(Dated: February 20, 2012)

We consider the nearest-neighbor spacing distributions of mixed random matrix ensembles inter-
ropolating between different symmetry classes, or between integrable and non-integrable systems.
We derive analytical formulas for the spacing distributions of $2 \times 2$ or $4 \times 4$ matrices and show
numerically that they provide very good approximations for those of random matrices with large
dimension. This generalizes the Wigner surmise, which is valid for pure ensembles that are recovered
as limits of the mixed ensembles. We show how the coupling parameters of small and large matrices
must be matched depending on the local eigenvalue density.

I. INTRODUCTION

Random matrix theory (RMT) is a powerful mathe-
matical tool which can be used to describe the statistical
behavior of quantities arising in a wide variety of com-
plex systems. It has been applied to many mathematical
and physical problems with great success, see [1–3] for
reviews. This wide range of applications is based on the
fact that RMT describes universal quantities that do not
depend on the detailed dynamical properties of a given
system but rather are determined by global symmetries
that are shared by all systems in a given symmetry class.

In RMT the operator governing the behavior of the sys-
tem, such as the Hamilton or Dirac operator, is replaced
by a random matrix with suitable symmetries. One then
studies statistical properties of the eigenvalue spectrum
of such random matrices, typically in the limit of large
matrix dimension. To compare different systems in the
same symmetry class with RMT, the eigenvalues of the
physical system as well as those of the random matrices
need to be “unfolded” [4]. The purpose of such an
unfolding procedure is to separate the average behavior
of the spectral density (which is not universal) from the
spectral fluctuations (which are universal). Unfolding is
effectively a local rescaling of the eigenvalues, resulting
in an unfolded spectrum with mean level spacing equal
to unity. How the rescaling is to be done is not unique
and may depend on the system under study.

In this paper we focus on the so-called nearest-neighbor
spacing distribution $P(s)$, i.e., the probability density to
find two adjacent (unfolded) eigenvalues at a distance $s$.
This quantity probes the strength of the eigenvalue repulsion due to interactions and can be computed an-
alytically for the classical RMT ensembles, resulting in
rather complicated expressions given in terms of prolate
spheroidal functions [5]. However, it was realized early
on that the level spacing distribution of large random
matrices is very well approximated by that of $2 \times 2$ ma-
trices in the same symmetry class [6]. For most practical
purposes it is sufficient to use this so-called Wigner sur-
mise [8, p. 199] instead of the exact analytical result. It
is given by

$$P_{\beta}(s) = a_{\beta} s^{\beta} e^{-b_{\beta} s^{2}} \quad (1.1)$$

with $\beta = 1, 2, 4$ corresponding to the Gaussian orthog-
onal (GOE), unitary (GUE), and symplectic (GSE) en-
semble of RMT, respectively. The quantities $a_{\beta}$ and $b_{\beta}$
are chosen such that

$$\int_{0}^{\infty} ds P_{\beta}(s) = 1 \quad \text{and} \quad \langle s \rangle = \int_{0}^{\infty} ds P_{\beta}(s) s = 1 \quad (1.2)$$
in all three cases. Explicit formulas will be given in Sec. [11]

RMT describes quantum systems whose classical coun-
terparts are chaotic [9] and correctly predicts the strong
short-range correlations of the eigenvalues due to inter-
actions. In contrast, the level spacing distribution of a
quantum system whose classical counterpart is integrable
is given by that of a Poisson process,

$$P_{0}(s) = e^{-s}, \quad (1.3)$$
corresponding to uncorrelated eigenvalues. We assign the
Dyson index $\beta = 0$ to ensembles of this kind, which is a
consistent extension of the generalized Gaussian ensem-
bles with arbitrary real $\beta > 0$ introduced in [10].

Often physical systems consist of parts with different
symmetries, or of a classically integrable and a chaotic
part. Changing a parameter of the system may then
result in transitions between different symmetry classes.
We assume the Hamiltonian describing the system to be of
the form

$$H = H_\beta + \lambda H_{\beta'}, \quad (1.4)$$

where $H_\beta$ represents the original system whose sym-
metry/integrability is broken by the perturbation $H_{\beta'}$ for

1 This does not work for non-Hermitian complex matrices [6, 7].

2 Other possibilities have also been investigated, see, e.g., [5, 11, 12], but will not be considered in this paper.
small coupling parameter $\lambda$, and vice versa for large $\lambda$. For the quantities we analyze the absolute scale of $H$ is irrelevant, only the relative scale between the different parts matters.

From the level statistics point of view, $H_{\beta}$ and $H_{\beta^{'}}$ correspond either to a Poisson process or to one of the three RMT ensembles. Hence, there are $(\beta')^3 = 6$ possibilities for a transition between two of these four cases in Eq. (1.4), i.e., Poisson-GOE, Poisson-GUE, Poisson-GSE, GOE-GUE, GOE-GSE, and GUE-GSE. If a GSE matrix is involved in the transition, there are two possibilities for the other matrix: self-dual or not This leads to an even larger variety of mixed ensembles. Many transitions of this kind have been studied in earlier works, usually for large matrix dimension. Transitions between Gaussian ensembles are considered in [3], but closed forms for the spacing distribution could not be obtained, and self-dual symmetry was not conserved in the transitions involving the GSE. Mixtures of Gaussian ensembles with conserved self-dual symmetry and small matrix size are considered in [3], but only numerical results are given for the spacing distributions. Other examples include the heuristic Brody distribution [13] interpolating between Poisson and the GOE, and a complete study of the transition between Poisson and the GUE [13]. Note that an exact analytical calculation of $P(s)$ for systems described by an Ansatz of the form (1.4) is much harder than, e.g., the analytical calculation of low-order spectral correlation functions, which are already difficult to obtain. Here, we do not attempt an analytical calculation of $P(s)$ for large matrix dimension. Rather, motivated by the reliability of the Wigner surmise, we study the possible transitions in Eq. (1.4) for $2 \times 2$ matrices (or, in the symplectic case, $4 \times 4$ matrices, because the smallest non-trivial self-dual matrix has this size) and compare the resulting level spacing distributions with that of large random matrices, the latter obtained numerically. The cases of Poisson-GOE and GOE-GUE were worked out earlier by Lenz and Haake [16], and the spacing distribution of a $2 \times 2$ matrix interpolating between Poisson and GUE is given in [17]. These cases will briefly be reviewed below, and the remaining ones are the main subject of this work.

This paper is organized as follows. In Sec. II we derive analytical results for $P(s)$ for small matrix sizes. If $H_{\beta^{'}}$ is from the GSE (i.e., $H_{\beta^{'}}$ is self-dual) we construct in Secs. II.D, II.F, and II.G self-dual matrices $H_{\beta}$ to maintain the Kramers degeneracy. In Sec. II.H we consider the case where a $4 \times 4$ GSE matrix is perturbed by a non-self-dual GUE matrix. Section III provides strong numerical evidence that the results obtained in Sec. II approximate the spacing distributions of large random matrices very well. We give a perturbative argument for the matching of the couplings used for the Wigner surmise and for large matrices, respectively, and derive an approximate result that involves the eigenvalue density. This result describes the numerical data rather well. We also show that the transitions from the GSE to either a non-self-dual Poissonian ensemble or the GOE proceed via an intermediate transition to the GUE and can also be described by the surmises calculated in Sec. II. We summarize our findings and conclude in Sec. IV. Technical details are worked out in several appendices.

## II. SPACING DISTRIBUTIONS FOR SMALL MATRICES

### A. Preliminaries

In the spirit of the Wigner surmise, we now calculate the distributions $P(s)$ of eigenvalue spacings $s$ of mixed ensembles for the smallest nontrivial (i.e., $2 \times 2$ or $4 \times 4$) matrices, with $P(s)$ normalized as in Eq. (1.2). Unfolding is not needed for these matrices since they have only two independent eigenvalues (except for Sec. II.H). We first study the transitions from the integrable to the chaotic case for the three Gaussian ensembles and then proceed to the transitions between different symmetry classes.

We define the $2 \times 2$ Poisson process by a matrix

$$H_0 = \begin{pmatrix} 0 & 0 \\ 0 & p \end{pmatrix},$$

(2.1)

where $p$ is a Poisson distributed non-negative random number with unit mean value, i.e., its probability density is $P_0(p) = e^{-p}$. The eigenvalue spacing of this matrix is obviously Poissonian, as the spacing is just $p$, and therefore we obtain Eq. (1.3).

The choice of $H_0$ may look like a special case, but it suffices for our purposes. The most general Hermitian $2 \times 2$ matrix with spacing $p$ can be obtained from Eq. (2.1) by a common shift of the eigenvalues (which does not influence the spacing) and a basis transformation. This transformation can be absorbed in the perturbing matrix since it does not change the probability distribution of the latter. To see this suppose we had started with a general nondiagonal $H_0$, also with eigenvalues $0$ and $p$, instead of Eq. (2.1). When added to a random matrix $H_{\beta^{'}}$ with $\beta' = 1, 2, 4$, we choose it to be real symmetric, Hermitian, or self-dual, respectively, in order to preserve the symmetry properties of $H_{\beta^{'}}$. Then $H_0$ is diagonalized by a suitable matrix $\Omega$, i.e., $\text{diag}(0, p) = \Omega^{-1}H_0\Omega$, where $\Omega$ is orthogonal ($\beta = 1$), unitary ($\beta = 2$), or symplectic ($\beta = 4$). In the total matrix $H$ this is equivalent to $\Omega^{-1}H_{\beta^{'}}\Omega$ perturbing $\text{diag}(0, p)$, but the probability distribution of the perturbation is invariant under the transformation $\Omega$.

For matrices $H_{1,2,4}$ from the GOE, GUE, and GSE, respectively, we choose the mean values of the matrix
elements to be 0 and the normalization
\[ \langle [(H_{1,2,4})_{ij}]^2 \rangle = 2 \langle [(H_{1,2,4})_{i\neq j}]^2 \rangle = 1. \tag{2.2} \]
The index $\nu = 0, \ldots, \beta - 1$ distinguishes the components of the complex/quaternion GOE/GSE matrix elements, while the GOE matrix elements possess only a real part.

All results we derive from Eq. (1.4) will be symmetric in $\lambda$ since the distribution of the elements of $H_{\beta}$ is symmetric about zero (the perturbation will be taken from one of the Gaussian ensembles in each case). This means that our results should be expressed in terms of $|\lambda|$. To avoid such cumbersome notation we restrict ourselves to non-negative $\lambda$.

B. Poisson to GOE

We first consider the case that corresponds to a classically integrable system perturbed by a chaotic part with anti-unitary symmetry squaring to 1. The integrable part is represented by a Poisson process, and the chaotic one by the GOE. The spacing distribution for this case has been derived in [16], and we state it here for the sake of completeness.

The $2 \times 2$ random matrix
\[ H = H_0 + \lambda H_1 = \begin{pmatrix} 0 & \alpha \\ 0 & 0 \end{pmatrix} + \lambda \begin{pmatrix} a & c \\ c & b \end{pmatrix} \tag{2.3} \]
consists of $H_0$ from (2.1) and $H_1$ from the GOE, i.e., a real symmetric matrix with normalization given in Eq. (2.2). The calculations are very similar to the ones for the transition from Poisson to the GSE, which are presented in Sec. 11D. The resulting spacing distribution of $H$ reads
\[ P_{0\to1}(s;\lambda) = C s e^{-D^2 s^2} \int_0^\infty dx e^{-\frac{x^2}{\pi s^2} - x} I_0 \left( \frac{\pi D s}{\lambda} \right) \tag{2.4} \]
with
\[ C(\lambda) = 2D(\lambda)^2, \tag{2.6} \]
where $U$ is the Tricomi confluent hypergeometric function (or Kummer function) [18 Eq. (13.1.3)] and $I_0$ is a modified Bessel function [18 Eq. (9.6.3)]. $P_{0\to1}(s;\lambda)$ is plotted in Fig. 4 (left) for various values of $\lambda$. The formula is equivalent to the one given in [16], but our integration variable $x$ is scaled differently.

