ABSTRACT

We explore the mid-infrared (mid-IR) through ultraviolet (UV) spectral energy distributions (SEDs) of 119,652 luminous broad-lined quasars with 0.064 < z < 5.46 using mid-IR data from \textit{Spitzer} and \textit{WISE}, near-infrared data from the Two Micron All Sky Survey and UKIDSS, optical data from the Sloan Digital Sky Survey, and UV data from the \textit{Galaxy Evolution Explorer}. The mean SED requires a bolometric correction (relative to 2500 Å) of BC\textsubscript{2500 Å} = 2.75 ± 0.40 using the integrated light from 1 μm–2 keV, and we further explore the range of bolometric corrections exhibited by individual objects. In addition, we investigate the dependence of the mean SED on various parameters, particularly the UV luminosity for quasars with 0.5 < z < 3 and the properties of the UV emission lines for quasars with z > 1.6; the latter is a possible indicator of the strength of the accretion disk wind, which is expected to be SED-dependent. Luminosity-dependent mean SEDs show that, relative to the high-luminosity SED, low-luminosity SEDs exhibit a harder (bluer) far-UV spectral slope (αUV), a redder optical continuum, and less hot dust. Mean SEDs constructed instead as a function of UV emission line properties reveal changes that are consistent with known Principal Component Analysis trends. A potentially important contribution to the bolometric correction is the unseen extreme UV (EUV) continuum. Our work suggests that lower-luminosity quasars and/or quasars with disk-dominated broad emission lines may require an extra continuum component in the EUV that is not present (or much weaker) in high-luminosity quasars with strong accretion disk winds. As such, we consider four possible models and explore the resulting bolometric corrections. Understanding these various SED-dependent effects will be important for accurate determination of quasar accretion rates.

1. INTRODUCTION

Most massive (bulge-dominated) galaxies are believed to harbor a supermassive black hole at their centers (Kormendy & Richstone 1995). For the most part, these black holes are passive, but when the host galaxy’s gas loses angular momentum, it accretes onto the black hole, creating a luminous quasar (Lynden-Bell 1969). This gas can be disrupted in a number of ways, including by galaxy mergers (e.g., Kauffmann & Haehnelt 2000; Hopkins et al. 2006) and secular fueling (e.g., Hopkins & Hernquist 2009, and references therein). Most of the energy output is due to an accretion disk that forms about the black hole which either directly or indirectly produces radiation across the whole population, it is important to expand our knowledge to cover the full quasar sample.

While Elvis et al. (1994) and Richards et al. (2006a) provide the most complete SEDs in terms of number of objects and overall wavelength coverage, further understanding of the SED comes from a variety of other investigations from both spectroscopy and multi-wavelength imaging across the EM spectrum. For example, composite SEDs, from the radio to the X-ray, for 85 optically and radio selected bright quasars (log (νLν) \textsubscript{ν=3000 Å} ≥ 44) with z < 1.5 were made by Shang et al. (2011), and the bolometric corrections for this sample were tabulated by Runnoe et al. (2012). Stern & Laor (2012) construct SEDs for over 3500 low-z (z < 0.2) type 1 active galactic nuclei (AGNs) with broad Hα lines ranging from the near-infrared (near-IR) up to the X-ray with log (νLν) \textsubscript{ν=2500 Å} ≥ 42, while Assef et al. (2010) present SEDs using over 5300 AGNs spanning the mid-infrared (mid-IR) up to the X-ray, with redshift going up to ~5.6, from the AGN and Galaxy Evolution Survey (AGES; Kochanek et al. 2012). While in the mid-IR, Deo et al.
Vanden Berk et al. (2001) used 2200 Sloan Digital Sky Survey (SDSS) spectra in the redshift range of $0.04 < z < 4.79$ to construct a mean quasar spectrum covering wavelengths from 800 Å to 8555 Å in the rest frame. From this they found that the mean UV continuum is roughly a power-law with $\alpha = -0.44$ ($f_\nu \propto \nu^{-0.44}$). To explore the far-UV (FUV) region of the quasar spectrum, Telfer et al. (2002) used $\sim 330$ Hubble Space Telescope spectra of 184 quasars, with $z > 0.33$, covering rest frame wavelengths from 500 Å to 1200 Å, and found an anti-correlation between the spectral index of the FUV ($\alpha_{\text{FUV}}$) and the luminosity at 2500 Å. This work was later supplemented at lower redshift and lower luminosity by Scott et al. (2004), who used 100 FUSE spectra covering the FUV. By combining their data with that from Telfer et al. (2002), they found an anti-correlation that can be characterized by

$$\alpha_{\text{FUV}} = 21.02-0.49\log \left( \frac{\lambda_{1100}}{\lambda_{1100}} \right) \frac{\text{erg s}^{-1}}{\text{Hz}}. \tag{1}$$

At shorter wavelengths, using 73 quasars, Avni & Tananbaum (1982) found a dependency of the spectral index between the optical and the X-ray and a quasar’s luminosity. This relation was further studied by a number of authors, including Steffen et al. (2006), who used 333 quasars with $z < 6$ and $\log (\nu L_\nu) |_{\lambda=2500} \geq 42$, to find the relationship between the UV and X-ray luminosities to be

$$\log (L_{2\text{keV}}) = (0.721 \pm 0.011) \log (L_{2500}) + (4.531 \pm 0.688). \tag{2}$$

while Just et al. (2007) have extended this result to higher luminosities. Recently, Russo et al. (2010) completed a similar study using 545 X-ray-selected quasars and found a similar relationship. In the X-ray regime, the mean SED appears to have $\alpha_s \sim -1$ (e.g., George et al. 2000) before cutting off at $\sim 500$ keV (Zdziarski et al. 1995).

To improve our understanding of the mean SED (and its range), we have constructed quasar SEDs, spanning from the mid-IR ($\sim 30$ Å the rest frame) to the FUV ($\sim 30$ nm in the rest frame), for quasars cataloged by the SDSS (York et al. 2000). The data used for this analysis are presented in Section 2. Section 3 describes all the corrections applied to the data. Section 4 gives an overview of our data analysis and construction of mean SEDs. Section 5 presents our findings for individual and mean bolometric corrections, and our discussion and conclusions are presented in Sections 6 and 7, respectively. Throughout this paper we use a flat-$\Lambda$CDM cosmology with $H_0 = 71$ km s$^{-1}$ Mpc$^{-1}$, $\Omega_M = 0.734$, and $\Omega_\Lambda = 0.266$, consistent with the Wilkinson Microwave Anisotropy Probe 7 cosmology (Jarosik et al. 2011).

### 2. DATA

Our sample starts with the SDSS-DR7 quasar catalog by Schneider et al. (2010), containing 105,783 spectroscopically confirmed broad-lined quasars. Each quasar has photometric data in the five SDSS optical bandpasses $ugriz$ (Fukugita et al. 1996). Only quasars that have nonzero flux in all five SDSS bandpasses after correcting for Galactic extinction have been kept in our catalog, bringing the sample size to 103,895. While the SDSS survey covers a large area of sky, it is limited to relatively bright quasars ($i < 19.1$ for $z < 3$ and $i < 20.2$ for $z > 3$). As such, in addition to these quasars, we included 15,757 lower luminosity, optically selected quasars taken from the Two Degree Field QSO Redshift survey (2QZ; $b_J < 20.85$ for $z < 3$; Croom et al. 2004), the Two Degree Field–SDSS LRG and QSO survey (2SLAQ; $g < 21.85$ for $z < 3$; Croom et al. 2009), and the AAT–UKIDSS–SDSS survey (AUS; $i < 21.6$ for $0 < z < 5$; S. Croom et al., in preparation). In the rest frame, we have over 70,000 QSOs with $\log (\nu L_\nu)$ ranging from $\sim13.7–15.4$ ($\lambda \sim 1200$ Å–6 μm) and at least 10,000 QSOs covering the range from $\sim13.3–15.6$ ($\lambda \sim 750$ Å–15 μm). All SDSS magnitudes have been corrected for Galactic extinction according to Schlegel et al. (1998) with corrections to the extinction coefficients as given by Schlafly & Finkbeiner (2011).

Table 1 presents the IR–UV photometry for the 119,652 quasars in our sample. Signs of dust reddening are seen in 11,468 of these, specifically with a color excess $A(g - i) > 0.3$ (Richards et al. 2003). These have been excluded from our analysis, bringing our final sample size to 108,184. Figure 1 shows the sky coverage of our multi-wavelength data and Figure 2 shows the 2500 Å luminosity versus redshift distributions for each survey. Note that, in the so-called SDSS “Stripe 82” region (Annis et al. 2011) along the Northern Equatorial Stripe, the SDSS imaging data reaches roughly 2 mag deeper than the main survey as a result of co-adding many epochs of data.

