. In addition to reporting deficient enzyme activities and substrate accumulation in these cells, the authors reported impaired embryonic body formation in MPS VII-specific iPSCs [8], a novel phenotype that, as the authors suggested, is possibly attributed to an elevated level of hyaluronic acid and may not be easily identified without using disease-specific iPSCs. According to the authors, two in vivo phenotypes are possibly related to

**Table 1. Continued**

| Disease                      | Gene/defective protein | Function                                                                 | Clinical symptoms (in vivo phenotypes)                                                                 | Biochemical/cellular pathology                                                                 | Available therapies |
|------------------------------|------------------------|--------------------------------------------------------------------------|--------------------------------------------------------------------------------------------------------|-------------------------------------------------------------------------------------------------|--------------------|
| Lipid storage disease        |                        |                                                                          |                                                                                        |                                                                                                |                    |
| Niemann-Pick disease, type C | NPC1/NPC1 protein      | Regulating intracellular cholesterol trafficking                          | Hepatosplenomegaly; neurological deterioration                                                      | Low-cholesterol esterification; lamellar inclusions in foam cells                               | Zavesca (miglustat; NB-DNJ) |
| Cereolipofuscinosis, neuronal, type 1 | PPT1/palmitoyl-protein thioesterase | Removing palmitate from cysteine residues during lysosomal degradation | Myoclonus; spasticity; ophthalmic problems, mental deterioration                                     | Granular osmiophilic cytoplasmic deposits in cells under EM                                     | Cystagon (cysteamine bitartrate) combined with N-acetylcysteine (trial); neural stem cells (trial) |

**Mucolipidosis**

| I-cell disease              | GNPTAB/N-Acetylg glucosaminyl-phosphotransferase alpha and beta subunits | Catalyzing the synthesis of the M-6-P determinant on lysosomal hydrolases | Alveolar ridge hypertrophy; dysostosis multiplex; heart failure; joint limitation; thick tight skin; mental retardation | Increased lysosomal enzyme secretion; membrane-bound vacuoles containing electron-lucent or fibrogranular contents | BMT                |

**Oligosaccharidosis**

| Fucosidosis                 | FUCA1/alpha-L-fucosidase | Degrading fucose-containing glycoproteins and glycolipids                | Angiokeratoma; psychomotor retardation; coarse face; dysostosis multiplex                         | Increased oligosaccharide secretion; elevated sweat chloride; vacuolated lymphocytes            | HSCT; BMT          |

**Transport defects through the lysosomal membrane**

| Cystinosis                  | CTNS/cystinosin         | Transporting cystine out of lysosomes                                    | Failure to thrive; renal tubular Fanconi syndrome; hepatosplenomegaly; skeletal problems         | Characteristic crystals within lysosomes causing cell expansion                                | Cystagon (cysteamine bitartrate) |

**Defective vesicular traffic**

| Chediak-Higashi syndrome    | CHS1/LYST protein       | Regulating protein trafficking to and from lysosomes                      | Recurrent pyogenic infections; ophthalmic problems; hepatosplenomegaly; neurological dysfunction | Giant granules in muscle cells; giant lysosomes; altered vesicular fusion; defective antigen presentation | BMT; HSCT |

---

*Regardless of their efficacy, only drugs that have been approved or are undergoing clinical trials are listed. BMT, bone marrow transplantation; DGJ, 1-deoxygalactonojirimycin; DNJ, 1-deoxynojirimycin; EM, electron microscopy; GB3, globotriaosylceramide; HSCT, hematopoietic stem cell therapy; M-6-P, mannose-6-phosphate; NB-DNJ, N-butyl-1-deoxynojirimycin; rhARSA, recombinant arylsulfatase A; rhASM, recombinant acid sphingomyelinase.
impaired embryoid body formation in MPS VII iPSCs: (1) the lower-than-expected 25% of MPS VII (GUSB−/−) mice born from heterozygous mating based on Mendelian inheritance and (2) hydrops fetalis, which is known to be relatively common in patients with MPS VII [8]. Moreover, the same group has shown that mouse Pompe disease iPSCs can be differentiated into skeletal muscles that are positively stained for myosin heavy chain, accumulate glycogen in lysosomes, and have typical ultrastructural features, including Z-, I-, A-, and H-bands [9]. Such an achievement is remarkable because skeletal muscles are among the most difficult mammalian cell types to obtain from in vitro differentiation of pluripotent stem cells [50].