In the limiting cases of $\lambda \to 0$ and $\lambda \to \infty$ we have
\[ D(\lambda) \sim \begin{cases} 1/(2\lambda) & \text{for } \lambda \to 0, \\ \sqrt{\pi}/2 & \text{for } \lambda \to \infty. \tag{2.7} \end{cases} \]
Using the asymptotic expansion of the Bessel function, it is straightforward to show that for $\lambda \to 0$ we obtain the Poisson result $e^{-s}$. It is even simpler to show that the Wigner surmise $(\pi s/2) e^{-\pi s^2/4}$ for the GOE is obtained for $\lambda \to \infty$.

The small-$s$ behavior of $P_{0\to1}(s;\lambda)$ shows interesting features. To investigate this behavior, we consider separately the cases $\lambda = 0$ and $\lambda > 0$. For $\lambda = 0$ we have by construction
\[ P_{0\to1}(s;0) = e^{-s} = 1 - s + O(s^3). \tag{2.8} \]
For $\lambda > 0$ we obtain from Eq. (2.4)
\[ P_{0\to1}(s;\lambda) = c(\lambda) s + O(s^3) \tag{2.9} \]
with
\[ c(\lambda) \sim \frac{\sqrt{\pi}}{2\lambda} \text{ for } \lambda \to 0. \tag{2.10} \]
which means that we recover the linear level repulsion of the GOE for arbitrarily small $\lambda$, i.e., for arbitrarily small admixture of the chaotic part as also observed in [19,21]. This implies that for $\lambda \to 0$ the distribution, viewed as a function of $\lambda$, develops a discontinuity at $s = 0$, since $P_{0\to1}(s = 0;\lambda = 0) = 1$ while $P_{0\to1}(s = 0;\lambda > 0) = 0$. This effect is clearly seen in Fig. 1 (left).

For small values of $\lambda$ and $s$, we observe something reminiscent of the Gibbs phenomenon, i.e., the interpolation

\[ \langle [(H_{1,2,4})_{ij}]^2 \rangle = 2 \langle [(H_{1,2,4})_{i\neq j}]^2 \rangle = 1. \tag{2.2} \]

\[ C(\lambda) = 2D(\lambda)^2, \tag{2.6} \]

\[ D(\lambda) \sim \begin{cases} 1/(2\lambda) & \text{for } \lambda \to 0, \\ \sqrt{\pi}/2 & \text{for } \lambda \to \infty. \tag{2.7} \end{cases} \]

\[ P_{0\to1}(s;\lambda) = c(\lambda) s + O(s^3) \tag{2.9} \]

\[ c(\lambda) \sim \frac{\sqrt{\pi}}{2\lambda} \text{ for } \lambda \to 0. \tag{2.10} \]
overshoots the Poisson curve considerably. In the limit of \( \lambda \to 0 \), one can show (see App. [A2]) that the maximum of \( P_{0 \to 1} \) is at \( s_{\text{max}} = 2.51393 \lambda \) with a finite value of \( P_{0 \to 1}(s_{\text{max}}; \lambda \to 0) = 1.17516 \). This implies an overshoot of 17.5% compared to the Poisson curve. Such an effect also occurs in the transitions from Poisson to GUE and GSE that are treated in Secs. II C and II D below, with a quadratic/quartic level repulsion in the small-s regime.

C. Poisson to GUE

We now consider the transition from Poisson to the GUE. This corresponds to a classically integrable system with a chaotic perturbation without anti-unitary symmetry. The \( 2 \times 2 \) random matrix

\[
H = H_0 + \lambda H_2 = \begin{pmatrix} 0 & 0 \\ 0 & p \end{pmatrix} + \lambda \begin{pmatrix} a & c_0 + ic_1 \\ c_0 - ic_1 & b \end{pmatrix}
\]

(2.11)

contains \( H_2 \) from the GUE, i.e., a complex Hermitian matrix with normalization \( (2.2) \). The spacing distribution of an equivalent setup with different normalizations of the random matrix elements was already considered in [17], so we just state the result,

\[
P_{0 \to 2}(s; \lambda) = Cs e^{-Ds^2} s \int_0^\infty dx e^{-x^2} \sinh \frac{xD}{2x} \frac{1}{x}
\]

(2.12)

with

\[
D(\lambda) = \frac{1}{\sqrt{\pi}} + \frac{1}{2\lambda} e^{\lambda^2} \text{erf}(\lambda) - \frac{\lambda}{2} \text{Ei}(\lambda^2)
\]

(2.13)

\[
C(\lambda) = \frac{4\lambda}{\sqrt{\pi}} D(\lambda)^2.
\]

(2.14)

Here, erf is the complementary error function [18 Eq. (7.1.2)], Ei is the exponential integral [18 Eq. (5.1.2)], and \( F_2 \) is a generalized hypergeometric function [22 Eq. (9.14.1)].

To check the validity of Eq. (2.12) and to see the emergence of the limiting spacing distributions, we now consider the limits \( \lambda \to 0 \) and \( \lambda \to \infty \). First note that for \( \lambda \to 0 \) we have

\[
D \sim \frac{1}{2\lambda} \quad \text{and} \quad C \sim \frac{1}{\lambda^{1/2}}
\]

(2.15)

so that Eq. (2.12) becomes for \( s > 0 \)

\[
P_{0 \to 2}(s; 0) = \lim_{\lambda \to 0} \frac{s}{\lambda^{1/2}} \int_0^\infty dx e^{-\frac{1}{4\lambda}(s^2 + x^2) - x} \sinh \frac{x^2}{2x}
\]

\[
= \frac{s}{2\sqrt{\pi}} \int_0^\infty dx \frac{e^{-x^2}}{x} \lim_{\lambda \to 0} \frac{1}{\lambda} \left( e^{-\frac{(s-x)^2}{4\lambda^2}} - e^{-\frac{(s+x)^2}{4\lambda^2}} \right)
\]

\[
= 2\sqrt{\pi} \delta(s-x) - \delta(s+x)
\]

(2.16)

which is the Poisson distribution as required. For \( \lambda \to \infty \) we have

\[
D \sim \frac{2}{\sqrt{\pi}} \quad \text{and} \quad C \sim \frac{16\lambda}{\pi^{3/2}}
\]

(2.17)

so that Eq. (2.12) becomes

\[
P_{0 \to 2}(s; \infty) = \lim_{\lambda \to \infty} \frac{16\lambda e^{-\frac{1}{4\lambda^2}}}{\pi^{3/2}} \int_0^\infty dx e^{-\frac{x^2}{4\lambda^2} - x} \sinh \frac{2xs}{\lambda^{1/2}}
\]

\[
= \frac{32s^2}{\pi^2} e^{-\frac{s^2}{4}}
\]

(2.18)

which is the Wigner surmise for the GUE.

The integral in Eq. (2.12) can be computed numerically without difficulties as the integrand decays like a Gaussian for large \( x \) and becomes constant for small \( x \).

The resulting distribution \( P_{0 \to 2}(s; \lambda) \) is plotted in Fig. 1 (middle).

As in Sec. II B, a discontinuity is found at \( s = 0 \) towards the Poisson result. For \( \lambda > 0 \) we obtain from Eq. (2.12)

\[
P_{0 \to 2}(s; \lambda) = c(\lambda)s^2 + O(s^4)
\]

(2.19)

with

\[
c(\lambda) \sim \frac{1}{2} \quad \text{for} \quad \lambda \to 0.
\]

(2.20)

Hence we obtain the quadratic level repulsion of the GUE for arbitrarily small coupling parameter. For \( \lambda \to 0 \), the maximum of the function is at \( s_{\text{max}} = 3.00395 \lambda \), with a value of \( P_{0 \to 2}(s_{\text{max}}; \lambda \to 0) = 1.28475 \) (see App. [A2]).

D. Poisson to GSE

In this case, a classically integrable system is perturbed by a chaotic part with anti-unitary symmetry squaring to \( -1 \) and hence represented by the self-dual matrices of the GSE. One has to consider \( 4 \times 4 \) matrices here, because a self-dual \( 2 \times 2 \) matrix is proportional to \( \mathbb{1}_2 \) and has only one non-degenerate eigenvalue. As mentioned in the introduction, there are now two possibilities: The Poisson process could be represented by a self-dual or a non-self-dual matrix. Here we only consider the former possibility, while the latter will be discussed in Sec. III E.

A self-dual Poisson matrix is obtained by taking a tensor product of Eq. (2.1) with \( \mathbb{1}_2 \). Thus the transition matrix is

\[
H = H_0 \otimes \mathbb{1}_2 + \lambda H_4 = \begin{pmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & p & 0 \\ 0 & 0 & 0 & p \end{pmatrix}
\]

4 Note that the integral can be expressed in terms of imaginary error functions, but for increasing \( s \) delicate cancellations occur that make it impractical to use this form for numerical evaluation. This is why we present Eq. (2.12) as the final formula, which is well suited for numerical integration.
where the GSE matrix $H_4$ is Hermitian and self-dual, and can be represented by a $2 \times 2$ matrix whose elements are real quaternions, see [K] for details.

We now explain the calculation of the spacing distribution for this transition. The computation of the previous cases, Poisson to GOE and Poisson to GUE, can be done in a similar fashion.

Due to the self-dual structure of $H$, the spacing $S$ between its non-degenerate eigenvalues spacing can be computed analytically and reads

$$S = \lambda \sqrt{(a - b - p/\lambda)^2 + 4c_\mu c_\mu}, \quad (2.22)$$

where the repeated index $\mu$ indicates a sum from 0 to 3. We have intentionally written $S$ instead of $s$ since we eventually need to rescale the spacing to ensure $\langle s \rangle = 1$.

The desired spacing distribution is proportional to the multi-dimensional integral in this expression is computed (with the saddle point at $x = -1$), resulting in the Poisson result $e^{-x}$. For $\lambda \to \infty$, we use the asymptotic expansion of erf and obtain the Wigner surmise $(64/9\pi)^{3/2}e^{-64x^2/9\pi}$ for the GSE.

Equation (2.26) is plotted in Fig. 1 (right) and again displays a discontinuity at $s = 0$ as $\lambda \to 0$. For $\lambda > 0$ we now have

$$P_{0 \to 4}(s; \lambda) = c(\lambda)s^4 + O(s^6) \quad (2.30)$$

with

$$c(\lambda) \sim \frac{1}{12\lambda^4} \quad \text{for } \lambda \to 0. \quad (2.31)$$

For $\lambda \to 0$, the maximum of the function is at $s_{\text{max}} = 3.76023\lambda$, with a value of $P_{0 \to 4}(s_{\text{max}}; \lambda \to 0) = 1.43453$ (see App. A.2).

E. GOE to GUE

With this subsection we start the investigation of transitions between different chaotic ensembles using the smallest possible matrix size.

We consider the $2 \times 2$ matrix

$$H = H_4 + \lambda H_2. \quad (2.32)$$

The spacing distribution for this transition was already computed in [19]. With the normalization of ensembles given in Eq. (2.2), it reads

$$P_{1 \to 2}(s; \lambda) = Cse^{-D^2s^2} \text{erf} \left( \frac{Ds}{\lambda} \right) \quad (2.33)$$

with

$$D(\lambda) = \frac{\sqrt{1 + \lambda^2}}{\sqrt{\pi}} \left( \frac{\lambda}{1 + \lambda^2} + \text{arccot} \lambda \right), \quad (2.34)$$

$$C(\lambda) = 2\sqrt{1 + \lambda^2} D(\lambda)^2. \quad (2.35)$$

This formula matches the result of [19] up to a rescaling of the coupling parameter $\lambda$ by a factor of $\sqrt{2}$, which is due to a different normalization of the ensembles used there.

In the limiting cases of $\lambda \to 0$ and $\lambda \to \infty$ we have

$$D(\lambda) \sim \begin{cases} \sqrt{\pi}/2 & \text{for } \lambda \to 0, \\ 2/\sqrt{\pi} & \text{for } \lambda \to \infty. \end{cases} \quad (2.36)$$
For $\lambda \to 0$, the error function in Eq. (2.33) can be replaced by unity (for $s > 0$), and we obtain the Wigner surmise for the GOE. For $\lambda \to \infty$, using the first-order Taylor expansion of the error function yields the Wigner surmise for the GUE.