### 2.1. Near-infrared

Near-IR data in the $JHK$ bandpasses are taken from the Two Micron All Sky Survey (2MASS; Skrutskie et al. 2006). These include values that were matched to the 2MASS All-Sky and “6×” point source catalogs using a matching radius of $2\arcsec$ with the $6\times$ deeper catalog taking priority. In addition to these data, we include $2\sigma$ extractions (i.e., “forced photometry”) at the positions of known SDSS quasars. These objects have sufficiently accurate optical positions that it is possible to perform aperture photometry at their expected locations in the near-IR imaging, despite being non-detections in 2MASS. These $2\sigma$ “detections” were cataloged by Schneider et al. (2010); we include those objects with a signal-to-noise ratio (S/N) greater than 2.

To supplement the 2MASS data, we have matched our catalog to the UKIRT (United Kingdom Infrared Telescope) Infrared Deep Sky Survey (UKIDSS; Lawrence et al. 2007). UKIDSS uses the $YJHK$ filter system (Hewett et al. 2006); see also Peth et al. (2011). In order to generate our combined optical and near-IR data sets, we begin by source matching samples of SDSS data with the UKIDSS LAS catalog using the Cross-ID form located...

Near-IR quasar footprint.

Mid-IR quasar footprint.

Figure 1. Footprints of the optically selected quasars in the matched surveys. Coverage of GALEX (blue), UKIDSS (teal), 2MASS (green), WISE (orange), and Spitzer (red) data are limited to the SDSS footprint (black) shown in the top left panel. (A color version of this figure is available in the online journal.)

on the Web site of the WFCAM Science Archive (WSA). In particular, we match against the UKIDSS DR5 LAS source table which contains the individual detections for a given object from each bandpass merged into a single entry. We use a matching radius of 0.4″ and the nearest neighbor pairing option, accepting only the nearest object with a detection in at least one band as an acceptable match.

Since UKIDSS is deeper than 2MASS, when a quasar has data in both surveys, we only use the UKIDSS data. Between UKIDSS and 2MASS, 77,864 of our sample quasars have data in the near-IR: 35,749 from UKIDSS data and 41,434 from 2MASS, including both 5σ detections and forced photometry. Figure 3 shows the difference between the UKIDSS and 2MASS magnitudes versus the UKIDSS magnitudes for the 12,130 quasars the two surveys have in common. We have split each figure into three distinct groups: quasars taken from the 2MASS 5σ catalog, quasars with 2σ 2MASS extraction values in more than one filter, and quasars with 2σ 2MASS extractions in only one filter. As the quasars in the third group have much larger scatter (up to 2.5 mag) that can result in a misestimation of the quasar’s luminosity by up to one order of magnitude, we have removed all quasars that fall into this group. This process leaves 23,088 objects in our 2MASS sample and brings our total number of QSOs with near-IR data to 58,837. In Table 1 all 2MASS and UKIDSS fluxes have been converted to the AB magnitudes using Hewett et al.’s (2006) conversions between AB and Vega magnitudes for the UKIDSS system.

2.2. Mid-infrared

To extend our SEDs into the mid-IR, we included matches to the WISE final data release (Wright et al. 2010). The WISE bandpasses are generally referred to as W1 through W4 and have effective observed frame wavelengths of 3.36, 4.61, 11.82, and 22.13 μm, respectively, for a typical quasar SED. The matching was performed by taking all non-contaminated WISE point sources within 2″ of an SDSS quasar as a match. This matching radius maximizes the number of true objects matched while also minimizing the number of false matches. Figure 4 shows the number of WISE matches found as a function of separation distance from SDSS quasars. To ensure only the best matches were included, we also required that all matched quasars have S/N ≥ 10 in both W1 and W2. In total, we have

7 http://surveys.roe.ac.uk:8080/wsa/crossID_form.jsp
Figure 2. Contour-scatter plot showing the 2500 Å luminosity vs. redshift for each quasar color coded by survey. The contours indicate the linear density of scatter points on the plot with level drawn at 0.005, 0.5, and 0.95 of the normalized distributions. The histograms are normalized by the total number of quasars in each survey: 119,652 in SDSS, 42,043 in GALEX, 35,749 in UKIDSS, 23,088 in 2MASS, 85,358 in WISE, and 1196 in Spitzer. The black dashed line represents the flux limit of the main SDSS survey before extending the sample to lower luminosities.

(A color version of this figure is available in the online journal.)

Figure 3. Contour-scatter plot showing the difference between the 2MASS and UKIDSS magnitudes vs. the UKIDSS magnitudes for the J and K filters. The blue contours/dots show the catalog 2MASS values, green shows the 2MASS 2σ extraction values with a detection in only one band, and red shows the rest of the extracted values. The blue dashed line shows the 2MASS point source catalog’s limiting magnitude. The two surveys contain 12,130 quasars in common. Green points were excluded as the errors are quite large (see text). Similar results were found for the H filter.

(A color version of this figure is available in the online journal.)

Figure 4. Angular separation between known quasars and nearby WISE sources (blue) and the known quasars with declinations shifted by 200″ (red). The green curve shows the best fit expected distribution (Rayleigh distribution for small separations and linear growth for larger separations). The vertical magenta dot-dashed line indicates the matching radius used. As seen in the inset, the blue histogram does not follow the expected distribution; this is due, in part, to the large beam size of WISE (FWHM = 6″).

(A color version of this figure is available in the online journal.)

85,358 matches to WISE; we estimate the false matching rate to be 1% based on the number of matches obtained after shifting all WISE data by 200″ in declination (red line in Figure 4). Since the WISE photometry was calibrated against blue stars it tends to overestimate the flux of red sources by about 10% in the W4 band (Wright et al. 2010), this correction has been applied to all quasars in our sample. When available, Spitzer IRAC data were also included. We specifically included data from the Extragalactic First Look Survey (XFLS; Lacy et al. 2005); Spitzer Deep Wide Field Survey (SDWFS; Ashby et al. 2009); SWIRE DR2 (Lonsdale et al. 2003), including the ELAIS-N1, -N2, and Lockman Hole fields; S-COSMOS (Sanders et al. 2007), and our own extraction of high redshift QSOs in Stripe 82 (S82HIZ, program number 60139). The fluxes for known SDSS quasars from the Stripe 82 program are reported here for the first time in Table 1 (Spitzer source labeled as S82HIZ). The IRAC bandpasses (ch1–ch4) have effective wavelengths of 3.52, 4.46, 5.67, and 7.7 μm for a typical quasar SED. There are a total of 1196 matches to Spitzer. For a small number of quasars (∼200) both Spitzer and WISE

Survey (SDWFS; Ashby et al. 2009); SWIRE DR2 (Lonsdale et al. 2003), including the ELAIS-N1, -N2, and Lockman Hole fields; S-COSMOS (Sanders et al. 2007), and our own extraction of high redshift QSOs in Stripe 82 (S82HIZ, program number 60139). The fluxes for known SDSS quasars from the Stripe 82 program are reported here for the first time in Table 1 (Spitzer source labeled as S82HIZ). The IRAC bandpasses (ch1–ch4) have effective wavelengths of 3.52, 4.46, 5.67, and 7.7 μm for a typical quasar SED. There are a total of 1196 matches to Spitzer. For a small number of quasars (∼200) both Spitzer and WISE
data are available; in these cases, we use both data sets. In Table 1 all Spitzer and WISE fluxes are reported in AB magnitudes.

2.3. Ultraviolet

To extend the SEDs into the UV, we use Galaxy Evolution Explorer (GALEX; Martin et al. 2005) data when available. The effective wavelengths for the near-UV (NUV) and the FUV bandpasses are 2267 Å and 1516 Å, respectively. Most of our matches are taken from Budavári et al. (2009) who matched GALEX-GR6 to SDSS-DR7. For this study, we have taken only the most secure matches; that is, only one SDSS quasar matched to only one GALEX point source. This algorithm gives 14,302 matches and leaves out 53,782 quasars that have multiple SDSS sources matching to the same GALEX source. In addition to these data, we include forced point-spread function (PSF) photometry (Bovy et al. 2011, 2012) on the GALEX images in the positions of the SDSS point sources, which adds 61,490 detections. As with 2MASS, we only kept the extracted data with S/N $\geq 2$, and as with the Budavári et al. (2009) limits, we limit the sample to those with no source confusion; this reduces the number of extracted quasars to 27,744. Combining both sets, the total number of matches is 42,046. All GALEX photometry has been corrected for Galactic extinction, assuming $A_{\text{NUV}} = 8.741 \times E(B-V)$ and $A_{\text{FUV}} = 8.24 \times E(B-V) - 0.67 \times E(B-V)^2$ (Wyder et al. 2007). The $E(B-V)$ values are taken from the Schneider et al. (2010) catalog. All the matched data are given in Table 1.