Human Pompe disease
Using a unique acid alpha-glucosidase (GAA) rescue-based strategy and fibroblasts from two patients with Pompe disease, we also successfully generated four Pompe disease-specific iPSC lines [10]. All of these lines exhibit Pompe disease-specific phenotypes, such as very low GAA activity and high glycogen content, and can be differentiated into cardiomyocytes that have disarrayed myofibrils and abundant glycogen-containing vacuoles. Unexpectedly, we also found that Pompe disease iPSCs have defective cellular respiration (whereas ESCs and normal iPSCs do not) and this is supported by our finding that the mitochondria of cardiomyocytes derived from Pompe disease iPSCs exhibit abnormal morphology. We have tested several drugs/chemicals by using Pompe disease iPSC-derived cardiomyocytes and found that glycogen accumulation can be reduced by recombinant GAA and that the deteriorated mitochondrial functions can be partially rescued by L-carnitine. In addition, using comparative transcriptome analysis, we have identified six marker genes whose expression robustly correlates with the therapeutic effect of recombinant GAA or L-carnitine [10]. We are currently using these Pompe disease iPSCs to test the therapeutic effects of other compounds (for example, autophagy inhibitors) because excessive autophagic build-ups have been documented as an important feature of cells of patients with Pompe disease [51,52].

Human mucopolysaccharidosis 1H
Presuming that iPSC-derived hematopoietic cells may have fewer immunological complications than regular donor cells in hematopoietic cell transplantation (HCT), Tolar and colleagues [11] generated iPSCs from a patient with MPS type IH, a severe form of alpha-L-iduronidase deficiency that can be treated by HCT but not by ERT, and successfully corrected the gene defect by using iPSCs transduced with lentivirus harboring the wild-type gene (called IDUA) encoding this enzyme. The authors reported that alpha-L-iduronidase activity is not required for stem cell renewal and that MPS IH-iPSCs already have lysosomal storage of GAG. Moreover, MPS IH-iPSCs can be differentiated into hematopoietic progeny...

Table 2. Disease modeling and drug testing of lysosomal storage disease induced pluripotent stem cells recorded in the literature

*Except for the impaired embryoid body formation found in mucopolysaccharidosis (MPS) VII induced pluripotent stem cells (iPSCs), all lysosomal storage disease iPSC phenotypes have been reported in patient tissues or cells. Gb3, globotriaosylceramide; ND, not described.
with a colony-forming capacity comparable to those of IDUA-corrected and wild-type iPSC-derived hematopoietic progeny. The authors emphasized the advantages of iPSCs for possible application in HCT; for example, iPSCs are more feasible for long-term culture, and gene correction of iPSCs is easier than that of hematopoietic stem cells, which are more sensitive to ex vivo manipulation. Clarification of whether such IDUA-corrected iPSCs can be used for therapeutic purposes without immunological complications awaits further studies.

**Human mucopolysaccharidosis IIIB**

A prominent advantage of iPSC technology is that it offers access to patient neuronal cells, because neuronal cells are not difficult to derive from iPSCs [40]. This is critical for studying diseases—such as MPS type IIIIB, a fatal LSD caused by the deficiency of α-N-acetylgalactosaminidase—that involve primarily the central nervous system. Lemonnier and colleagues [12] successfully generated MPS IIIB-iPSCs and demonstrated that severe cellular pathology, including storage vesicles and disorganized Golgi complex, exists in undifferentiated iPSCs and differentiated neurons but not in neuronal progenitors. It is worth noting that the authors used exogenous recombinant enzyme to complement the enzymatic defect in order to clone MPS IIIB-iPSCs efficiently, an approach similar to our rescue strategy mentioned above [10]. Considering quantitative reverse transcription-polymerase chain reaction and Western blot results, the authors suggested that accumulation of heparin sulfate modifies the extracellular matrix constituents and related signaling pathways, which cause disorganization of Golgi architecture. Mild phenotypes in floating neuronal progenitors were explained by their non-adherent nature and less dependence on extracellular matrix-bound signals.