The result (2.33) is plotted in Fig. 2 (left). In the small-$s$ region, we now have for $\lambda > 0$

$$P_{1\to2}(s;\lambda) = c(\lambda) s^2 + \mathcal{O}(s^4) \quad (2.37)$$

with

$$c(\lambda) \sim \frac{\pi}{2\lambda} \quad \text{for} \quad \lambda \to 0. \quad (2.38)$$

Similar to the previous subsections, a non-analytic transition between weaker and stronger level repulsion develops as $\lambda \to 0$, except that now there is no jump in the function itself but rather in its derivative at $s = 0$. Therefore, the stronger level repulsion takes over immediately in the small $s$-regime, if $\lambda > 0$. As we shall see below, this also happens in the remaining transitions, GOE to GSE and GUE to GSE, and seems to be a characteristic feature of the mixed ensembles.

**F. GOE to GSE**

As the GSE is involved in this transition, we need matrices of size $4 \times 4$. Again there are two possibilities: The GOE matrix could be made self-dual, or it could be non-self-dual (as it generically is). Here we only consider the former case, while the latter case will be discussed in Sec. III E. As in 13 we define a modified GOE matrix by

$$H_1 \otimes 1_2 = \begin{pmatrix} a & 0 & c & 0 \\ 0 & a & 0 & c \\ c & 0 & b & 0 \\ 0 & c & 0 & b \end{pmatrix} \quad (2.39)$$

with real parameters $a, b, c$. This matrix is self-dual, so we can add it to a matrix from the GSE without spoiling the symmetry properties of the latter. Thus we consider

$$H = H_1 \otimes 1_2 + \lambda H_4, \quad (2.40)$$

where $H_1$ and $H_4$ are normalized according to Eq. (2.22). The eigenvalues of the sum are doubly degenerate and can be calculated easily due to self-duality.

After some algebra (see App. B 2) we obtain for the spacing distribution of $H$

$$P_{1\to4}(s;\lambda) = C s^4 e^{-(1+2\lambda^2)D^2s^2} \times \int_0^1 dx (1 - x^2)^2 e^{(xD_0)^2} [I_0(z) - I_1(z)] , \quad (2.41)$$

where $z = (1-x^2)D^2s^2$, $I_0$ and $I_1$ are modified Bessel functions, and

$$D(\lambda) = \frac{\lambda - \lambda^3 + (1 + \lambda^2)^2 \arccot \lambda}{\sqrt{2\pi} \lambda \sqrt{1 + \lambda^2}} , \quad (2.42)$$

$$C(\lambda) = \frac{2^{9/2}}{\sqrt{\pi}} \lambda^2 (1 + \lambda^2)^{3/2} D(\lambda)^5 . \quad (2.43)$$

In the limiting cases of $\lambda \to 0$ and $\lambda \to \infty$ we have

$$D(\lambda) \sim \begin{cases} \sqrt{\pi}/(2^{3/2}\lambda) & \text{for} \quad \lambda \to 0 , \\ 8/(3\sqrt{2}\pi\lambda) & \text{for} \quad \lambda \to \infty . \end{cases} \quad (2.44)$$

For $\lambda \to 0$, we use the asymptotic expansion of the Bessel functions to simplify the integral over $x$ in Eq. (2.41) and obtain the Wigner surmise for the GOE. For $\lambda \to \infty$, the exponential and the difference of the Bessel functions in the integral over $x$ can be replaced by unity, and the Wigner surmise for the GSE follows trivially.

The distribution $P_{1\to4}(s;\lambda)$ is plotted for several values of $\lambda$ in Fig. 2 (middle) and displays a continuous interpolation between the GOE and GSE curves. In the small-$s$ region, the level repulsion is of fourth order for non-vanishing $\lambda$. This is visible in the plots and can be shown by expanding $P_{1\to4}(s;\lambda)$ for $\lambda > 0$ and small $s$,

$$P_{1\to4}(s;\lambda) = c(\lambda) s^4 + \mathcal{O}(s^6) \quad (2.45)$$
with

\[ c(\lambda) \sim \frac{\pi^2}{12\lambda^3} \quad \text{for } \lambda \to 0. \quad (2.46) \]

G. GUE to GSE

Again, due to the presence of the GSE, we have two possibilities for the GUE: self-dual or not. The former case is simpler and analyzed here, while the latter case will be considered in Sec. IIII. We first have to clarify how to obtain a self-dual \(4 \times 4\) matrix whose eigenvalues have the same probability distribution as those of a \(2 \times 2\) matrix from the GUE. In analogy to Sec. IIII one could try \(H_2 \otimes 1_2\), but the resulting matrix is not self-dual. Instead, we consider the matrix

\[ H_2^d = \begin{pmatrix} 0 & 0 & 0 & 0 \\ 0 & H_2 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix} \quad (2.47) \]

with \(H_2\) given in Eq. (2.11). The eigenvalues of \(H_2^d\) are obviously equal to those of \(H_2\), but twofold degenerate. Interchanging the second and third row and column of \(H_2^d\), we obtain the matrix

\[ H_2^{sd} = \begin{pmatrix} a & 0 & c_0 + ic_1 & 0 \\ 0 & a & 0 & c_0 - ic_1 \\ c_0 - ic_1 & 0 & b & 0 \\ 0 & c_0 + ic_1 & 0 & b \end{pmatrix}, \quad (2.48) \]

which is self-dual and has the same eigenvalues as \(H_2^d\). A matrix of this form was already introduced in [13].

The proper self-dual matrix for the GUE to GSE transition is thus

\[ H = H_2^{sd} + \lambda H_4 \quad (2.49) \]

with \(H_4\) given in Eq. (2.21). The calculation of the corresponding spacing distribution proceeds in close analogy with the one presented in App. IIII and we find the closed expression

\[ P_{2 \to 4}(s; \lambda) = C e^{-(\lambda D s)^2} \times \left[ 2(Ds)^2 - 3\sqrt{\pi}Dse^{-(Ds)^2} \text{erfi}(Ds) \right] \quad (2.50) \]

with the imaginary error function \(\text{erfi}(x) = -i \text{erf}(ix)\) and

\[ D(\lambda) = \frac{1}{\lambda \sqrt{\pi}} \left( 2 + \lambda^2 - \lambda^4 \frac{\text{arcsch} \lambda}{\sqrt{1 + \lambda^2}} \right), \quad (2.51) \]

\[ C(\lambda) = \frac{2\lambda^3}{\sqrt{\pi}} (1 + \lambda^2) D(\lambda), \quad (2.52) \]

where \(\text{arcsch}\) is defined in [18, Eq. (4.6.17)].

In the limiting cases of \(\lambda \to 0\) and \(\lambda \to \infty\) we have

\[ D(\lambda) \sim \begin{cases} \frac{2}{\lambda \sqrt{\pi}} & \text{for } \lambda \to 0, \\ \frac{8}{3 \lambda \sqrt{\pi}} & \text{for } \lambda \to \infty. \end{cases} \quad (2.53) \]

For \(\lambda \to 0\), the asymptotic expansion of the second term in the square brackets of Eq. (2.50) yields \(-1\). This can be neglected compared to the first term in the square brackets, which gives the Wigner surmise for the GUE. For \(\lambda \to \infty\), Taylor expansion of the square brackets in Eq. (2.50) yields the Wigner surmise for the GSE.

The result (2.50) is plotted in Fig. 2 (right). In the small-s region, we have for \(\lambda \neq 0\)

\[ P_{2 \to 4}(s; \lambda) = c(\lambda)s^4 + \mathcal{O}(s^6) \quad (2.54) \]

with

\[ c(\lambda) \sim \frac{256}{3\pi^2\lambda^2} \quad \text{for } \lambda \to 0. \quad (2.55) \]

H. GSE to GUE without self-dual symmetry

In this section, we consider a matrix taken from the GSE whose Kramers degeneracy is lifted by a perturbation taken from the GUE without self-dual symmetry. As we shall see, this case also gives a surmise for other transitions involving the GSE and another ensemble without self-dual symmetry. We will return to this point in Sec. IIIE.

1. General considerations

The \(4 \times 4\) transition matrix is

\[ H = H_4 + \lambda H_2 \quad (2.56) \]

with \(H_4\) taken from the GSE and \(H_2\) from the GUE, both in standard normalization, Eq. (2.2). As \(H_2\) has no self-dual symmetry, the two-fold degeneracy of the GSE spectrum is removed and eigenvalue pairs split up. If the perturbation is small, there are two different spacing scales in this setup, as shown in Fig. 3 where the perturbation of two nearest-neighbor eigenvalues is sketched:

![FIG. 3. Perturbation of GSE eigenvalues removing the degeneracy.](image-url)
• \( S_1 \): The spacings between previously degenerate eigenvalues, which are of the same order of magnitude as the coupling parameter for small couplings. They are formed by the two smallest/largest eigenvalues of \( H \).

• \( S_2 \): The intermediate spacing, which is formed by the second and third largest eigenvalue of \( H \). In the limit \( \lambda \to 0 \) this is the original spacing of the GSE matrix \( H_4 \).

The joint probability density of the eigenvalues of \( H \) is given, up to a rescaling, by [5, Eq. (14.2.7)]

\[
P(\theta_1, \theta_2, \theta_3, \theta_4) = C_0 \exp \left( -\sum_{i=1}^{4} \theta_i^2 \right) \Delta(\theta_1, \theta_2, \theta_3, \theta_4) 
\times [h(d_{21})h(d_{43}) + h(d_{32})h(d_{41}) - h(d_{31})h(d_{42})] 
\tag{2.57}
\]

with
\[
\Delta(\theta_1, \theta_2, \theta_3, \theta_4) = \prod_{i<j} (\theta_j - \theta_i), 
\tag{2.58}
\]
\[
h(x) = xe^{-x^2/\lambda^2}, 
\tag{2.59}
\]
\[
d_{ij} = \theta_i - \theta_j, 
\tag{2.60}
\]
\[
C_0 = \frac{1}{9\pi^2} \lambda^{-6} (2 + \lambda^2)^5. 
\tag{2.61}
\]

As we are only interested in spacings and thus in differences of eigenvalues, we introduce new variables
\[
t_1 = d_{21} = \theta_2 - \theta_1, 
\tag{2.62}
\]
\[
t_2 = d_{32} = \theta_3 - \theta_2, 
\tag{2.63}
\]
\[
t_3 = d_{43} = \theta_4 - \theta_3. 
\tag{2.64}
\]

and keep the original variable \( \theta_1 \). The Jacobi determinant of this transformation is 1, and we can now perform the \( \theta_1 \) integration, which results (up to a constant factor) in

\[
P(t_1, t_2, t_3) = \Delta(-t_1, 0, t_2, t_2 + t_3) 
\times \exp \left\{ -\frac{1}{4} \left[ (t_1 + 2t_2 + t_3)^2 + 2t_1^2 + 2t_2^2 \right] \right\} 
\times [h(t_1)h(t_3) - h(t_1+t_2)h(t_2+t_3) + h(t_1+t_2+t_3)h(t_2)] .
\tag{2.65}
\]

We now derive the distributions of the two different kinds of spacings from this formula. We assume \( \theta_1 \leq \theta_2 \leq \theta_3 \leq \theta_4 \) and include the resulting combinatorial factor of \( 4! \) explicitly.

2. \textit{Spacings between originally degenerate eigenvalues}

To obtain the distribution of the spacing between the two smallest eigenvalues of \( H \) (the two largest ones give the same result due to symmetry), we set \( t_1 = S_1 \) and integrate over \( t_2 \) and \( t_3 \) from 0 to \( \infty \). This results in the spacing distribution

\[
P_{1\to2}^1(s_1;\lambda) = CD \int_0^\infty dt_2 dt_3 P(Ds_1, t_2, t_3) 
\tag{2.66}
\]

with
\[
C(\lambda) = \frac{4}{3} \pi^{-3/2} \lambda^{-6} (2 + \lambda^2)^5, 
\tag{2.67}
\]
\[
D(\lambda) = C(\lambda) \int_0^\infty ds_1 dt_2 dt_3 S_1 P(S_1, t_2, t_3). 
\tag{2.68}
\]

We replaced \( S_1 \) by \( s_1 \) to indicate that this is the spacing on the unfolded scale, i.e., with a mean value of 1. One of the integrals could in principle be done analytically, but this results in such a lengthy expression that it seems more sensible to evaluate all integrals numerically.