2.4. X-Ray

To construct full SEDs, we must extend our data into the X-ray regime. Due to comparatively limited sky coverage of sensitive X-ray observations, the number of our quasars with X-ray data is quite small compared to the size of the samples in the optical and IR. For example, there are only 277 matches in the ChaMP data set (Green et al. 2009). So instead we take advantage of the careful work on mean X-ray properties as a function of UV luminosity as compiled by Steffen et al. (2006). Specifically, we determine the X-ray flux of each quasar using the $L_{\text{UV}} - L_X$ relation that parameterizes the correlation between the 2500 Å and 2 keV luminosity of quasars. We find the 2500 Å luminosity by extrapolation from the closest filter using an $\alpha_{\text{opt}} = -0.44$ (Vanden Berk et al. 2001). The 2 keV luminosity is estimated using Equation (2) and our 2500 Å luminosities. An X-ray energy spectral index $\alpha_{\text{x}} = -1$ (photons index $\Gamma = -2$) was assumed between 0.2 keV and 10 keV (e.g., George et al. 2000). In this way, we can estimate the X-ray part of the SED for all of our sources rather than using just the small fraction of objects with robust X-ray detections. This process ignores the correlations between $\alpha_{\text{ox}}$ (and $\alpha_{\text{opt}}$) and $\alpha_{\text{x}}$ as discussed in Kruczek et al. (2011); however, these trends are small as compared to the overall trend with luminosity.

As a check we have compared our X-ray extrapolations to ChaMP data from Green et al. (2009; see Section 4). In all cases we found the X-ray data to fall within the 1.5$\sigma$ limits of the $\alpha_{\text{ox}}$ extrapolation.

3. CORRECTIONS

When studying quasar SEDs, we are interested in the true continuum level of the radiated light. The continuum may be contaminated by, for example, spectral emission lines, absorption by intergalactic hydrogen clouds, host galaxy contamination, and beaming effects. Here we address each of these features. For the hydrogen absorption and broad emission lines, we determine a magnitude correction by folding a model through the filter curves as discussed below. For the host galaxy correction, we subtract a model template. We do not consider beaming specifically, but refer the reader to Runnoe et al. (2012) for a discussion of how our results would change under the assumption of non-isotropic emission; see also Nemmen & Brotherton (2010).

3.1. Lyman Forest and Limit

A particular challenge is to determine the SED in the extreme UV (EUV) ($\lambda_{\text{rest}} < 1216$ Å) part of the spectrum where intergalactic hydrogen causes significant attenuation of the quasar signal (Ly$\alpha$ forest; Lynds 1971). To account for this attenuation, the redshift-dependent effective optical depth, $\tau_{\text{eff}}(z, \lambda)$, of Meiksin (2006) was used. This optical depth model gives the average attenuation of a source assuming Poisson-distributed intergalactic hydrogen along the line of sight, out to a given redshift. This optical depth is split into three parts: the contribution due to resonant scattering by Lyman transitions, systems with optically thin Lyman edges, and Lyman Limit Systems (LLS). Figure 5 shows this model for redshifts of 1, 2, and 3 for both LLS and non-LLS.

Because our investigation uses photometry and not spectra, we do not know whether a LLS is present. Furthermore, we only have spectral coverage of the LLS region for a fraction of our sources. Thus, to be as conservative as possible, we assume that there is no LLS present; that way we only make the minimum correction needed for each SED. However, it is important to note that the SDSS quasar selection algorithm has been shown to preferentially select quasars possessing a LLS in the range $3 \lesssim z \lesssim 3.5$ (Worseck & Prochaska 2011).

For the continuum ($F_\nu$) we have assumed a power-law of the form $\nu^{-0.44}$ (Vanden Berk et al. 2001), consistent with the results of Scott et al. (2004). Continuum weighting is...
necessary since we are dealing with broadband photometry and not spectroscopy. With high resolution spectroscopic data the correction is exact as the Meiksin (2006) corrections themselves are independent of the SED. However, for broadband photometry, where the bandpass can overlap features in the τ distribution, the convolution of the SED with the filter response changes the effective wavelength of the bandpass.

To apply the Lyman forest correction, we convolve a continuum with the Meiksin (2006) optical depth and each filter over $0 < z < 6$ in Δz steps of 0.01 and use linear interpolation to precisely match redshifts. Following Meiksin (2006), the correction is given in magnitudes as a transmission-weighted average of τ:

$$K_{\text{IGM}} = -2.5 \times \log \left( \frac{\int S_\lambda F_\lambda e^{-\tau_{\text{eff}}} \, d\lambda}{\int S_\lambda F_\lambda \, d\lambda} \right),$$

where $S_\lambda$ is a transmission filter curve, $F_\lambda$ is the continuum, and $\tau_{\text{eff}}$ is the redshift-dependent effective optical depth. This value is calculated independently for each filter and makes $m(\tau = 0) = m(\tau) - K_{\text{IGM}}$ such that all quasars are made brighter in the Lyman absorption regions as a result of the correction.

### 3.2. Emission Lines

The presence of emission lines in a photometric bandpass affects quasar magnitudes as illustrated by Richards et al. (2006b, e.g., see their Figures 8 and 17). Thus, to make a fair comparison between sources at all redshifts, we endeavor to remove first-order effects of the emission line contributions to the measured magnitudes. Our emission-line template takes the position, width, and equivalent width (EW) of the 13 strongest spectral lines (as labeled in Figure 6) from Vanden Berk et al. (2001). We make no attempt to correct for the small blue bump (i.e., Balmer continuum or Fe II emission), but recognize

$$K_{\text{em}} = -2.5 \times \log \left( \frac{\int S_\lambda F_\lambda(c&l) \, d\lambda}{\int S_\lambda F_\lambda(c) \, d\lambda} \right),$$

where $S_\lambda$ is a transmission filter curve, $F_\lambda(c)$ is the continuum, and $F_\lambda(c&l)$ is the continuum with spectral lines. This value is calculated independently for each filter and makes $m(c) = m(c&l) - K_{\text{em}}$, such that all quasars are made fainter by the removal of the emission line contribution.

We further use this template to illustrate the correction for hydrogen absorption (assuming the quasar is at $z = 3.75$ and there is a LLS). Overall, we find reasonable agreement (by eye) with the mean composite spectrum from Vanden Berk et al. (2001) in terms of the continuum, broad emission lines, and intergalactic medium (IGM) attenuation.

In Figure 7, we illustrate the effect of those emission-line and IGM corrections using a mock spectrum of a $z = 3$ quasar. The closed diamonds bifurcated by solid lines indicate the “measured” instrumental magnitudes, while open diamonds bifurcated by dashed lines indicated the corrected values (assuming an underlying power-law SED). The width of the lines indicate the width of the bandpasses. Here we have corrected for IGM attenuation (Section 3.1) and emission line flux (Section 3.2).

It is also necessary to correct the data for host galaxy contamination. Since we lack the data to measure this directly, we must estimate the host galaxy contribution. To do this, we combine two different models: the relation outlined in Shen et al. (2011) for the higher luminosity quasars, and the relationship from Richards et al. (2006a) for the lower luminosity quasars.

![Figure 6. Vanden Berk et al. (2001) composite spectra (black) with our model spectrum with a LLS (red) at a redshift of 3.75. Since the SDSS spectra cover 3800–9200 Å, the contributors to the points at λrest < 1216 Å are high-z quasars and are consistent with the model used. Since we model the main emission line features, on average, they should not appear in the SEDs. However, unmodeled residuals in Fe II and the Balmer continuum (small blue bump) can clearly be seen in the SEDs on either side of the Mg II emission line at 2800 Å. We use a double power law continuum in this figure since the composite spectra do not correct for host galaxy contributions on the red end. Model spectra used to correct our SEDs are placed on a single power law as shown in Figure 7.](image1)

![Figure 7. Observed frame mock spectrum (solid line) and λrest = 4.4 continuum (dotted line) for a z = 3 quasar. The closed diamonds bifurcated by solid lines indicate the “measured” instrumental magnitudes, while open diamonds bifurcated by dashed lines indicated the corrected values (assuming an underlying power-law SED). The width of the lines indicate the width of the bandpasses. Here we have corrected for IGM attenuation (Section 3.1) and emission line flux (Section 3.2).](image2)
The Shen et al. (2011) relationship is

\[
\frac{L_{\lambda=5100\,\text{Å},\,\text{host}}}{L_{\lambda=5100\,\text{Å},\,\text{QSO}}} = 0.8052 - 1.5502x + 0.9121x^2 - 0.1577x^3
\]

where

\[x \equiv \log \left( \frac{\lambda_{5100}\,\text{Å} \times L_{\lambda=5100\,\text{Å},\,\text{total}}}{\text{erg s}^{-1}} \right) - 44\]

and

\[0 \leq x < 1.053,\]

which sets the relative scaling at 5100 Å. To extend this expression to all wavelengths, we use the elliptical galaxy template of Fioc & Rocca-Volmerange (1997) scaled to 5100 Å. When \(x \geq 1.053\), the quasar completely outshines the host galaxy and no correction needs to be applied. We note that this relationship was found using quasars that have \(\log (L_{\lambda=5100\,\text{Å},\,\text{total}}) \geq 44\), and cannot, in general, be extrapolated to lower luminosities.