**Strategies for drug design and screening for lysosomal storage diseases based on iPSCs**

**1. Pharmacological chaperones**

The introduction above reveals that researchers around the world have generated proof-of-principle patient-specific iPSCs for several LSDs. Most of the published results of LSD-iPSC research have not advanced to the stage of drug design or medium-scale drug testing, not to mention attempts at high-throughput screening of chemical libraries for novel drug targeting of LSDs using iPSCs. However, compared with other disease iPSCs, LSD-iPSCs are more suitable for the purpose of drug design and high-throughput chemical screening because they are caused by defects of lysosomal enzymes, whose activities are measurable in vitro on a large-scale basis and the accumulated lysosomal substrates in LSDs can be assayed by either biochemical or immunochemical methods. Moreover, novel drugs can be designed or identified to enhance the activity, stability, or trafficking of mutant enzymes by assisting their folding or to target the pathways that synthesize the accumulated substrates. One class of small molecules termed pharmacological chaperones, which are reversible and competitive inhibitors of their target enzymes, may be suitable drug candidates.

In the past decade, many pharmacological chaperones have been developed to target the affected enzymes in various LSDs; this topic has been extensively reviewed elsewhere [22,53]. The chaperones can be taken orally, cross the blood-brain barrier, and have biodistributions that are better than those of ERT. Some of these chaperones are already prescribed formally in clinical practice [53]. The common strategies for identifying candidate pharmacological chaperones include both looking for molecules that have structural homology with the target natural substrates [54] and direct high-throughput screenings of compound libraries [55]. The methodology comprises initial in vitro assays such as enzyme inhibition assays in different pH environments [22,56], physical stability assays [22,57] using recombinant wild-type enzymes, and subsequent cell-based assays to estimate the effect of chaperones on enzyme activity and enzyme trafficking [22]. Chaperones identified to work for wild-type enzymes are not necessarily helpful for mutant enzymes and need be tested in different patients’ fibroblasts or cell lines to evaluate the therapeutic effect [22]. For this purpose, LSD-iPSCs can offer a limitless source of human diseased cells containing various mutations for the second-round drug screening that is based on various cell-based assays, especially for those biochemical or cellular phenotypes seen in distinct differentiated cells (for example, neurons) that can be obtained only through directed differentiation of iPSCs. It is also theoretically possible that LSD-specific iPSCs can be used directly in first-round or even large-scale cell-based screening using similar strategies because a number of these cell-based assays have been successfully developed to meet the requirements of high-throughput screening formats [22], including the high-content imaging platforms [58] to evaluate enzyme trafficking.

**2. Proteostasis regulators and other compounds**

In addition to pharmacological chaperones, other ways to improve the protein folding of mutant enzymes are available. Two alternative methods have been developed [59-61]. First, it has been demonstrated [59,60] that two common L-type calcium channel blockers [59], either diltiazem or verapamil, and ryanodine receptor blockers, such as lacidipine [60], can partially restore the activity of two glucocerebrosidase mutants in fibroblasts derived from patients with Gaucher disease; the authors suggested...
that these drugs exert their effects by upregulating a subset of molecular chaperones, such as BiP and Hsp40, which in turn ameliorate the capacity of the endoplasmic reticulum to rescue misfolded mutant enzymes. Second, Mu and colleagues [61] showed that two proteostasis regulators, celastrol and MG-132, can increase the concentrations and functions of mutant enzymes associated with two LSDs: Gaucher disease and Tay-Sachs disease. Moreover, the authors demonstrated that the combined use of pharmacological chaperones and such proteostasis regulators can generate a synergistic rescue effect on mutant enzymes in cells derived from patients with either LSD [61].

A more comprehensive review on the multiple aspects of protein folding or degradation that are related to pharmacological intervention can be found elsewhere [62]. Obviously, future efforts should be aimed at identifying more compounds of these two classes by using LSD-iPSCs and proving that the chemicals identified by using these strategies can be successfully applied next in animal studies and finally in clinical trials.