The distribution in the limit \( \lambda \to 0 \) can either be obtained by perturbation theory, see App. C 1, or by directly evaluating the spacing distribution in the limit \( \lambda \to 0 \). First note that

\[
\lim_{\lambda \to 0} \frac{2}{\sqrt{\pi} \lambda^3} x h(x) = \delta(x), 
\tag{2.69}
\]

where the \( \lambda \)-dependence of \( h \), which is suppressed in our notation, plays a crucial role. As the mean value of the spacing \( S_1 \) on the original scale has to become arbitrarily small in the GSE-limit due to the Kramers degeneracy, we consider a rescaled spacing \( \tilde{s}_1 = S_1/\lambda \). Therefore \( h(S_1) \) becomes for small \( \lambda \)

\[
h(S_1) = h(\tilde{s}_1) \xrightarrow{\lambda \to 0} \tilde{s}_1 e^{-\tilde{s}_1^2}. 
\tag{2.70}
\]

With these considerations we obtain from Eq. (2.65)

\[
P(\lambda \tilde{s}_1, t_2, t_3) \propto \lambda e^{-\frac{1}{4} \left[ (\lambda \tilde{s}_1 + 2t_2 + t_3)^2 + 2\lambda^2 \tilde{s}_1^2 + 2t_3^2 \right]} 
\times \left[ \frac{2\tilde{s}_1^2}{\sqrt{\pi} \lambda} e^{-\tilde{s}_1^2} \delta(t_3)(\lambda \tilde{s}_1 + t_2)(\lambda \tilde{s}_1 + t_2 + t_3)t_2(t_2 + t_3) 
- \delta(\lambda \tilde{s}_1 + t_2) \delta(t_2 + t_3) \lambda \tilde{s}_1 t_2 t_3(\lambda \tilde{s}_1 + t_2 + t_3) 
+ \delta(\lambda \tilde{s}_1 + t_2 + t_3) \delta(t_2) \lambda \tilde{s}_1(\lambda \tilde{s}_1 + t_2 + t_3) t_3 \right] 
\tag{2.71}
\]

as \( \lambda \to 0 \). The last two terms in square brackets vanish upon evaluation of the \( t_2 \) and \( t_3 \) integrals, because the zeros of the arguments of their \( \delta \)-functions lie outside of the integration region. Performing the \( t_3 \) integration in the first term we obtain for nonzero \( \lambda \) and \( \tilde{s}_1 \)

\[
P_{1\to2}^1(\tilde{s}_1;\lambda) \xrightarrow{\lambda \to 0} \frac{s_1^2}{\pi} e^{-s_1^2}. 
\tag{2.72}
\]

Up to normalization and rescaling this is the spacing distribution of a \( 2 \times 2 \) GUE matrix.

In the opposite limit \( \lambda \to \infty \) the result (2.66) reduces to the distribution of the first and last spacings of a pure \( 4 \times 4 \) GUE matrix. This distribution can be obtained from similar considerations, starting from [5, Eq. (3.3.7)].

The result (2.66) is shown in Fig. 3 (left and middle) for several values of \( \lambda \), along with the limiting distributions for \( \lambda \to 0 \) and \( \lambda \to \infty \). All these curves are very similar and can only be distinguished by the naked eye in the zoomed-in plot.

We have validated the result (2.66) by comparing it to the spacing distribution of numerically obtained \( 4 \times 4 \) random matrices.
3. Perturbed GSE-spacing

We now consider the perturbed spacing of the original GSE matrix, which was formed by the two degenerate eigenvalue pairs of $H_4$. The distribution of this spacing is obtained by setting $t_2 = S_2$ and integrating $P$ defined in Eq. (2.65) over $t_1$ and $t_3$ from 0 to $\infty$. With proper normalization as given in Eq. (2.2), this yields

$$P_{s_2 \to 2}^2(s_2; \lambda) = CD \int_0^\infty dt_1 dt_3 P(t_1, Ds_2, t_3)$$  \hspace{1cm} (2.73)

with

$$C(\lambda) = \frac{4}{3} \pi^{-3/2} \lambda^{-6} (2 + \lambda^2)^{-5},$$  \hspace{1cm} (2.74)

$$D(\lambda) = C(\lambda) \int_0^\infty dS_2 dt_1 dt_3 S_2 P(t_1, S_2, t_3).$$  \hspace{1cm} (2.75)

Again, the replacement of $S_2$ by $s_2$ means that this is the intermediate spacing on the unfolded scale, i.e., with a mean value of 1.

In the limit $\lambda \to 0$ the result (2.73) reduces to the Wigner surmise for the GSE, while in the opposite limit $\lambda \to \infty$ it reduces to the spacing distribution of the intermediate spacing of a pure $4 \times 4$ GUE matrix, which can again be obtained from similar considerations.

The result (2.73) is shown in Fig. 4 (right) for several values of $\lambda$, along with the limiting distributions for $\lambda \to 0$ and $\lambda \to \infty$. The maximum of the interpolation first drops down as $\lambda$ is increased from 0, while at a value of $\lambda$ around 1 it starts to rise again as the distribution approaches its $\lambda \to \infty$ limit. Note that the limiting distributions of $s_1$ and $s_2$ for $\lambda \to \infty$, i.e., the red dashed curves in Fig. 4, turn out to be almost identical to each other and to the Wigner surmise for the GSE.

We have also validated the result (2.73) by comparing it to the spacing distribution of numerically obtained $4 \times 4$ random matrices.

III. APPLICATION TO LARGE SPECTRA

In this section we will show numerically that the formulas derived in Sec. III for small matrices describe the spacing distributions of large random matrices very well. This observation should be viewed as our main result.

When comparing the results obtained from large matrices to our generalized Wigner surmise, a natural question is how the corresponding coupling parameters, i.e., $\lambda$ in Eq. (1.4), should be matched. This question will be addressed in the next subsection based on perturbation theory, while the numerical results will be presented in the remaining subsections.

A. Matching of the coupling parameters

The setup is most easily explained by means of the transition from Poisson to the GUE. The Poisson case is represented by a diagonal $N \times N$ matrix $H_0$ with independent entries $\theta_i$ ($i = 1, \ldots, N$), each distributed according to the same distribution $P(\theta)$, which we choose independent of $N$. The eigenvalue density of $H_0$ is thus $\rho_0(\theta) = N P(\theta)$, and the local mean level spacing is $1/\rho_0(\theta)$. We consider

$$H = H_0 + \alpha H_2,$$  \hspace{1cm} (3.1)

where $H_2$ is an $N \times N$ random matrix taken from the GUE, subject to the usual normalization, Eq. (2.2).

As in the $2 \times 2$ case, the eigenvalues $\theta_i$ will experience a repulsion through $H_2$. We will show in first-order perturbation theory that the relevant quantity for the repulsion is a combination of the eigenvalue density of $H_0$ and the variance of the matrix elements of $H_2$.

Ordinary perturbation theory in $\alpha$ yields a first-order eigenvalue shift of the $\theta_i$ of

$$\Delta \theta_i^{(1)} = \alpha \langle H_2 \rangle \theta_i.$$  \hspace{1cm} (3.2)
This shift does not lead to a correlation of the eigenvalues, as it just adds an independent Gaussian random number to each of them. Therefore, the eigenvalues remain uncorrelated, and their spacing distribution remains Poissonian.

However, if there is a small spacing of order $\alpha$ between two adjacent eigenvalues $\theta_k$ and $\theta_l$ of $H_0$, first-order almost-degenerate perturbation theory predicts that the perturbed eigenvalues are the eigenvalues of the matrix

$$\begin{pmatrix} \theta_k & 0 \\ 0 & \theta_l \end{pmatrix} + \alpha \begin{pmatrix} (H_2)_{kk} & (H_2)_{kl} \\ (H_2)_{lk} & (H_2)_{ll} \end{pmatrix}. \quad (3.3)$$

This matrix is almost identical to the $2 \times 2$ matrix considered in Sec. II C Eq. (2.11), with two differences: (i) The unperturbed eigenvalues $\theta_k$ and $\theta_l$ are shifted, but this does not affect the spacing distribution. (ii) The mean spacing of the unperturbed eigenvalues is not $1$, but $1/\rho_0(\theta)$. We dropped the subscript on the eigenvalue $\theta$ here, because adjacent eigenvalues are very close for large $N$, and therefore $\rho_0(\theta_k) \approx \rho_0(\theta_l) = \rho_0(\theta)$.

To be able to match to the $2 \times 2$ formulas, we have to correct for the different mean spacing of the unperturbed matrix. We can do this by multiplying the matrix in Eq. (3.3) by $\rho_0(\theta)$ without affecting the normalized spacing distribution. This results in the relation

$$\lambda(\theta) = \rho_0(\theta) \alpha \quad (3.4)$$

between the coupling parameters of the $2 \times 2$ and the $N \times N$ case. Note that the $2 \times 2$ parameter $\lambda$ has acquired a dependence on the eigenvalue $\theta$ of $H$ through the local eigenvalue density of $H_0$. To be able to describe the spacing distribution of $H$ in the spectral region around $\theta$ by the generalized Wigner surmise, we assume that we have to insert this $\lambda(\theta)$ into the $2 \times 2$ formulas. This choice of universal coupling parameter is in line with an “unfolded” coupling parameter mentioned in Ref. 15 and a similar result from perturbation theory Ref. 25. Appendix D contains a calculation for large matrices in second-order perturbation theory, also showing that the strength of the perturbation to be used in the generalized Wigner surmise only depends on the combination $\rho_0(\theta) \alpha$.

We now turn from the example “Poisson to GUE” to the general case, which we write as

$$H = H_\beta + \alpha H_{\beta'} \quad (3.5)$$

The same considerations hold with two modifications: (i) The unperturbed matrix is not necessarily diagonal by construction. However, it can be diagonalized by a transformation that can be absorbed in the perturbation. We can therefore treat it as diagonal (with eigenvalues correlated as dictated by the unperturbed ensemble). (ii) The mean spacing $\bar{s}_\beta$ of the unperturbed $2 \times 2$ ($4 \times 4$) matrix from Sec. II is

$$\bar{s}_0 = 1 \quad \text{(Poisson)}, \quad \bar{s}_1 = \sqrt{\pi} \quad \text{(GOE)}, \quad \bar{s}_2 = \frac{4}{\sqrt{\pi}} \quad \text{(GUE)}, \quad \bar{s}_4 = \frac{16}{3\sqrt{\pi}} \quad \text{(GSE)} \quad (3.6)$$

Therefore, we now have to multiply Eq. (3.5) by $\bar{s}_\beta \rho_\beta(\theta)$ to get the correct mean spacing $\bar{s}_\beta$ for the unperturbed matrix. This results in a universal, but $\theta$-dependent, coupling parameter

$$\lambda(\theta) = \bar{s}_\beta \rho_\beta(\theta) \alpha \quad (3.7)$$

with the eigenvalue density $\rho_\beta(\theta)$ of the unperturbed matrix. Equation (3.7) holds for all the transitions we consider, and in each case $\beta$ is the Dyson index of the unperturbed ensemble.

In turn, this perturbative argument provides us with a formula of how to choose the coupling $\alpha$ in large matrices in order to approximate the spacing distribution of $H$ by $2 \times 2$ ($4 \times 4$) formulas with parameter $\lambda$, i.e.,

$$\alpha = \frac{\lambda}{\rho_\beta(\theta) \bar{s}_\beta} \quad (3.8)$$

where $\rho_\beta(\theta)$ is the eigenvalue density in the spectral region we wish to study. In this way we can choose a value of $\lambda$ resulting in a spacing distribution roughly in the middle of the two limiting cases. Choosing $\alpha$ in Eq. (3.5) without this guidance is likely to result in a spacing distribution that is dominated by one of the limiting cases.