We found that, for lower luminosity quasars, the Shen et al. (2011) equation overestimates the host galaxy; we instead use the relationship from Richards et al. (2006a) which was adapted from the relationship used by Vanden Berk et al. (2006):

\[
\begin{align*}
\log (L_{\lambda=6156\,\text{Å},\,\text{host}}) &= 0.87 \log (L_{\lambda=6156\,\text{Å},\,\text{AGN}}) \\
&+ 2.887 - \log (L_{\text{bol}}/L_{\text{Edd}}),
\end{align*}
\]

where \(\log (L_{\lambda=6156\,\text{Å},\,\text{AGN}}) = \log \left( \frac{L_{\lambda=6156\,\text{Å},\,\text{total}}}{\text{erg s}^{-1} \text{Hz}^{-1}} - \frac{L_{\lambda=6156\,\text{Å},\,\text{host}}}{\text{erg s}^{-1} \text{Hz}^{-1}} \right)\).

This system of equations is then solved numerically for the host galaxy luminosity. As in Richards et al. (2006a) we take \(L_{\text{bol}}/L_{\text{Edd}}\) to be unity, since this provides the minimum correction needed. This sets the relative scaling at 6156 Å and, as before, we use the elliptical galaxy template of Fioc & Rocca-Volmerange (1997) to extend this to all wavelengths. To ensure a smooth transition between these two methods, we have chosen the crossover luminosity to be the point at which both methods agree, \(\log (L_{\lambda=5100\,\text{Å},\,\text{total}}) = 44.75\). As host galaxy subtraction can have a large impact on the SED near 1 µm and it is not a well-established procedure, we note that other methods include Croom et al. (2002), and Maddox & Hewett (2006).

It was brought to our attention that the host galaxy model used in Richards et al. (2006a) was incorrect (K. Leighly, private communication). The model was converted from \(F_{\nu}\) to \(F_{\nu}\), but not converted to \(\nu F_{\nu}\) before subtracting it from the SEDs. This does not affect the SED at 5100 Å, where the SEDs are normalized, but it is systematically wrong on either side of this wavelength. Herein we correct that error.

3.4. Gap Repair

Since all the quasars in our sample have been selected from SDSS photometric data, they all have \(ugriz\) measurements, but are not guaranteed to have measurements in the other bandpasses that we utilize. To address this issue we will “gap repair” all missing data in a way similar to Richards et al. (2006a). Specifically, we replace missing values with those determined by normalizing an interpolation/extrapolation of the continuum in the next nearest bandpass for which we have data. Sometimes this will be a previously constructed mean SED; other times it will be a functional form. To estimate errors for the gap filled points, we have fit up to third-order polynomials to plots of the magnitude errors, \(\log(\sigma_m)\), versus magnitudes, \(m\), for each of the filters. These functions were then used to estimate \(\sigma_m\) for the gap filled value for \(m\).

This procedure works well where we can interpolate between filters (e.g., at wavelengths longward of the Lyman limit). Beyond the Lyman limit, we are no longer interpolating, but extrapolating, which is a trickier process. Using limiting magnitudes does not solve the problem as redshift effects mean that even if all quasars had coverage from all of the filters, the same rest-frame wavelengths are not observed for both high- and low-redshift quasars.

On the long wavelength end, we always extrapolate to longer wavelengths using the mean SED from Richards et al. (2006a), normalized to the nearest measured bandpass. On the short wavelength end, the gap repair process depends on whether we are making a mean SED or attempting to reconstruct the SED for an individual quasar (e.g., to determine its bolometric luminosity). See below for details for specific cases.

Unless otherwise stated, the X-ray part of the SED is determined using Equation (2), the \(L_{\text{bol}}-\alpha_{\text{bol}}\) relation from Steffen et al. (2006), and linearly interpolating between the X-ray and the bluest data point after gap repair. The errors in this region are determined from the uncertainties of the Steffen et al. (2006) relation.

4. MEAN SEDs

4.1. Overall Mean SED

To determine the mean quasar SED, we converted all the flux densities for each quasar to luminosity densities and shifted each broadband observation to the rest frame. The data were then placed onto a grid with points separated by 0.02 in \(\log (\nu)\); kriging was then used to align the broadband luminosities to our grid points. Kriging is a nonparametric interpolation method that predicts values and errors for regions between observed data points. Rybicki & Press (1992) were among the first to present this technique in the astronomical literature (under the name Wiener filtering). Since then it has been mainly used to estimate light curves (e.g., Koźlowski et al. 2010).

Kriging estimates the correlation between data points as a function of separation, then uses this correlation to interpolate between the data points. We used the R package gstat to perform variance-weighted kriging using an exponential variogram model. Once the data are rebinned in the rest-frame, the arithmetic mean and standard deviation are taken at each grid point. Because kriging estimates variance values at each of the new grid points, we are able to estimate errors on our bolometric luminosities and the derived bolometric corrections.

Figure 8 shows the “raw” data points (without the corrections described in Section 3) and mean for all the quasars in our sample. On the red end, the SED drops due to a lack of data and on the blue end, shortward of the Ly\(\alpha\) line, there is a clear drop due to intergalactic extinction. The flattening in the mean shortward of the Lyman limit is due to redshift effects; low-redshift sources have no rest-frame measurements at this frequency, biasing the data toward higher luminosity.

To find the corrected mean SED, we first construct a “gap filling” SED by looking at the mean SED of \(\sim2100\) quasars with full wavelength coverage; i.e., they have at least four data points in mid-IR, at least three data points in the near-IR, and full coverage with GALEX in the UV. Redshift effects cause the SED coverage in the rest frame to drop off sharply around the Lyman series. To avoid the mean being biased toward the
## Table 2
Mean Quasar SEDs

| log (ν [Hz]) | All | σ_{All} | Low Lum. | Mid Lum. | High Lum. | C IV Line Zone 1 | C IV Line Zone 2 | UV Bump | Scott UV | Casebeer UV |
|-------------|-----|---------|---------|----------|----------|-----------------|-----------------|---------|----------|-------------|
| 13.0        | 45.201 | 0.52    | 44.844  | 0.24     | 45.272   | 0.2             | 45.434          | 0.31    | 45.213   | 0.55        |
| 13.02       | 45.221 | 0.52    | 44.864  | 0.24     | 45.292   | 0.2             | 45.454          | 0.31    | 45.233   | 0.55        |

| 13.06       | 45.241 | 0.52    | 44.884  | 0.24     | 45.312   | 0.2             | 45.474          | 0.31    | 45.253   | 0.55        |
| 13.08       | 45.251 | 0.52    | 44.894  | 0.24     | 45.322   | 0.2             | 45.484          | 0.31    | 45.263   | 0.55        |
| 13.1        | 45.271 | 0.52    | 44.914  | 0.24     | 45.342   | 0.2             | 45.504          | 0.31    | 45.273   | 0.55        |
| 13.12       | 45.281 | 0.52    | 44.924  | 0.24     | 45.352   | 0.2             | 45.514          | 0.31    | 45.283   | 0.55        |
| 13.14       | 45.291 | 0.52    | 44.934  | 0.24     | 45.362   | 0.2             | 45.524          | 0.31    | 45.293   | 0.55        |
| 13.16       | 45.301 | 0.52    | 44.944  | 0.24     | 45.372   | 0.2             | 45.534          | 0.31    | 45.303   | 0.55        |
| 13.18       | 45.301 | 0.52    | 44.944  | 0.24     | 45.372   | 0.2             | 45.534          | 0.31    | 45.313   | 0.55        |

**Notes.** All of the SEDs are taken to have $\alpha_x = -1$ above 0.2 keV. Units are log(erg s$^{-1}$).

(This table is available in its entirety in a machine-readable form in the online journal. A portion is shown here for guidance regarding its form and content.)

---

**Figure 8.** Top: mean uncorrected SED (solid line), data points for all quasars, and 1σ level (dash-dotted line) for the raw sample (no corrections applied, see Section 3). The steep drop-off on the red end is caused by the lack of high luminosity, low redshift quasars in our sample; this is caused by both quasar evolution and the fact that at lower redshifts we sample a smaller volume of the universe. The white wedges between the filters are caused by the limiting magnitudes for each filter. The drop-off just shortward the Ly$\alpha$ line is due to IGM attenuation, but the flattening shortward of the Lyman limit is due to the lack of low-luminosity, high-redshift quasars, caused by the detection limits of the surveys. Bottom: the number of SEDs averaged at each frequency. The two vertical magenta lines show the positions of the Ly$\alpha$ line at 1216 Å and the Lyman limit at 912 Å.

(A color version of this figure is available in the online journal.)

**Figure 9.** Top: mean “gap filling” SED (solid line), based on ~2100 quasars with full broadband wavelength coverage. To avoid a bias toward high luminosity at the blue end where the number of quasars drops off, the mean is truncated at 1216 Å, and connected with the X-ray (see text). Bottom: the number of SEDs averaged at each frequency. The dotted line indicates the data that is not used due to truncation (see text). The two vertical magenta lines show the positions of the Ly$\alpha$ line at 1216 Å and the Lyman limit at 912 Å.

(A color version of this figure is available in the online journal.)