On the other hand, novel adjunct therapies also deserve to be developed to better preserve various cellular functions after correcting the disease-specific cellular pathology in different organelles (for example, the autophagic build-up and mitochondrial dysfunction in Pompe disease [52] and Golgi abnormalities in MPS type IIIB [12]). In this respect, candidate drugs may include some well-known autophagy inhibitors used in clinical trials [63], drugs or nutrient supplements [64] for treating mitochondrial dysfunction, and chemicals known to reverse endoplasmic reticulum-to-Golgi trafficking defects [65]. High-throughput screening of chemical libraries for this purpose is also a possibility because similar approaches in other fields using ESCs/iPSCs have been reported [66,67] and because proper screening-based formats of some amenable biochemical and cellular assays for such organelle dysfunctions have been reported [65,68,69] and may be exploited in the iPSC system as well. However, this is still a challenging task because successful purification of differentiated cells is a prerequisite and iPSCs may need to be passaged as single cells that can survive. A Rho-associated kinase inhibitor [70] or Accutase (Millipore Corporation, Billerica, MA, USA) [71] may be helpful to achieve this goal.

**Caveats in drug screening for lysosomal storage diseases based on iPSCs**

Several caveats are associated with using patient-specific iPSCs for drug screening [72,73]. First, mutational heterogeneity exists in most LSDs, but establishment of patient-specific iPSCs is time-consuming and labor-intensive. Thus, it may not be practical for a single laboratory to generate patient-specific iPSCs for all of the mutations found in a single disease, and determining whether the drugs identified to work for certain mutants are also helpful for other mutants would be a problem. Second, as seen in other classic cell-based platforms for drug screening, there is no guarantee that drug candidates identified from *in vitro* assays can be used successfully *in vivo*. Third, to test drugs that target the phenotypes existing only in differentiated cells (for example, electrophysiological anomalies in cardiomyocytes), a highly homogenous cell population differentiated from iPSCs may be needed to obtain consistent readouts [22]. Therefore, extensive collaborations among different laboratories on the basis of consensus and standardized protocols for generating iPSC lines and comparing drug effects will be essential. Moreover, other assays and systems — such as using LSD animal models to determine the pharmacokinetics, pharmacodynamics, and toxicities of candidate drugs — should always be used to complement iPSC-based drug screening. Finally, a more efficient and economic, and less time-consuming, set of protocols for obtaining homogenous differentiated cell types of interest in LSDs should be established in advance.

**Conclusions**

iPSC technology offers a revolutionary method for modeling LSDs and other diseases and the hope of future cell-based therapy. Since most LSDs are characterized by defects in enzymes whose activities are readily measurable *in vitro*, disease-specific iPSCs offer an ideal *in vitro* cellular system for designing LSD-specific pharmacological chaperones and for possible high-throughput compound screening. However, the application of iPSC technology for drug discovery is still at an early stage, and several major challenges — such as the difficulty of generating highly enriched disease-relevant desired cell types in large quantities from diseased iPSCs, the influence of culture and reprogramming artifacts on cell behavior, and the inability to recapitulate disease features in the diseased iPSC derivatives — must be resolved before it can be rendered an efficient and robust system for developing drugs targeting LSDs. With the advances in generating transgenic human pluripotent stem cells [74], the difficulty of enriching desired cell types from differentiating diseased iPSCs is likely to be resolved soon as specific cell types can be purified from cell mixtures by lineage-specific genetic markers or directly differentiated by ectopically expressed lineage determinant(s) in diseased iPSCs or both. In addition to iPSCs, induced somatic cells, which directly convert from fibroblasts by defined transcription factors [75,76], can potentially provide another source of disease-relevant cell types for the purpose of disease modeling. The advantage of the direct cell fate conversion technology is that a desired cell type can be directly generated from a patient’s fibroblasts.
by using a fast and simple protocol without the need of further cell purification. However, it has been suggested that the conventional pathological phenotypes of certain forms of diseases depend on cell interaction and may require a longer time to arise in a disease iPSC model [77,78]. Nevertheless, the disease process might be initiated much earlier than the emergence of clinical symptoms. Therefore, iPSC disease modeling can potentially provide an opportunity for earlier identification of phenotypic changes in diseases of interest. Despite these concerns, evidence supporting iPSC disease modeling of genetic diseases as a valuable in vitro cellular system through which to understand the mechanisms underlying the pathologies of diseases and future drug discovery has rapidly accumulated in the past few years.