B. Transitions from integrable to chaotic

1. Check of Wigner surmise

We first consider transitions from Poisson to RMT for matrices with $N$ non-degenerate eigenvalues. The explicit numerical realization is the Hamiltonian

$$H = H_0 + \frac{\Lambda}{\rho_0(0)} H_{\beta'} \quad (3.9)$$

where $H_{\beta'}$ is a matrix taken from one of the Gaussian ensembles, with normalization as given in Eq. (2.2). $H_0$ is the same matrix as in Eq. (3.1) for the perturbation $H_{\beta'}$ in GOE or GUE, whereas a self-dual $H_0$ is constructed when the ability distribution is always invariant under the transformations that diagonalize $H_{\beta}$, just like in the Poisson to RMT cases. However, this does not work for some of the transitions between the GSE and ensembles without self-dual symmetry, which we discuss separately in Sec. III E.

---

5 For small $\alpha$, we are unlikely to find three or more small (i.e., of order $\alpha$) consecutive spacings.

6 Note that we choose the perturbations $H_{\beta'}$ such that their probability distribution is always invariant under the transformations that diagonalize $H_{\beta}$, just like in the Poisson to RMT cases. However, this does not work for some of the transitions between the GSE and ensembles without self-dual symmetry, which we discuss separately in Sec. III E.
by a direct product with 1₂ as in Sec. III D if the perturbation is taken from the GSE. We choose a Gaussian for the distribution of the eigenvalues of $H₀$, i.e., $P(\theta) = (1/\sqrt{2\pi}) \exp(-\theta^2/2)$, so $ρ₀(0) = N/\sqrt{2\pi}$. From Eq. (3.8) we would then expect the spacing distribution in the center of the spectrum around $θ = 0$ to be approximated by the corresponding $2 \times 2$ formulas, see Secs. II B through II D. The quantity $Δ₂$ defined in App. E is a measure of the fit quality, which is small for a good fit. Each plot has been obtained by diagonalizing 50,000 matrices with 400 non-degenerate eigenvalues.

As can be seen in Fig. 5 the formulas for the $2 \times 2$ matrices indeed describe the spectra of large matrices quite well in a wide range of the coupling parameter $Λ$. The spacing distribution was evaluated in the center of the spectrum, defined as the interval $(-0.2, 0.2)$, because the eigenvalue density is almost constant and equal to $ρ₀(0)$ in this region so that no unfolding is needed. The analytical curve was obtained by a fit (see App. E for details) of the $2 \times 2$ (or $4 \times 4$) formula to the numerical data with fit parameter $λ$. As expected by the perturbative considerations, $λ$ comes out on the same order of magnitude as $Δ₂$ and almost matches for small $Δ₂$. However, $λ$ is considerably smaller than $Λ$ for stronger couplings. Presumably, the repulsion of the many other eigenvalues in the spectrum not present in the smallest matrices has a squeezing effect on the spacing, which works against the repulsion caused by the perturbation. This would explain the smaller coupling parameter.

2. Dependence of coupling parameter on eigenvalue density

The considerations in Sec. III A imply a linear relation between local eigenvalue density and effective coupling parameter, Eq. (3.7), for matrices of the form given in Eq. (3.1). This means that a perturbation should have a different impact on the spacing distribution of a single matrix in different regions of its spectrum (as qualitatively observed in Fig. 5). This subsection provides a detailed analysis of this phenomenon.

Again, we consider a diagonal Poissonian matrix $H₀$ of large dimension perturbed by a matrix taken from one of the Gaussian ensembles $H_{β'}$,

$$H = H₀ + αH_{β'}.$$  

(3.10)

This time we will choose some fixed $α$ and look separately
at different parts of the spectrum of $H$ with a varying eigenvalue density. According to Eq. (3.7) the effective $2 \times 2$ ($4 \times 4$) coupling parameter $\lambda$ should be the product of $\alpha$ and the local eigenvalue density of $H_0$. In App. [D] we show in perturbation theory up to second order that the local coupling parameter is in fact a function of this product.

To treat such a system numerically one has to construct a Poissonian ensemble with a varying eigenvalue density, perturb it, and measure the coupling parameter in different parts of the spectrum. This is done by cutting the spectrum into small windows with approximately constant eigenvalue density and fitting (see App. [E] for details) the spacing distributions inside the windows to the formulas for the $2 \times 2$ ($4 \times 4$) matrices. We therefore obtain a fitted coupling parameter $\lambda$ for each window.

For the numerical calculations, the eigenvalues $\theta_i$ of the matrix $H_0$ were distributed in the interval $(-N/2, N/2)$ according to the somewhat arbitrarily chosen distribution

$$P(\theta_i) = \frac{1}{N} \left[ \frac{1}{2} + 6 \left( \frac{\theta_i}{N} \right)^2 + 8 \left( \frac{\theta_i}{N} \right)^3 \right].$$ (3.11)

$N$ being the number of independent eigenvalues of $H_0$. The matrix $H_{\beta'}$ is normalized in the usual way, Eq. (2.2).

The eigenvalue density $\rho(\theta)$ of the total matrix $H$ is plotted along with the analytical $\rho_0(\theta) = N P(\theta)$ of $H_0$ in the top row of Fig. 6. One can see that the perturbation only has a negligible effect on the spectral density.

The dependence of the coupling parameter on the eigenvalue density is plotted in the bottom row of Fig. 6 for $\alpha = 0.1$. No error bars are shown because the statistical errors are negligibly small. A linear fit through the origin with minimized squared deviation was performed to obtain the proportionality factor between the eigenvalue density and the coupling parameter. The quantity $\delta_2$ shown in the plots is a measure of the fit quality and defined by

$$\delta_2 = \sqrt{\frac{\sum_{i=1}^{N} (\lambda_i - \hat{\lambda})^2}{N} / \frac{\sum_{j=1}^{N} \lambda_j}{N}},$$ (3.12)

where the $\lambda_i$ are the numerically obtained coupling parameters for each spectral window and the $\hat{\lambda}_i$ are the corresponding predictions from the linear fit at the given eigenvalue density. Because $\delta_2$ is a monotonically increasing function of the squared deviation it is also minimized by our fitting procedure.

As can be seen, the linear dependence of the effective coupling parameter on the eigenvalue density is confirmed very well by the numerical data for all the transitions. Note that the fit quality gets better with increasing Dyson index $\beta'$, i.e., it is worst for the GOE and best for the GSE. This is most likely explained by the fact that the spacing distributions change more rapidly with respect to the coupling parameter for larger $\beta'$ (cf. Fig. 4).
which allows for a more precise measurement of the coupling.

Although the linear dependence of the effective coupling on the eigenvalue density has been demonstrated beyond reasonable doubt, the proportionality factor is less clear. As can be read off from Fig. 6, the proportionality factor is smaller than \( \alpha \), i.e., the measured coupling parameter is smaller than the expected one. This agrees with the observation in Sec. III B where an explanation was given in terms of the effect of other eigenvalues.

C. Transitions from one symmetry class to another

1. Check of Wigner surmise

We now consider chaotic systems composed of different symmetry classes, the latter represented by pure Gaussian ensembles. If the GSE is involved, we consider the case of a self-dual perturbed ensemble in this section (see Sec. III D for the case of a non-self-dual perturbed ensemble). A self-dual GOE can be constructed by taking the direct product with \( \mathbb{1}_2 \) as in Sec. III F while the self-dual GUE is more involved, see App. E. All ensembles are normalized as in Eq. (2.2). Again motivated by Eq. (3.8), the Hamiltonian under consideration is

\[
H = H_\beta + \frac{\Lambda}{\rho_\beta(0)} s_\beta H_{\beta'}. \tag{3.13}
\]

For large matrix size, the eigenvalue density of \( H_\beta \) is a semicircle which extends to \( r_\beta = \sqrt{2\beta N} \), and its eigenvalue density in the center is

\[
\rho_\beta(0) = \frac{\sqrt{2N}}{\sqrt{\beta\pi}}. \tag{3.14}
\]

The results for the three transitions among the Gaussian ensembles are shown in Fig. 7 for \( N = 400 \). Again, only the center of the spectrum, defined as the interval \((-5, 5)\), was evaluated (the whole semicircle extends to about \( \pm 28 \) for \( H_\beta \in \text{GOE} \) and about \( \pm 40 \) for \( H_\beta \in \text{GUE} \)). The coupling parameter \( \lambda \) was obtained by a fit (see App. E for details) to the corresponding \( 2 \times 2 (4 \times 4) \)
formula, which yields a good approximation to the numerical data throughout the transition in each case. As in Sec. III B 1, $\lambda$ is close to $\Lambda$ as expected.

For $\Lambda = 1$ and $N = 400$ the mixed matrix is roughly given by $H = H_\beta + O(10^{-1})H_\beta'$. From the $\lambda$-values given in Fig. 7 which should be compared to those in Fig. 2 we see that the transition is almost completed in this case and that the spacing distribution is already very similar to the one of the perturbing ensemble. What is relevant for the transition is not the relative average magnitude of the matrix elements (which depends on $N$ through the local eigenvalue density) but the rescaled coupling parameter $\Lambda$, i.e., the transition occurs for $\Lambda = O(1)$. The same phenomenon was found for the two-point function [24], which is related to the spacing distribution for small $s$.

2. Dependence of coupling parameter on eigenvalue density

We now consider the dependence of the coupling parameter on the local eigenvalue density as in Sec. III B 2, but now for transitions between Gaussian ensembles. In these cases, the fitting procedure of the effective coupling becomes less precise, because the functions of the spacing distributions change only very slowly with $\lambda$, as can be seen in Fig. 2. Therefore, we restrict ourselves to the case of a self-dual GOE matrix $H_1$ that is perturbed by a GSE matrix $H_4$ as the level repulsion differs the most in these two ensembles.

In Fig. 8 we show results from the mixed matrix

$$H = H_1 + \alpha H_4, \quad \alpha = \frac{\gamma}{\rho_1(0)s_1}$$

with $\gamma = 0.2$ (for details about the self-dual GOE and the normalization, see Sec. III C 1). According to Eq. (3.8) the effective $4 \times 4$ coupling parameter $\lambda$ should be $\alpha \rho(\theta)s_1 = \gamma \rho(\theta)/\rho_1(0)$, i.e., proportional to the local eigenvalue density normalized by the density $\rho_1(0)$ in the center, with proportionality factor given by the input parameter $\gamma$. As one can see, there is again a linear dependence of the fitted coupling parameter $\lambda$ on the local density (and again, the perturbation has no measurable effect on the eigenvalue density). The proportionality factor is almost compatible with the expected value $\gamma$.

D. Perturbation of a GSE matrix by a non-self-dual GUE matrix

In this section, we apply the formulas derived in Sec. IIII for the spacing distributions of a $4 \times 4$ matrix from the GSE perturbed by a matrix from the GUE, this time without self-dual symmetry, to large matrices. We consider a $2N \times 2N$ matrix

$$H = H_4 + \frac{\Lambda}{\rho_4(0)s_4} H_2,$$}

where $H_4$ is taken from the GSE and $H_2$ is the perturbation from the GUE. Both $H_4$ and $H_2$ are normalized in the usual way, see Eq. (2.2), and for the prefactor of $H_2$ we again restrict the measurements to the center of the spectrum, defined by the interval $(-5, 5)$. The numerically obtained spacing distributions were rescaled to a mean value of 1.

As in Sec. IIII we will separately consider the spacings between originally degenerate eigenvalues and the remaining ones. The distributions of the former were obtained by measuring every second spacing, starting with
FIG. 9. Spacing distributions between previously degenerate eigenvalues \( s_1 \) (top) and previously non-degenerate eigenvalues \( s_2 \) (bottom) for the transition GSE \( \rightarrow \) GUE without self-dual symmetry for various values of the coupling parameter \( \Lambda \) in Eq. (3.16). The histograms show the numerical data, while the full curves are the \( 2 \times 2 \) GUE surmise \( P_2 \) (top) and the surmise \( P_{4-2}^{1}(s_2; \lambda) \) given in Eq. (3.17) (bottom), the latter with fitted coupling parameter \( \lambda \). The quantity \( \Delta_2 \) defined in App. E is a measure of the fit quality, which is small for a good fit. The numerical data were obtained by diagonalizing 50,000 random matrices of dimension 400 for each plot.

E. Other transitions between the GSE and ensembles without self-dual symmetry

Let us now consider the transition from the GSE to either the GOE or Poisson, both without self-dual symmetry. These two cases are more complicated than the cases discussed so far because, as we shall discuss now, the transitions proceed via an intermediate transition to the GUE.