Higher luminosity SEDs in this region have truncated this gap filling mean SED where the total number of quasars drops (around 1216 Å) and use the UV luminosity, $\langle L_{2500 \AA} \rangle$, to find the X-ray luminosity using Equation (2). We do this instead of using actual X-ray data since there are too few X-ray detections and Steffen et al. (2006) have already done the careful work of extracting the relationship between the UV and the X-ray parts of the SED.

Both radio-loud and radio-quiet quasars are included. The mean SED of 108,184 quasars is given in tabular form in Table 2. Figure 10 shows the resulting mean with the Richards et al. (2006a) mean, the Vanden Berk et al. (2001) power law, a typical host galaxy, and the ChaMP X-ray data included for comparison. The difference between our mean SED and that of Richards et al. (2006a) in the 912–1216 Å region is due to our region that is not well sampled with our gap-filling SED. We then truncate the mean at 912 Å and use the mean UV luminosity, $\langle L_{2500 \AA} \rangle$, to find the X-ray luminosity using Equation (2). We do this instead of using actual X-ray data since there are too few X-ray detections and Steffen et al. (2006) have already done the careful work of extracting the relationship between the UV and the X-ray parts of the SED.

Both radio-loud and radio-quiet quasars are included. The mean SED of 108,184 quasars is given in tabular form in Table 2. Figure 10 shows the resulting mean with the Richards et al. (2006a) mean, the Vanden Berk et al. (2001) power law, a typical host galaxy, and the ChaMP X-ray data included for comparison. The difference between our mean SED and that of Richards et al. (2006a) in the 912–1216 Å region is due to our
more careful corrections of systematic effects in this region as described in Section 3. The abrupt change in the slope of the SED at ~1100 Å is not expected to be real, but rather represents our lack of knowledge of this region of the SED. We are largely limited to simply connecting the two better known regions of the NUV and soft X-ray with a power law. We will further discuss the range of possible FUV continua in Section 6.

4.2. Sub-sampled Mean SEDs

While the overall mean quasar SED is a useful tool, examining how the SED changes as a function of various quasar parameters may shed light on the physical processes of the central engine. For example, Richards et al. (2006a) found that bolometric corrections (see Section 5) differed by as much as a factor of two in the extremes of quasar types, but with only 259 objects Richards et al. (2006a) did not have the data necessary to comment on what physics is behind the range of bolometric corrections. Marconi et al. (2004) provide a luminosity-dependent bolometric correction, but this is largely dependent on the $L_{\text{UV}} - \alpha_{\text{ox}}$ relationship and is built into the Richards et al. (2006a) bolometric corrections. What we seek (with the aid of a substantially larger sample) is a more physical understanding of the SED differences and the resulting changes in bolometric correction.

In an attempt to better understand the physics that lead to differences in SEDs (and bolometric corrections), we consider two parameters herein, specifically the UV luminosity and C iv emission line properties. While it is also important to consider SEDs as a function of mass and accretion rate, those quantities are not directly measurable; we will leave that analysis to future work (C. M. Krawczyk et al. 2013, in preparation). Luminosity-dependent SEDs (Section 4.2.1) are of interest because of the known $L_{\text{UV}} - \alpha_{\text{ox}}$ relationship and strong dependence of accretion disk wind physics on the UV to X-ray flux ratio (e.g., Proga et al. 2000). Examining the mean SED as a function of C iv emission line properties (Section 4.2.2) is interesting because that line may be an indicator of the true SED as it serves as a diagnostic of which two components dominate the broad emission line region (BELR; Richards et al. 2011; Wang et al. 2011). In fact, UV emission lines like C iv, with ionization potentials in the EUV part of the spectrum, may even be an indicator of the unseen EUV part of the SED (see Section 6).

4.2.1. Luminosity-dependent Mean

The well-known nonlinear relationship between the UV and X-ray luminosities means that the SED (and thus the bolometric correction) must be a function of luminosity. As a first test, we have split the sample into three equally populated luminosity bins, each containing 36,061 quasars. Figure 11 shows the cumulative histogram of log($\nu L_\nu$) at $\lambda = 2500$ Å for all quasars, with the vertical lines showing the luminosity cuts. In order to separate the changes that potentially arise from evolution from those that are luminosity-dependent, we marginalize over redshift by selecting sub-samples from each bin that each have the same redshift distribution. The inset of Figure 11 shows the redshift distribution for the three bins; the shaded region shows the redshift distribution of the sub-samples. This process leaves ~10,000 quasars in each luminosity bin as compared to the 259 total objects in Richards et al. (2006a) across all luminosity bins.

We calculated the luminosity-dependent mean SEDs in an iterative way. As a first step we follow the same steps as the overall mean SED: we used our gap-filling SED to interpolate/extrapolate over gaps in the photometry with $\lambda > 912$ Å and truncated the mean SEDs at 912 Å. These mean SEDs were then connected to the X-ray points determined using the mean
Figure 12. Mean SEDs for low (log ($\nu L_{\nu}$) | $\lambda = 2500$ Å $\leq 45.41$) luminosity quasars (a), mid (45.41 < log ($\nu L_{\nu}$) | $\lambda = 2500$ Å $\leq 45.85$) (b), and high (45.85 < log ($\nu L_{\nu}$) | $\lambda = 2500$ Å) (c). Panel (d) shows the three curves overplotted. See Figure 8 for an explanation of the scatter points in panels (a)–(c) and the bottom histogram of panel (d). The high luminosity SED has more hot dust emission (at 2–4 μm), a smaller Balmer continuum (λ < 3000 Å), a harder (bluer) optical spectrum (λ < 3000 Å), and a softer (redder) UV spectrum (λ > 3000 Å); see Figures 13(a) and (b).

UV luminosity for each sample. The resulting mean SEDs were then used as the new gap-filling SEDs for each luminosity bin. For all remaining iterations all missing photometry was filled, and the resulting mean SEDs were truncated at 800 Å (where the sampled number starts to fall) before connection to the X-ray. Figure 12 shows the mean SEDs and data for each of the luminosity bins after 10 iterations. The iteration process described above ensures that our mean SED follows the quasars with data in each luminosity bin instead of the initial gap filling model. The redshift marginalization process means that the mean redshift of all three luminosity samples is $z \sim 1.5$. The mean SEDs are given in tabular form in Table 2.

Figure 13(a) shows the mid-IR region of the three SEDs when they are normalized at 1.3 μm and Figure 13(b) shows the optical (λ < 3000 Å) and UV region (λ > 3000 Å) when normalized at 1450 Å. The thick lines indicate where a Welch’s t test shows the mean SEDs have less than a 1% chance of being the same ($p < 0.01$). The high-luminosity SED has more hot dust emission (at 2–4 μm), a small Balmer continuum (λ < 3000 Å), a harder (bluer) optical spectrum, and a softer (redder) UV spectrum. The low-luminosity quasars would have to have host galaxies $\sim 8$ times more luminous than assumed in order for the optical slopes at λ < 3000 Å to agree between the low-luminosity and high-luminosity SEDs (thus the redder continuum is likely to be intrinsic and not due to host-galaxy contamination). The UV region is sensitive to the Lyman series corrections (Section 3.2), but these corrections are not luminosity dependent. The Welch’s t test shows the prominent 10 μm silicate bumps in the high-luminosity objects are present.

Krawczyk et al.

(a) Luminosity SEDs normalized at 1.3 μm
(b) Luminosity SEDs normalized at 1450 Å
(c) C IV SEDs normalized at 2027 Å
(d) BC SEDs normalized at 2500 Å

Figure 13. Normalized SEDs with the y-axis showing relative luminosity. The thick lines indicate where the probability of the mean SEDs being the same is less than 1% and the vertical dashed lines indicate the normalization frequency. (a) Luminosity-dependent SEDs normalized at 1.3 μm; high-luminosity quasars appear to have more hot dust emission. (b) Luminosity-dependent SEDs normalized at 1450 Å; high-luminosity quasars have softer EUV continua. (c) C IV-dependent SEDs normalized at 2027 Å. Zone 1 (disk-dominated) quasars have more Balmer continuum and stronger Lyα emission than Zone 2 (wind-dominated) quasars. See Figure 14. (d) Bolometric correction-dependent SEDs normalized at 2500 Å, showing the effect that most of the range in BC comes from the range of UV and EUV continua (and dust).

(A color version of this figure is available in the online journal.)

statistically significant. The IR bumps are discussed in more detail in Gallagher et al. (2007).

One of our goals in considering the luminosity-dependent mean is to investigate the shape of the SEDs over 500 < λ_rest (Å) < 1200. Given the corrections necessary in this region (Section 3.2), the shape here is necessarily uncertain; however, the data supports a harder slope with lower luminosity (see Figure 13(b)). This is consistent with the results of Scott et al. (2004) and suggests that the X-ray flux may not be the only part of the SED that has a nonlinear relationship to $L_{2500\text{Å}}$. This behavior is also seen in the spectral principal component analysis of Yip et al. (2004) who found that their third eigenvector shows an anti-correlation of the continua on either side of Lyα. In short, quasars that are bluer longward of Lyα have softer (redder) continua in the Lyα forest region. This can have important consequences for bolometric corrections; see Section 5.