Let us first focus on the case

\[
H = H_4 + \frac{\Lambda}{\rho_4(0)s_4} H_1 ,
\]

where \( H_4 \) is from the GSE, \( H_1 \) is from the GOE without self-dual symmetry, and we again concentrate on the central part of the spectrum (near zero). For small \( \Lambda \), we show in App. E in first-order perturbation theory that the perturbation by the GOE has exactly the same effect on the eigenvalues as the perturbation by the GUE considered in Sec. IIH modulo a rescaling of the coupling parameter, i.e.,

\[
P_{4-1}^{1}(s_1; \lambda) = P_{4-2}^{1}(s_1; \lambda/\sqrt{2}) \simeq P_2(s_1) , \quad (3.18)
\]

\[
P_{4-1}^{2}(s_2; \lambda) = P_{4-2}^{2}(s_2; \lambda/\sqrt{2}) . \quad (3.19)
\]

Therefore, we first expect a transition from the GSE to the GUE, corresponding to the breaking of the self-dual symmetry. This expectation is confirmed in Fig. 10 (top and middle).

As \( \Lambda \) is increased to very large values, a transition to GOE behavior must eventually occur. The question is whether this transition is described by the surmise of Sec. II F. We show in Fig. 10 (bottom) that this is indeed the case. Note that a rising \( \Lambda \) amounts to a shrinking fitted coupling parameter \( \lambda \) because the direction of the transition is turned around compared to Sec. II F. Here, \( \Lambda \rightarrow \infty \) means that \( H \) is a pure GOE matrix, which is described by the surmise with \( \lambda = 0 \).

The case of GSE to Poisson without self-dual symmetry is analogous. For small values of the coupling parameter, the self-dual symmetry of the GSE is broken by the perturbation so that we expect a GSE to GUE transition for the spacings \( s_1 \) and \( s_2 \) as in the GSE to GOE case considered above. For very large values of the cou-
We have shown that all of these distributions yield a

FIG. 10. Spacing distributions for the transition GSE → GOE without self-dual symmetry for various values of the coupling parameter Λ in Eq. (3.17). Top: spacings s₁ between previously degenerate eigenvalues (for small Λ). Middle: spacings s₂ between previously non-degenerate eigenvalues (also for small Λ). Bottom: all spacings (for large Λ). The histograms show the numerical data, while the full curves are the 2×2 GOE surmise $P_2$ (top), the surmise $P_{2→1}(s; λ)$ given in Eq. (3.19) (middle), and the surmise $P_{1→2}(s; λ)$ given in Eq. (2.33), the latter two with fitted coupling parameter λ. The quantity $\Delta_2$ defined in App. E is a measure of the fit quality, which is small for a good fit. The numerical data were obtained by diagonalizing 50,000 random matrices of dimension 400 for each plot.

plugging parameter we should eventually find a transition to Poisson behavior, described by the surmise of Sec. II C. We have confirmed these expectations numerically but do not show the corresponding plots here.

Note that in the transitions considered in Secs. III B through III D a single anti-unitary symmetry (or integrability in the case of Poisson) was broken or restored. In contrast, we now have two transitions. As Λ increases from zero, an anti-unitary symmetry $T$ with $T^2 = −1$ gets broken. As Λ decreases from infinity, either an anti-unitary symmetry with $T^2 = 1$ gets broken (in the case of GOE) or integrability gets broken (in the case of Poisson). For intermediate values of Λ the system follows GUE statistics because all anti-unitary symmetries and/or integrability are broken. This is illustrated in Fig. 11.

IV. SUMMARY

We have derived generalized Wigner surmises for the nearest-neighbor spacing distributions of various mixed RMT ensembles from 2×2 and 4×4 matrices. If the GSE was involved in the transition, we have distinguished two cases: (i) perturbations of the GSE by a self-dual ensemble, and (ii) perturbations of the GSE by a non-self-dual ensemble, for which we separately considered two different kinds of spacings.

We have shown that all of these distributions yield a
denote its Fourier transform by \( F_{\omega} \) (or to the convergence of the Fourier series with a cut-off in the integral). The inverse Fourier transform with a cut-off in the integral tends to the original function \( f(s') \) as known from textbooks such as [26] (which, however, primarily discuss the Gibbs phenomenon only in the Fourier view of the Gibbs phenomenon in the Fourier transform, \( \lambda \to 0 \) limit of \( f(s'; \lambda) \) is related to the original function \( f(s) \). If \( f(s) \) is smooth and \( \lambda \to 0 \) limit of \( f(s; \lambda) \) approaches \( f(s) \) everywhere. Accordingly, the Dirichlet kernel approaches the delta distribution in the sense of acting on smooth test functions. 

At discontinuities of the original function \( f(s) \), however, \( f(s; \lambda) \) approaches the average of the left and right limit of \( f(s) \). Intuitively, this comes from the nonzero width of the Dirichlet kernel which in the convolution \( \delta_{\lambda}(s - s') = \frac{\sin((s - s')/\lambda)}{\pi(s - s')} \). (A4)

The question is how in the \( \lambda \to 0 \) limit \( f(s; \lambda) \) is related to the original function \( f(s) \). If \( f(s) \) is smooth and \( \lambda \to 0 \) limit of \( f(s; \lambda) \) approaches \( f(s) \) everywhere. Accordingly, the Dirichlet kernel approaches the delta distribution in the sense of acting on smooth test functions. 

At discontinuities of the original function \( f(s) \), however, \( f(s; \lambda) \) approaches the average of the left and right limit of \( f(s) \). Intuitively, this comes from the nonzero width of the Dirichlet kernel which in the convolution \( \delta_{\lambda}(s - s') = \frac{\sin((s - s')/\lambda)}{\pi(s - s')} \). (A4)

The question is how in the \( \lambda \to 0 \) limit \( f(s; \lambda) \) is related to the original function \( f(s) \). If \( f(s) \) is smooth and \( \lambda \to 0 \) limit of \( f(s; \lambda) \) approaches \( f(s) \) everywhere. Accordingly, the Dirichlet kernel approaches the delta distribution in the sense of acting on smooth test functions. 

At discontinuities of the original function \( f(s) \), however, \( f(s; \lambda) \) approaches the average of the left and right limit of \( f(s) \). FIG. 12. The Gibbs phenomenon in the Fourier transform of the Poisson curve, with \( \lambda = 0.01, 0.005, 0.0025 \), respectively. Top: the functions \( f(s; \lambda) \) approaching the original function \( e^{-s} \) (dashed), first maximum moving to the left as \( \lambda \) decreases. Bottom: the rescaled functions \( \hat{f}(s; \lambda) \) approaching the limiting function \( g(s) \) (dashed) with decreasing \( \lambda \), see text.

\[
\frac{i}{2\pi} e^{-d\lambda} [\text{Ei}(d\lambda - i\hat{s}) - \text{Ei}(d\lambda + i\hat{s})].
\]  

(A9)

Keeping \( \hat{s} \) fixed, these functions have a well-defined limit \( \lambda \to 0 \),

\[
g(\hat{s}) = \lim_{\lambda \to 0} \hat{f}(\hat{s}; \lambda)
\]

\[
= \frac{i}{2\pi} [\text{Ei}(-i\hat{s}) - \text{Ei}(i\hat{s})] = \frac{1}{2} + \frac{\text{Si}(\hat{s})}{\pi}
\]  

(A10)

with the sine integral \( \text{Si}(\hat{s}) = \int_0^\hat{s} dx \sin x/x \). As Fig. 12 (bottom) shows, this limiting function captures infinitely many maxima at \( \hat{s} = \pi, 3\pi, \ldots \) and infinitely many minima at \( \hat{s} = 2\pi, 4\pi, \ldots \). The overshoot at the first maximum is the well-known number

\[
\frac{1}{2} + \frac{\text{Si}(\pi)}{\pi} - 1 = 0.0894899.
\]  

(A11)

Concerning the convergence of the Fourier transform, we conclude that in the limit \( \lambda \to 0 \) the functions \( f(s; \lambda) \) have a maximum at \( s = \pi\lambda \), with an overshoot approaching 8.9%.

Note that the limiting function \( g \) is the same for all these functions independently of the decay constants \( d \), i.e., it is solely determined by the discontinuity. In other words, the smooth part of the function \( f(s) \) drops out when going from \( \hat{f}(s; \lambda) \) to \( g(s) \) in the \( \lambda \to 0 \) limit, see Eq. (A9) vs (A10).

This can be shown to be universal. Rescaling the integration variable in Eq. (A3) and using \( \lambda \delta_1(\lambda x) = \delta_1(x) \) one has

\[
f(s; \lambda) = \int_0^\infty ds'' f(\lambda s'') \delta_1\left(\frac{s}{\lambda} - s''\right),
\]

(A12)

\[
\hat{f}(\hat{s}; \lambda) = \int_0^\infty ds'' f(\lambda s'') \delta_1(\hat{s} - s''),
\]

(A13)

where we still assume \( f(s < 0) = 0 \) for simplicity. The limiting function is

\[
g(\hat{s}) = f(0^+) \int_{-\infty}^{\hat{s}} dt \delta_1(t) = f(0^+) \left[ \frac{1}{2} + \frac{\text{Si}(\hat{s})}{\pi} \right],
\]

(A14)

which agrees with (A10) for all functions with \( f(0^+) = 1 \).

The last equation in particular relates the Dirichlet kernel \( \delta_1 \) and the limiting function \( g \). Therefore, \( f(s; \lambda) \) can also be reconstructed by a convolution with (the derivative of) \( g \),

\[
f(s; \lambda) = \int_0^\infty ds' f(s') \frac{1}{\lambda} g'\left(\frac{s - s'}{\lambda}\right),
\]

(A15)

where \( g'(x) = dg/dx \).

2. Gibbs Phenomenon in the Poisson to RMT transitions

For the Gibbs-like phenomenon in the mixed spacing distributions we start with the Poisson to GSE case. For this transition we found the spacing distribution Eq. (2.26). In analogy to the previous subsection we rescale the argument and define

\[
\tilde{P}_{0 \to 4}(\tilde{s}; \lambda) = P_{0 \to 4}(\tilde{s} \lambda; \lambda) = C\lambda^4 \tilde{s}^4 e^{-D^2 \lambda^2 \tilde{s}^2}
\times \int_1^1 dx (1 - x^2) e^{(x D^2 \lambda^2 \tilde{s}^2 + 2\lambda^2 x D \tilde{s} \text{erfc}(x D \lambda \tilde{s} + \lambda)}.
\]

(A16)

In the limit \( \lambda \to 0 \) we make use of the behavior of \( C(\lambda) \) and \( D(\lambda) \),

\[
D(\lambda) \sim \frac{1}{2\lambda^2} \quad \text{and} \quad C(\lambda) \sim \frac{1}{(2\lambda)^4},
\]

(A17)

to arrive at the limiting function

\[
g_{0 \to 4}(\tilde{s}) = \lim_{\lambda \to 0} \tilde{P}_{0 \to 4}(\tilde{s}; \lambda)
\]
This concludes our empirical results on the Gibbs-like phenomenon.

Concerning the analogies at a more fundamental level, the spacing distribution $P_{0→4}(s;λ)$ is related to the integral of the unperturbed Poisson distribution with the kernel

$$\delta_λ(S,p) = \int \delta(S−λp) \, dp \, \frac{e^{−p}}{\sqrt{2\pi t^2}} \left( S−λp \right)^{-\frac{1}{2}} \left( S−λp + 4\lambda_0^2 \right)^{-\frac{1}{2}} \right) \delta(0−c_3(c_3)).$$

The nonzero width of this kernel causes the Gibbs phenomenon in the spacing distribution near the discontinuity of the Poisson distribution $e^{−p}$ at $p = 0$. Note that in the limit $λ → 0$ the second line of Eq. (A22) approaches $δ(S−p)$, thus decoupling from the integrals over $a, ..., c_3$. The latter are normalized by construction so that the kernel $δ_λ(S,p)$ approaches $δ(S−p)$.

There are (at least) two features that are different from the Fourier case. First, the kernel is not a function of $S−p$, and thus Eq. (A22) is not a convolution, in contrast to the Fourier case, Eq. (A15). Second, at the discontinuity $P_{0→4}(0;λ) = 0$ is not the average (equal to $1/2$) of the left and right limit of the original Poisson curve $e^{−p}$ (put to zero for negative $p$).

Appendix B: Explicit calculation of spacing distributions

1. Poisson to GSE

We start from Eq. (2.25), transform $c_0, ..., c_3$ to polar coordinates with $e^2 = e_{\mu} e_{\mu}$, and introduce $u = a + b$ and $t = a − b$. This yields

$$I(S) \propto \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \frac{e^{−p}}{\sqrt{2\pi t^2}} \left( S−λp \right)^{-\frac{1}{2}} \left( S−λp + 4\lambda_0^2 \right)^{-\frac{1}{2}} \right) \delta(0−c_3(c_3)).$$

where in the last step we have integrated over $u$. We now use the $δ$-function to integrate over $c$, resulting in

$$I(S) ≃ \int_{-\infty}^{\infty} \frac{e^{−p}}{\sqrt{2\pi t^2}} \left( S−λp \right)^{-\frac{1}{2}} \left( S−λp + 4\lambda_0^2 \right)^{-\frac{1}{2}} \right) \delta(0−c_3(c_3)).$$

This integral is evaluated as

$$I(S) = \int_{-\infty}^{\infty} \frac{e^{−p}}{\sqrt{2\pi t^2}} \left( S−λp \right)^{-\frac{1}{2}} \left( S−λp + 4\lambda_0^2 \right)^{-\frac{1}{2}} \right) \left( S−λp + 4\lambda_0^2 \right)^{-\frac{1}{2}} \right) \delta(0−c_3(c_3)).$$

FIG. 13. The rescaled spacing distributions $P_{0→4}(s;λ)$ in the Poisson to GSE transition, Eq. (2.19), for $λ = 0.05, 0.025, 0.01$ (maxima increasing) approaching the limiting function $g_{0→4}(s)$, Eq. (A18) (dashed).

$\frac{d}{ds} \int_1^s e^{-\lambda s/2} \, ds = \frac{s^4}{16} e^{-\lambda s/2} \int_1^s e^{-\lambda s/2} \, ds = \frac{s^2}{8} \left( 2 + \tilde{s}^2 \right) \sqrt{\pi} e^{-\lambda \tilde{s}^2/4} \, d\tilde{s}/2.$

$g_{0→4}(\tilde{s}) = \frac{\sqrt{\pi}}{2} \tilde{s} e^{-\tilde{s}^2/4} \, I_0(\tilde{s}^2/4), \quad (A19)$

$g_{0→2}(\tilde{s}) = \frac{\sqrt{\pi}}{2} \tilde{s} e^{-\tilde{s}^2/4} \, I_0(\tilde{s}^2/4), \quad (A20)$

These have maxima at $\tilde{s} = 2.51$ and $\tilde{s} = 3.00$, overshooting the Poisson curve by $17.5\%$ and $28.5\%$, respectively, as quoted in the body of the paper. We observe that these numbers grow with the Dyson index $\beta'$ of the perturbing ensemble.

From the small-$\tilde{s}$ behavior $g_{0→4}(\tilde{s}) = \tilde{s}^4/12 + O(\tilde{s}^6)$ we conclude that $P_{0→4}(s;λ) = s^4/(12\lambda^4) + O(s^6)$ for small $\lambda$, which reproduces our observation in Eqs. (2.30) and (2.31). Analogous agreement is obtained with Eqs. (2.9), (2.10), and Eqs. (2.19), (2.20) for the other two cases.
where we have integrated over $p$ and substituted $t = xS$.

The proper level spacing distribution $P_{0 \to 4}(s)$, Eq. (2.26), is obtained from $I(S)$ by rescaling and normalization, i.e., $P_{0 \to 4}(s) = C \cdot J(2DS)/(2D)^4$. Defining the moments of the distribution,

$$I_n = \int_0^\infty dS S^n I(S),$$  \hspace{1cm} (B3)

we obtain from Eq. (1.2)

$$D = \frac{I_1}{2 \sigma_0^2} \quad \text{and} \quad C = \frac{(2D)^5}{I_0}. \hspace{1cm} (B4)$$

Explicit evaluation of $I_0$ and $I_1$ gives

$$I_0 = \frac{16}{\lambda} e^{-\lambda^2}, \hspace{1cm} (B5)$$

$$I_1 = \frac{16}{\sqrt{\pi}} e^{-\lambda^2} \int_0^\infty dx \, e^{-2\lambda x} \times \frac{(4x^2 + 2x)e^{-x^2} + \sqrt{\pi}(4x^4 + 4x^2 - 1) \operatorname{erf}(x)}{x^3}, \hspace{1cm} (B6)$$

from which we obtain Eqs. (2.27) and (2.28).

2. GOE to GSE

We consider the matrix $H$ in Eq. (2.40). With a small change in notation for $H_1$, we have

$$H = H_1 \otimes 1_2 + \lambda H_4 = \begin{pmatrix} A & 0 & C & 0 \\ 0 & A & 0 & C \\ C & 0 & B & 0 \\ 0 & C & 0 & B \end{pmatrix}$$

$$+ \lambda \begin{pmatrix} a & 0 & c_0 + ic_3 & c_1 + ic_2 \\ 0 & a & c_0 - ic_3 & -c_1 - ic_2 \\ c_1 - ic_2 & c_0 + ic_3 & b & 0 \\ c_0 - ic_3 & -c_1 - ic_2 & b & 0 \end{pmatrix}, \hspace{1cm} (B7)$$

where the variances of the random variables are given by Eq. (2.2). If two variables are Gaussian distributed with variances $\sigma_1^2$ and $\sigma_2^2$, their sum is again Gaussian distributed with variance $\sigma_1^2 + \sigma_2^2$. Since $H$ depends on $A, B, C$ and $a, b, c_0$ only through the combinations $A + \lambda a, B + \lambda b, C + \lambda c_0$, we can immediately integrate out $A, B, C$, with the corresponding change in the variances of $a, b, c_0$. To simplify the notation, we absorb $\lambda$ in $H_4$ and divide all matrix elements of $H$ by $\sqrt{1 + \lambda^2}$. This yields a problem equivalent to Eq. (B7),

$$H \rightarrow \begin{pmatrix} a & 0 & c_0 + ic_3 & c_1 + ic_2 \\ 0 & a & c_0 - ic_3 & -c_1 - ic_2 \\ c_1 - ic_2 & c_0 + ic_3 & b & 0 \\ c_0 - ic_3 & -c_1 - ic_2 & b & 0 \end{pmatrix} \hspace{1cm} (B8)$$

with

$$\sigma_{a,b}^2 = 2\sigma_{c_0}^2 = 1, \quad 2\sigma_{c_i}^2 = \frac{\lambda^2}{1 + \lambda^2} \equiv \sigma^2. \hspace{1cm} (B9)$$

where $i = 1, 2, 3$. The matrix in Eq. (B8) has two non-degenerate eigenvalues whose spacing is given by

$$S = \left[(a - b)^2 + 4 \sum_{\nu = 0}^{3} \sigma_{c_\nu}^2 \right]^{1/2}, \hspace{1cm} (B10)$$

where we have again written $S$ instead of $s$ since we still need to enforce the normalizations (1.2). The spacing distribution is proportional to the integral

$$I(S) = \int_{-\infty}^{\infty} da \, dB \, dc_0 \, dc_1 \, dc_2 \, dc_3 \, e^{-\frac{1}{2}(a^2 + b^2 + 2c_0^2)} \times \delta \left(S - \sqrt{(a - b)^2 + 4c_0^2 + 4c_1c_2 + 4c_3c_3}\right), \hspace{1cm} (B11)$$

where repeated indices indicate a sum over $i$ and $j$ from 1 to 3. We now transform $c_1, c_2, c_3$ to spherical coordinates with $c^2 = c_i c_i$ and introduce $u = a + b$ and $t = a - b$. This yields

$$I(S) \propto \int_{-\infty}^{\infty} du \, dt \, dc_0 \, dc \, e^{-\frac{1}{2}(u^2 + t^2 + 4c_0^2)} \times \delta \left(S - \sqrt{t^2 + 4c_0^2 + 4c_3^2}\right), \hspace{1cm} (B12)$$

The integral over $u$ can be performed trivially and only results in a prefactor. Using the $\delta$-function to integrate over $c$, we obtain

$$I(S) \propto \int_{0}^{\infty} dt \, dc_0 \, e^{-\frac{1}{4}(t^2 + 4c_0^2)} \cdot \frac{1}{4\pi} (S^2 - t^2 - 4c_0^2)$$

$$\times S \sqrt{S^2 - t^2 - 4c_0^2} \theta \left(S^2 - t^2 - 4c_0^2\right), \hspace{1cm} (B13)$$

where we have used the symmetries of the integrand to raise the lower limit of the integrations to zero. We now perform the transformation

$$t = Sx \quad \text{and} \quad c_0 = \frac{1}{2} Sy \sqrt{1 - x^2} \hspace{1cm} (B14)$$

with Jacobian $\frac{1}{2} S^2 \sqrt{1 - x^2}$. Since $t$ and $c_0$ are non-negative, so are $x$ and $y$. The $\theta$-function in Eq. (B13) then implies $0 \leq x, y \leq 1$. Reinserting the definition of $\sigma^2$ from Eq. (B9), we obtain

$$I(S) \propto S^4 \int_{0}^{1} dx \, dy \, (1 - x^2) \sqrt{1 - y^2} \times e^{-\frac{x^2}{4\lambda} [\lambda^2 + (1 - x^2)(1 - y^2)]}. \hspace{1cm} (B15)$$

We now substitute $y = \cos \phi$, note that $\cos^2 \phi = \frac{1}{2}(1 - \cos 2\phi)$, and use the integral representation [19] Eq. (9.6.19)] of the modified Bessel functions $I_0$ and $I_1$ to obtain after some algebra

$$I(S) \propto S^4 e^{-\frac{1 + 2\lambda^2}{8\lambda^2} S^2} \int_{0}^{1} dx \, (1 - x^2) e^{\frac{2x^2}{2\lambda^2} [I_0(z) - I_1(z)]}$$

$$\equiv J(S) \hspace{1cm} (B16)$$
with \( z = (1 - x^2)S^2/(2\lambda^2) \). This corresponds to Eq. (2.4) with \( S = \sqrt{\lambda}D_s \). The properly normalized spacing distribution is therefore given by \( P_{1 \to 4}(s) = CJ(\sqrt{\lambda}D_s)/(\sqrt{\lambda}D)^4 \). Defining
\[
I_n = \int_0^\infty dS S^n J(S)
\]
we obtain from Eq. (1.2)
\[
D = \frac{I_1}{\sqrt{\lambda}I_0} \quad \text{and} \quad C = \frac{\sqrt{\lambda}I_0}{I_0}.
\]
Explicit evaluation of \( I_0 \) and \( I_1 \) gives
\[
I_0 = 8\sqrt{\pi} \left( \frac{\lambda^2}{1 + \lambda^2} \right)^{3/2},
\]
\[
I_1 = 16\lambda^3 \left[ \frac{\lambda(1 - \lambda^2)}{(1 + \lambda^2)^2} + \text{arccot} \lambda \right],
\]
from which we obtain Eqs. (2.42) and (2.43).

**Appendix C: Perturbation of a large GSE matrix by a non-self-dual matrix**

We consider a mixed \( 2N \times 2N \) matrix that interpolates between the GSE and one of the other Gaussian ensembles,
\[
H = H_4 + \frac{\Lambda}{\rho_4(0)\delta_4} H_{\beta'},
\]
where \( H_4 \) is taken from the GSE and \( H_{\beta'} \) from the GOE or GUE. We study this matrix for large \( N \) in first-order degenerate perturbation theory to show similarities between the two different perturbations and to make a connection to the case of GSE to non-self-dual GUE for \( N = 2 \), which was treated in Sec. IIIH.