4.2.2. C IV-dependent Mean

While the Baldwin Effect (Baldwin 1977) reveals that there is a relationship between the strength of UV emission lines and the continuum luminosity, Richards et al. (2011) have argued that the C IV (and other UV emission lines) properties are better diagnostics of the shape of the SED than its absolute scaling. If that is the case, SEDs made as a function of emission line properties such as C IV blueshift and EW (Richards et al. 2011) or Principal Component Analysis (e.g., “Eigenvector 1”; Boroson & Green 1992; Brotherton & Francis 1999) may reveal interesting differences. Any such differences would have important implications for bolometric corrections of individual objects.

Thus, in addition to luminosity sub-samples, we have also divided the data as a function of C IV blueshift and rest-frame EW (Richards et al. 2011). To see if the SED shape depends on these properties, we have taken two zones that are representative of extrema in disk-wind structures according to Richards et al. (2011; see also Wang et al. 2011): Zone 1, blueshifts <600 km s$^{-1}$ and EW > 50 Å (i.e., with “disk-dominated” BELRs) and Zone 2, blueshifts > 1200 km s$^{-1}$ and EW < 32 Å (i.e., with “wind-dominated” BELRs). These cuts are chosen to have roughly the same number of objects in each sample. In Zone 1 there are 5736 quasars with a mean log $(\nu L_{\nu}) |_{\lambda=2500\text{Å}} = 45.9$, and Zone 2 contains 5713 quasars with a mean log $(\nu L_{\nu}) |_{\lambda=2500\text{Å}} = 46.2$. Figure 14 shows the data and mean SEDs for the quasars in each zone. For these
mean SEDs, we used the mean mid-luminosity SED for the initial gap repair to all the filters and truncated the mean at 800 Å before connecting it with the X-ray. We then took the resulting mean SED and used that to gap repair in the same way; this was repeated 10 times. We note that there is a difference in mean luminosity between Zones 1 and 2; however, we have not gap-filled with the luminosity-dependent SEDs in order to isolate any residual differences. The mean SEDs are given in tabular form in Table 2.

Our primary interest in these SEDs lies in the UV part of the spectrum; however, it seems that there is relatively little that can be learned about that region from this sample. Seeing C iv requires that the sample is restricted to $z \geq 1.6$, which has a number of consequences. In particular, it limits the sample to the highest luminosities and the redshift limit introduces a bias toward LLS (Worseck & Prochaska 2011), which may be the cause of the steep fall-off beyond Ly$\alpha$. However we are able to see differences in the optical/UV continuum consistent with eigenvector 1 analyses (Brotherton & Francis 1999). In particular, Figure 13(c) shows that the Zone 1 mean SED has a larger Balmer continuum ($\lambda < 3000$ Å) and stronger Ly$\alpha$ emission, consistent with eigenvector 1 analyses. Figure 13 shows an expanded version of panel (c).

(A color version of this figure is available in the online journal.)

**Figure 14.** Mean SEDs for quasars in two zones of the C iv blueshift vs. C iv EW plane. Panel (a) shows Zone 1: BS $< 600$ km s$^{-1}$ and EW $> 50$ Å (disk-dominated objects in Richards et al. 2011). Panel (b) shows Zone 2: BS $> 1200$ km s$^{-1}$ and EW $< 32$ Å (wind-dominated objects in Richards et al. 2011). Panel (c) shows the two curves overplotted. See Figure 13(c) for explanation of scatter points in panels (a and b) and the bottom histogram of panel (c). The Zone 1 mean SED shows a larger Balmer continuum ($\lambda < 3000$ Å) and stronger Ly$\alpha$ emission, consistent with eigenvector 1 analyses. Figure 13 shows an expanded version of panel (c).
5. BOLOMETRIC CORRECTIONS

One of the main goals of this study is to characterize the bolometric luminosities of quasars. The bolometric luminosity is the integrated area under the SED curve and can be calculated as

\[ L_{\text{bol}} = \int_0^\infty L_\nu d\nu = \int_{-\infty}^{\infty} \ln(10)\nu L_\nu \, d\log(\nu), \]  

(7)

where Figures 8 and 10 plot the quantity \( \nu L_\nu \). Normally, we do not have an accurate measurement of the full SED for a quasar, but we can estimate the bolometric luminosity by assuming some SED template and using a known monochromatic luminosity, \( L_{\nu_0} \). This “bolometric correction” (BC) is given as

\[ \text{BC}_\nu = \frac{L_{\text{bol}}}{\nu L_{\nu_0}}. \]  

(8)

In the next sections we will discuss our choices for limits of integration, normalization wavelength/frequency, and SED models.

5.1. Limits of Integration

As was discussed by Marconi et al. (2004), the full observed SED includes light that is not directed to the observer along its original line of sight. Thus, the SED determined in this manner is not the intrinsic one. For example, most of the IR radiation (~30 \( \mu \)m–1 \( \mu \)m) is believed to be produced in a large toroidal dusty region beyond the accretion disk (e.g., Krolik & Begelman 1988; Elitzur & Shlosman 2006). The radiation from this “dusty torus” arises from the reprocessing of higher energy photons emitted by the accretion disk and re-radiated by the torus in the IR. Any optical–UV radiation that does not come directly to the observer, but is instead reprocessed by dust, is effectively double-counted when determining the true bolometric luminosity. Because of this effect, Marconi et al. (2004) do not include the IR bump when computing their bolometric corrections. Their choice of integration limits of 1 \( \mu \)m–500 keV is well justified, although strictly speaking the optical/UV bump must also be corrected for dust reddening along the direct line of sight; otherwise, the observed luminosity will be smaller than the true intrinsic luminosity.

Here we describe a similar effect in the hard X-ray band (energies larger than 2 keV). While it is thought that IR flux can include reprocessed disk emission, so too can the hard X-ray emission. The accretion disk itself can emit thermal soft X-ray photons from the inner part of the accretion disk, but hard X-ray photons are believed to come from Compton upscattering of accretion disk photons off hot electrons in the so-called corona. Depending on the geometry of the corona, it may or may not be appropriate to include the hard X-ray part of the SED in the bolometric luminosity in the same way that Marconi et al. (2004) suggest avoiding the IR emission. If the corona is a hot spherical region surrounding the black hole (Sobolewska et al. 2004a) then one should exclude the highest energy photons from the tabulation of the “intrinsic” luminosity. However, if the corona is more like a patchy skin to the accretion disk as in Sobolewska et al. (2004b), including the hard X-ray flux in the SED would be more appropriate. Our solution here is an agnostic one; instead of presenting the full integrated luminosity, we will give it in four pieces: 30 \( \mu \)m–1 \( \mu \)m, 1 \( \mu \)m–2 keV, 2 keV–10 keV, and 10 keV–500 keV (see Table 3), allowing the user to determine which approach is best. Although, given the small amount of data and the large uncertainties in the X-ray, we do not recommend taking BCs based on monochromatic X-ray luminosities as proposed by Vasudevan & Fabian (2007).

5.2. Normalization Wavelength

Typically, bolometric corrections are computed with respect to 5100 Å and we will report those values herein for backward compatibility with previous work. However, we will generally report BCs relative to 2500 Å. There are a number of reasons for this choice. While 5100 Å makes sense for low-redshift sources, especially when using the H\( \beta \) line to estimate black hole masses and then the Eddington ratio from the ratio of \( L_{\text{bol}} \) to \( M_{\text{BH}} \), that rest-frame wavelength is inaccessible for the vast majority of SDSS quasars. The SDSS quasar sample peaks at \( z \sim 1.5 \), which corresponds to rest-frame spectral coverage of \( \sim 1500–3700 \) Å. As such, the majority of SDSS quasars have observed flux density measurements at 2500 Å. For this reason, Richards et al. (2006b) chose to \( K \)-correct to \( z = 2 \) where the SDSS \( i \)-band roughly corresponds to \( \lambda_{\text{eff}} = 2500 \) Å. Moreover, 2500 Å is typically used as the optical anchor point in the \( L_{\alpha\nu}–L_{\alpha \alpha} \) relationship. In addition to this, the 5100 Å luminosity always has a larger host galaxy contamination. As such, we have chosen to use 2500 Å as our fiducial wavelength.

5.3. Integrated Luminosities and Bolometric Corrections

For comparison with previous work, we compute the bolometric luminosity in a number of ways, including the tabulation of integrated optical and IR luminosities. In terms of bolometric corrections, we start by computing BCs for each individual object in our sample, and, with those, compute mean BCs for the full sample. In computing BCs we used SEDs constructed as discussed above; namely, using broadband observations where available, the \( L_{\alpha\nu}–L_{\alpha \alpha} \) relationship, and “gap-filling” (with the mid-luminosity mean SED) as needed. The overall mean BC_{2500 Å} and corresponding standard deviation values are 2.75 ± 0.40 using limits of 1 \( \mu \)m and 2 keV (hereafter called \( L_{\text{disk}} \), which avoids the issue of IR and hard X-ray double counting); at 5100 Å this corresponds to 4.33 ± 1.29. For comparison with Elvis et al. (1994) and Richards et al. (2006a), we also determine the bolometric correction to 5100 Å in the range of 30 \( \mu \)m up to 10 keV. We find BC_{5100 Å} = 7.79 ± 1.69, as compared to the results of Elvis et al. (1994) and Richards et al. (2006a) who found 11.8\textsuperscript{±}12.9 and 10.3 ± 2.1, respectively. Using the range 1 \( \mu \)m to 500 keV from Marconi et al. (2004) we find that BC_{2500 Å} = 2.97 ± 0.43.

Recent studies by Nemmen & Brotherton (2010) and Runnoe et al. (2012) suggest the relationship between a quasar’s monochromatic and bolometric luminosity is nonlinear. As is expected given the nonlinear relationship used to connect the UV and the X-ray, we also find this to be the case; our best fit is a power-law of the form

\[ \log (L_{\text{Bol}}) = (0.9869 \pm 0.0003) \log (\nu_{2500 Å} L_{2500 Å}) + (1.051 \pm 0.014). \]  

(9)

Note that while we allow for a nonlinear slope, the best-fit slope is very close to linear. The errors quoted on this fit are small because of our large sample size and only statistical, not systematic, errors are included.

In addition to mean BCs, we give BCs and error estimates for each of the objects in our sample; these are shown by the points and contours in Figure 15. As did Marconi et al. (2004),
### Table 3
Bolometric Luminosities and Bolometric Corrections

| SDSS ID        | log ($\nu L_{2500\text{Å}}$) | log ($\nu L_{5100\text{Å}}$) | BC$_{\text{disk}}^a$ | log ($L_{30\mu\text{m}–1\mu\text{m}}$) | log ($L_{1\mu\text{m}–2\text{keV}}$) | log ($L_{2\text{keV}–10\text{keV}}$) | log ($L_{10\text{keV}–500\text{keV}}$) |

**Notes.** All luminosities are reported in log (erg s$^{-1}$).

$a$ Taken over the range of 1 $\mu$m to 2 keV.

(This table is available in its entirety in a machine-readable form in the online journal. A portion is shown here for guidance regarding its form and content.)
we investigate how the BCs are dependent on quasar luminosity and, in turn, on the $L_{\alpha}$–$\alpha_{\text{ox}}$ relation that was assumed. The black dotted line in Figure 15 shows the luminosity-independent BC that one gets for our mean SED and assuming a linear dependence between $L_{\alpha}$ and $L_{X}$ (i.e., re-normalizing the mean SED without changing $\alpha_{\text{ox}}$). To illustrate the importance of the observed nonlinear correlation between $L_{\alpha}$ and $L_{X}$ we do the following. We re-normalize our mean SED to $L_{2500}$ values that span the range shown in Figure 15, stepping in small increments. We then truncate the mean SED at 1216 Å and connect it to 2 keV using the $L_{\alpha}$–$\alpha_{\text{ox}}$ relationship and assuming $\alpha_{\text{ox}} = -1$ beyond 0.2 keV. We then calculate the resulting BCs over a range of luminosities; the results are given by the dashed blue line in Figure 15. This line tracks the outliers well, but the core of our sample shows a weaker luminosity dependence to the BCs (as expected from Equation (9)). This weaker luminosity dependence may reflect the trend of redder optical continua in low-luminosity quasars are bluer optical continua in high-luminosity quasars, which would counteract the trends in $\alpha_{\text{ox}}$ with $L_{\alpha}$.

We have also included the line found by Marconi et al. (2004, maroon) for comparison. The Marconi et al. (2004) line has been adjusted to match our limits of integration and the BC normalization wavelength. We see that the form of the Marconi line and ours are similar, and the offset is due to the fact that the Marconi SEDs use a shallower $L_{\alpha}$–$\alpha_{\text{ox}}$ relation that is extrapolated to 2 keV (which would predict a soft X-ray excess in all quasars), whereas we use a steeper $L_{\alpha}$–$\alpha_{\text{ox}}$ relation extrapolated to 0.2 keV.

The general shape of the distribution of individual BCs shows that the main luminosity dependence of our BCs is indeed due to the $L_{\alpha}$–$\alpha_{\text{ox}}$ relation. We do, however, see a large spread of $\sim 1$ on either side of the dashed line. In particular, it is possible for a high-$L$ quasar to have a BC that is higher than a low-$L$ quasar even though the general trend is in the other direction.

In order to facilitate the determination of bolometric corrections using different limits of integration and normalizing wavelengths, in Table 3 we have tabulated the integrated luminosity and errors for individual SEDs over 30 $\mu$m–1 $\mu$m, 1 $\mu$m–2 keV, 2 keV–10 keV, and 10 keV–500 keV. The second range is our recommended range as it corresponds to $L_{\text{disk}}$, but the sum of the first three ranges matches that used by Richards et al. (2006a) and the sum of the last three ranges is that used by Marconi et al. (2004). We further give $L_{5100}$, $L_{2500}$, and the resulting BC$_{2500}$ (relative to $L_{\text{disk}}$). We have not corrected for non-isotropic emission (i.e., the emitted light is not the same in all directions) in our tabulations; however, taking anisotropy into account, Runnoe et al. (2012) suggest scaling the bolometric luminosities by 0.75 when calculating the bolometric luminosity over the range of 1 $\mu$m–10 keV.

With individual BCs for each quasar, we are able to construct BC-dependent mean SEDs using $L_{\text{disk}}$. For this we split our sample into four equally populated bins: BC < 2.65, 2.65 ≤ BC < 2.87, 2.87 ≤ BC < 3.15, and BC ≥ 3.15, each containing ∼ 29,000 quasars. Unlike the luminosity- and CIV-dependent SEDs, these mean SEDs do not truncate the individual SEDs and connect the mean to the X-ray, but instead connects each individual SED to the X-ray and then takes the mean. This is done since each SED needs to be connected to the X-ray in order to calculate the BC. Figure 16 shows the resulting means and Figure 13(d) shows the UV region when the SEDs are normalized at 2500 Å. From these figures we see that the mean SEDs only differ significantly in the UV ($\lambda < 2000$ Å) and the largely unknown regions of the SED in FUV could have significant effects as compared to the differences seen over 1000–2000 Å where the SED is well measured. Although they were not included in the mean SEDs, the 11,468 quasars that show signs of significant dust reddening ($\Delta(g-i) > 0.3$) all fall in the two lowest BC bins; this is expected since quasars with
heavy dust reddening will appear to have a smaller BC. This cut only accounts for strong dust reddening; if there is only a small amount of dust reddening then a high-BC quasar could easily fall into the low-BC bin. We might expect the low-BC bin to be contaminated by quasars with mild dust reddening, which could be the cause of the steep drop-off in the low-BC SED just past Lyα.

6. DISCUSSION: THE UNSEEN EUV CONTINUUM

One of the reasons that we explored the mean SED in sub-samples as a function of various quasar parameters is that we expect that the diversity of quasar properties (especially in broad emission lines) is a direct consequence of the diversity in SEDs (e.g., Richards et al. 2011). In particular, quasars with significant UV luminosity relative to the X-ray are capable of driving strong winds through radiation pressure on resonance line transitions (Murray et al. 1995; Proga et al. 2000). Given the nonlinear relationship between \( L_{\text{uv}} \) and \( L_x \) (e.g., Steffen et al. 2006), one might expect to see significant differences in the SEDs of quasars as a function of luminosity. Richards et al. (2011) have argued that a potential wind diagnostic may be the properties of the C\( \text{ iv} \) emission line in the context of the Boroson & Green (1992) eigenvector 1 parameter space which looked at the difference between quasars using principal component analysis. This was the main motivation for exploring the mean SED as a function of these parameters in Section 4. While we saw significant differences in the mean SEDs as a function of luminosity, we saw fewer differences between the C\( \text{ iv} \) composites than might have been expected.

While it is possible that the SEDs of quasar extrema (in UV emission) truly are similar, it is difficult to understand how BELR properties could be so different, yet have similar SEDs. For example, there is a large range in the strength of the He \( \text{ ii} \) \( \lambda 1640 \) line (with an ionization potential of 54.4 eV) in Figures 11 and 12 of Richards et al. (2011). As such, we are led to a similar conclusion as Netzer & Davidson (1979), Korista et al. (1997), Done et al. (2012), and Lawrence (2012)—namely that the EUV SEDs may be quite different from the standard power-law parameterization between the optical and X-ray. This variation could be in a number of forms, including a second bump in the EUV or simply that the SED seen by the BELR is different from what we view (e.g., Korista et al. 1997).

Here we suggest that the solution may be more than just a different mean SED in the EUV than is normally assumed, but rather that the shape of the EUV SED must be quite different for quasars at opposite extrema in terms of their BELR properties; i.e., there is no universal quasar SED (even after accounting for the \( L_{\text{uv}}-\alpha_{\text{ox}} \) relationship)! While Grupe et al. (2010) find that only a factor of a few difference can be hidden in the EUV, their sample is restricted to low-redshift AGNs, whereas our suggestion is that the differences might be significant when considering the extremes of the distribution as spanned by the full SDSS quasar sample. In terms of a model where the BELR emission comes from both disk and wind components (Collin-Souffrin et al. 1988; Leighly et al. 2004), quasars with strong winds would have a weaker EUV continuum than quasars with strong disk components. What Richards et al. (2011) refer to as disk-dominated objects have emission line features that are consistent with a much harder EUV continuum than the wind-dominated objects (Kruczek et al. 2011). If the SEDs over the observable range of the EM spectrum are similar, the unseen part of the EM spectrum may yield very different SEDs.

![Figure 17](image-url) This hypothesis is consistent with radiation line driving being sensitive to the UV to ionizing flux ratio (Proga et al. 2000).

If this hypothesis is correct, it would have important consequences for the determination of bolometric corrections (and thus \( L_{\text{bol}}/L_x \)). A full investigation into the range of EUV continuum properties is beyond the scope of this paper; however, herein we have created some examples showing how different values might be for different assumptions of the EUV SED at the extrema of BELR properties.

The most obvious deviation from our baseline prescription (using \( L_{\text{uv}}-\alpha_{\text{ox}} \) to describe the unseen part of the SED) follows from the work of Scott et al. (2004) in the FUV. The UV spectral index just shortward of Ly\( \alpha \) was found to be different by Telfer et al. (2002) and Scott et al. (2004) (\( \alpha_{\text{FUV}} = -1.42 \) as compared to \( \alpha_{\text{ox}} = -1.54 \) for the average quasar luminosity). These differences can be explained by a luminosity-dependent spectral index given in Equation (1) (Scott et al. 2004) that is similar to that seen for \( \alpha_{\text{ox}} \) and by the fact that these two samples probe different ranges of \( L_{\text{uv}} \). Thus, we create \( L \)-dependent model SEDs that do not just connect 2500 Å directly to 0.1 keV, but instead that connect 2500 Å first to 500 Å following Equation (1) and then connect 500 Å to 0.2 keV using the \( L_{\text{uv}}-\alpha_{\text{ox}} \) relationship to set the X-ray continuum level. Such an SED is illustrated (green lines) in Figure 17 for three different luminosities, where it can be seen that these SEDs have a small (luminosity-dependent) excess of EUV flux as compared to a power-law fit between the optical and the X-ray.

We compare this to model SEDs taken from Casebeer et al. (2006) that are adapted from the CLOUDY (Ferland 2002) so-called AGN continuum. The functional form of this continuum is given in Casebeer et al. (2006, Equation (A1)). Essentially this SED consists of a power law representing the optical/UV continuum with exponential cutoffs in the infrared and UV, plus a power law in the X-rays, where the normalization of the two components is set by \( \alpha_{\text{ox}} \) (calibrated to Wilkes et al. 1994). Casebeer et al. (2006) used a range of \( \alpha_{\text{ox}} \) and UV
cutoffs to test the influence of the SED on emission line ratios (and not to determine BCs); we show in Figure 17 the ones with $kT_{\text{cut}} = 50, 37, 27$ eV and $\alpha_{\text{ox}} = -1.5, -1.57, -1.66$, from lowest to highest luminosity, respectively (chosen to have the same optical luminosities as the Scott et al. lines).

While we cannot directly measure the EUV part of the spectrum, it is interesting to compare the Scott et al. and Casebeer et al. SEDs in the $\sim 800$ Å range. For low-luminosity quasars, the data-driven Scott-based SED and the more theoretical (but empirically calibrated) Casebeer et al. SED (chosen to have the same $\alpha_{\text{ox}}$) follow the same upward trend. This leads one to wonder if low-luminosity objects may indeed have much more EUV flux shortward of 500 Å (i.e., that the Casebeer et al. 2006 model is correct) than is typically assumed when applying the $L_{\text{UV}}-\alpha_{\text{ox}}$ prescription, as the EUV is unconstrained for the green curves between 500 Å and 0.2 keV. However, for the high-luminosity quasars, the Scott et al. and Casebeer et al. SEDs do not follow the same trend even at $\sim 800$ Å, which suggests a model like the Casebeer et al. (2006) SED likely overestimates the EUV emission in the most luminous quasars. Indeed, a comparison of the UV emission lines in the extrema shown in Figure 12 of Richards et al. (2011) suggests that the SEDs of quasars with "disk"- and "wind"-dominated BELRs may be very different in the range of $\sim 50$ eV where the ionization potentials of many UV lines lie (e.g., Richards et al. 2011, Figure 13).

Since the wind-dominated objects are more luminous on average than the disk-dominated objects (as can be seen in Figure 14(c)), we also consider a model where we add a blackbody component of fixed luminosity, such that it is significant in low-luminosity sources, but contributes little to the EUV continuum for high-luminosity sources.

To construct a toy model to illustrate such a situation, we start by extending our SEDs to the X-ray range using the Steffen et al. (2006) $L_{\text{ox}}-\alpha_{\text{ox}}$ relation and then added a blackbody peaking at 23 eV. This peak was chosen in order to add photons of the typical energy needed to produce the spectral lines we see (e.g., CIV and HeII). The normalization of the blackbody was taken to have $\log (\nu L_{\nu}) = 44.5$ at its peak (see the dashed black curve in Figure 17) so that the highest luminosity quasars remain unaffected but the lower luminosity quasars gain an extra feature which has the correct sign to explain the broad range of EWs for, e.g., CIV and HeII (Richards et al. 2011). This model leads to a larger spread in their bolometric corrections than when no extra component is used (see Figure 18(b)). While we lack direct observational evidence for such a component, the range of emission line strengths for lines with ionization potentials of $\sim 50$ eV, suggests that some, but not all, quasars have a need for more ionizing flux in this region of the EM spectrum in order to understand their emission line properties. We include it here as a way to illustrate how significantly such a component would change the bolometric corrections of low-luminosity quasars.

We compare these four models, which were chosen to bracket the range of reasonable EUV shapes for a given $\alpha_{\text{ox}}$, shown in Figure 18(a) for a single luminosity. Figure 18(b) then shows how the BC distribution would change under the assumption of each of these models. The biggest deviation from the standard model results when using the Casebeer et al. SEDs. These SEDs may have too much EUV flux for high-luminosity sources, while being more reasonable at low-luminosities (see Figure 17). On the other hand, the Scott-based and extra EUV component SEDs depict a more subtle shift in the mean BCs. More importantly, however, is that these deviations from our standard SED produce BC changes that are systematic with $L_{\text{ox}}$. Although there is a lack of data in the EUV, in Figure 15, the solid black line shows how much we would expect the BCs to change for low-luminosity sources if there were an extra EUV continuum component. Adding the $L$-dependence from Scott to this model would make this contrast even stronger.

While this extra EUV component is speculative, the ramifications are such that it is important to consider the possibility. Moreover, the $L$-dependence of the FUV continuum based on the work of Scott et al. (2004) already suggests that a correction in this direction is needed. Achieving a better understanding of the EUV continuum is clearly of importance for understanding quasars physics, as a change of a factor of a few in BCs for
low-luminosity sources translates to the same correction factor for both $L_{\text{sed}}$ and the Eddington ratio (i.e., accretion rates). Ideally, we would also like to consider the BC distribution as a function of quantities like the accretion rate, but such analysis is difficult without first understanding any systematic effects in the unseen EUV part of the spectrum.

7. CONCLUSIONS

We have compiled a sample of 119,652 quasars detected in the SDSS. These data are supplemented with multi-wavelength data spanning from the mid-IR through the UV (Table 1). This data set was used to construct a new mean SED consisting from $20 \mu m$–912 Å (Table 2). By splitting our sample into luminosity bins we constructed three luminosity-dependent mean SEDs and found $\alpha_{\text{FUV}}$ to be dependent on luminosity in the sense that more luminous quasars have redder $\alpha_{\text{FUV}}$ continua (Figure 13(b)), consistent with Scott et al. (2004). In addition, the high-luminosity quasars also show signs of having bluer optical continua (Figure 13(b)) and more hot dust emission than the low-luminosity quasars (Figure 13(a)). When splitting our sample based on CIV properties we saw differences in the Balmer continuum, Ly$\alpha$ and CIV (by construction) line strengths (Figure 15(c)) that are consistent with eigenvector 1 trends (Brotherton & Francis 1999).

We also constructed SEDs for each quasar and, from those, found bolometric corrections (Table 3). The overall mean is BC$_{2500\AA} = 2.75 \pm 0.40$ using integration limits of 1 μm–2 keV. While the range of bolometric corrections indicated by the IR through UV data alone is reasonably small, there can be significant changes in the distribution of bolometric corrections when different models are assumed in the unseen EUV part of the SED (Figure 18(b)). Although more work has to be done to determine which model should be used in the EUV, it is nevertheless clear that it is important to consider potentially significant differences in the EUV part of the SED at the extrema of quasar properties (e.g., in luminosity and in eigenvector 1 parameter space). In future work, we will further explore the cause(s) of the width in the bolometric correction distribution (after correcting for known luminosity trends) and will characterize the systematic error in the accretion rate estimates.