Degenerate perturbation theory predicts that each of the \( N \) previously degenerate eigenvalue pairs splits up and that the shifts of the two members of the pair are the eigenvalues of the matrix
\[
\frac{\Lambda}{\rho_4(0)\delta_4} M_{ij}, \quad \text{with} \quad M_{ij} = \langle \psi_i | H_{\beta'} | \psi_j \rangle; \quad i, j = 1, 2. \tag{C2}
\]

The \( |\psi_{1,2}\rangle \) are the orthonormal eigenvectors of the unperturbed matrix \( H_4 \) that span the degenerate subspace of the eigenvalue pair under consideration.

We show in the following that \( M \) is a \( 2 \times 2 \) GUE matrix for \( \beta' = 2 \) as well as for \( \beta' = 1 \), in the latter case with a normalization different from Eq. (2.2).

### 1. GUE

This case is very simple, because the GUE is invariant under unitary transformations, which contain the symplectic transformations. This means that the transformation diagonalizing the GSE matrix \( H_4 \) can be absorbed in \( H_2 \) without loss of generality, and therefore one can choose \( |\psi_i\rangle_k = \delta_{ik} \) with \( i = 1, 2 \) and \( k = 1, \ldots, 2N \). Thus, we obtain
\[
M_{ij} = \sum_{k,l=1}^{2N} \delta_{ik} (H_2)_{kl} \delta_{lj} = (H_2)_{ij}, \tag{C3}
\]
which is obviously a \( 2 \times 2 \) matrix from the GUE with the usual normalization, Eq. (2.2). As this holds also for \( N = 2 \), it is a perturbative explanation for the fact that in the limit \( \lambda \to 0 \) the spacings between previously degenerate eigenvalues are distributed exactly like the ones of \( 2 \times 2 \) GUE matrices.

### 2. GOE

We will show that in this case \( M \) is again a matrix from the GUE with the only difference that the variances of its elements are only half as large as in the previous subsection. This case is a bit more involved because one cannot generally diagonalize a self-dual matrix by an orthogonal transformation (which would preserve the probability distribution of \( H_1 \)), and thus it is impossible to choose the eigenvectors of \( H_4 \) as in the previous subsection. Explicitly, the matrix elements read
\[
M_{ij} = \langle \psi_i | H_1 | \psi_j \rangle = \langle \psi_i^{\text{re}} | H_1 | \psi_j^{\text{re}} \rangle + \langle \psi_i^{\text{im}} | H_1 | \psi_j^{\text{im}} \rangle + i \langle \psi_i^{\text{re}} | H_1 | \psi_j^{\text{im}} \rangle - \langle \psi_i^{\text{im}} | H_1 | \psi_j^{\text{re}} \rangle,
\]
where we split the eigenvectors \( |\psi_i\rangle \) in real and imaginary parts: \( |\psi_i\rangle = |\psi_i^{\text{re}}\rangle + i|\psi_i^{\text{im}}\rangle \), and \( H_1 \) is real.

We will now show that the four vectors \( |\psi_1^{\text{re}}\rangle \), \( |\psi_1^{\text{im}}\rangle \), \( |\psi_2^{\text{re}}\rangle \), and \( |\psi_2^{\text{im}}\rangle \) are orthogonal in the limit of infinite matrix size. For some combinations of them one can show this also for finite \( N \) using the quaternionic structure of the eigenvectors,
\[
\left( \begin{array}{c} \langle \psi_1^{\text{re}} \rangle \\ \langle \psi_1^{\text{im}} \rangle \\ \langle \psi_2^{\text{re}} \rangle \\ \langle \psi_2^{\text{im}} \rangle \end{array} \right) = \left( \begin{array}{cccc} q_1 & q_2 & \cdots & q_N \end{array} \right),
\]
with quaternions in matrix representation
\[
q_k = \left( \begin{array}{cc} q_k^{(0)} + i q_k^{(3)} & q_k^{(1)} + i q_k^{(2)} \\ q_k^{(1)} - i q_k^{(2)} & q_k^{(0)} - i q_k^{(3)} \end{array} \right).
\]
One can read off immediately that
\[
\langle \psi_1^{\text{re}} | \psi_1^{\text{im}} \rangle = \langle \psi_1^{\text{im}} | \psi_1^{\text{re}} \rangle = 0,
\]
\[
\langle \psi_1^{\text{re}} | \psi_2^{\text{im}} \rangle = - \langle \psi_2^{\text{re}} | \psi_1^{\text{im}} \rangle,
\]
\[
\langle \psi_1^{\text{im}} | \psi_2^{\text{im}} \rangle = \langle \psi_2^{\text{im}} | \psi_1^{\text{im}} \rangle,
\]
i.e., there are only two independent scalar products.

Let us assume that for large \( N \) the \( q_k^{(3)} \) can be treated as independent random variables with mean value zero. Then the mean values of those scalar products are zero as well, e.g.,
\[
\langle \langle \psi_1^{\text{re}} | \psi_1^{\text{im}} \rangle \rangle = \sum_{k=1}^N q_k^{(0)} q_k^{(1)} + q_k^{(1)} q_k^{(2)} = 0,
\]
\[
\langle \langle \psi_1^{\text{re}} | \psi_2^{\text{im}} \rangle \rangle = \sum_{k=1}^N q_k^{(0)} q_k^{(2)} - q_k^{(1)} q_k^{(2)} = 0,
\]
\[
\langle \langle \psi_1^{\text{im}} | \psi_2^{\text{im}} \rangle \rangle = \sum_{k=1}^N q_k^{(1)} q_k^{(3)} - q_k^{(2)} q_k^{(3)} = 0.
\]
where the outer angular brackets indicate an average over the random matrix ensemble. From the normalization of the eigenvectors $|\psi_i\rangle$ the variances of the $q_k^{(r)}$ are proportional to $1/N$. This yields for the variances of the scalar products

$$\langle (|\psi_1^r\rangle| |\psi_1^m\rangle)^2 \rangle = \sum_{k=1}^{N} \left( \langle |q_k^{(0)}|^2 \rangle \langle |q_k^{(3)}|^2 \rangle + \langle |q_k^{(1)}|^2 \rangle \langle |q_k^{(2)}|^2 \rangle \right)$$

$$\propto \sum_{k=1}^{N} \frac{1}{N^2} = \frac{1}{N}$$

(C11)

and likewise for $\langle (|\psi_2^r\rangle| |\psi_2^m\rangle)^2 \rangle$. Since in the $N \to \infty$ limit both the mean values and the variances of the scalar products vanish, the four vectors become orthogonal in this limit for every single realization of the random matrix. We have checked this numerically, which implies that the assumption of the independence of the $q_k^{(r)}$ was valid.

As for the normalization of the four vectors, the squared norms of the real and imaginary parts agree on average and sum up to 1 due to the normalization of the eigenvectors $|\psi_i\rangle$. Invoking the central limit theorem, we observe that in the limit $N \to \infty$ the norms of the real and imaginary parts equal $1/\sqrt{2}$ even for a single realization of the random matrix. Hence, multiplying the four real vectors $|\psi_1^r\rangle$, $|\psi_1^m\rangle$, $|\psi_2^r\rangle$, and $|\psi_2^m\rangle$ by $\sqrt{2}$, one obtains, in the limit $N \to \infty$, an orthonormal real basis in the subspace under consideration.

Finally, we use the fact that the matrix elements of a GOE matrix $H_0$ are independent random numbers in every orthonormal (real) basis, with variances 1 and 1/2 on and off the diagonal, respectively. Thus we conclude that the $M_{ij}$ are also independent random numbers with variances

$$\langle [M_{11}^{re}]^2 \rangle = \langle [M_{22}^{re}]^2 \rangle = \frac{1}{2},$$

$$\langle [M_{12}^{re}]^2 \rangle = \langle [M_{12}^{im}]^2 \rangle = \frac{1}{4}.$$  

(C12)

These are half the variances of a GUE matrix, which is equivalent to a multiplication of each element of $M$ by $1/\sqrt{2}$. This explains the rescaling of the coupling parameter in the definitions of $P^1_{4\to1}(s_1; \lambda)$ and $P^2_{4\to1}(s_2; \lambda)$, Eqs. 3.18 and 3.19.

For small $N$ the argumentation in this section does not work. Presumably, this is the reason why the spacing distributions for the transition from GSE to GOE differ from those for the transition from GSE to GUE in the case of $4 \times 4$ matrices (not shown in this paper, but checked numerically), whereas they match very well for large matrices.

### Appendix D: Perturbative calculation of the relation between eigenvalue density and coupling parameter

We consider a diagonal Poissonian matrix $H_0$ perturbed by a matrix taken from one of the Gaussian ensembles $H_{\beta'}$,

$$H = H_0 + \alpha H_{\beta'},$$

where $H_{\beta'}$ is chosen in the usual normalization, see Eq. (2.2). The calculations are done for arbitrary matrix dimension, which will be sent to infinity at the end. We denote the number of generically non-degenerate eigenvalues by $N$, i.e., we consider $N \times N$ matrices. If $H_{\beta'}$ is taken from the GSE, these are quaternion valued and correspond to complex $2N \times 2N$ matrices.

To obtain an $N$-independent eigenvalue density of the Poissonian ensemble, we define the probability distribution of the individual eigenvalues $\theta_i$ of $H_0$ by

$$\mathcal{P}_0(\theta_i) = \frac{1}{N} \tilde{\mathcal{P}}_0(\theta_i/N),$$

(D2)

where $\tilde{\mathcal{P}}_0$ is some $N$-independent probability distribution. Both $\mathcal{P}_0$ and $\tilde{\mathcal{P}}_0$ are normalized to one. The eigenvalue density of the Poissonian ensemble is thus

$$\rho_0(\theta) = N \mathcal{P}_0(\theta) = \tilde{\mathcal{P}}_0(\theta/N) = \tilde{\mathcal{P}}_0(\theta/N),$$

(D3)

where we have defined $\tilde{\theta} = \theta/N$. Generically we have $\theta_i = O(N)$ and $\theta_i = O(1)$.

We now consider a fixed spacing $S$ between two adjacent eigenvalues of $H_0$, $\theta_1$ and $\theta_2$ equal to $S$. The remaining eigenvalues have to reside outside the interval $(\theta_1, \theta_2)$. This results in the conditional probability distribution

$$\mathcal{P}^{\text{out}}_0(\theta_i) = \frac{1}{N} \mathcal{P}^{\text{out}}_0(\theta_i/N) = \begin{cases} 0 & \text{for } \theta_i \in (\theta_1, \theta_2), \\ \int_{S}^{\theta_i} d\tilde{\theta} \tilde{\mathcal{P}}_0(\tilde{\theta}) & \text{otherwise.} \end{cases}$$

(D4)

The eigenvalue density is assumed to be almost unaffected by the perturbation, which is confirmed in Fig. 9 (top). Of course, this assumption is expected to hold only for small values of the coupling parameter.

We want to calculate the effect of the perturbation on the spacing $S$. If the remaining eigenvalues of $H_0$ are close to $\theta_1$ or $\theta_2$ we have to apply almost-degenerate perturbation theory. Up to second order in $\alpha$ we obtain for the perturbation of the spacing

$$\Delta S = \left\langle \left( \text{EVD} \left[ (H_0 + \alpha H_{\beta'})_{kl(\theta_i, \theta_j \in W)} \right] - S \right) \right\rangle_{\text{first-order almost-degenerate pert. theory}}$$

$$+ \alpha^2 \sum_{i=3}^{N} \sum_{\theta \neq \theta_i} \left( \frac{|H_{\beta'}|_{2i}^2}{\theta_2 - \theta_i} - \frac{|H_{\beta'}|_{1i}^2}{\theta_1 - \theta_i} \right),$$

(D5)

where the absolute values are taken with respect to the real/complex/quaternionic standard norm, EVD denotes the difference of the two eigenvalues of the matrix $(H_0 + \alpha H_{\beta'})_{kl}$ that correspond to the unperturbed eigenvalues, and $W$ is the interval in which eigenvalues have
to be considered almost degenerate with \( \theta_1 \) or \( \theta_2 \). This is defined by the eigenvalue range \((\theta_1 - C_W, \theta_2 + C_W)\), where we choose \( C_W = C_W^{(0)} N \varepsilon \alpha \) with \( 0 < \varepsilon < 1 \) and \( C_W^{(0)} > 1 \). This choice ensures that the closest possible eigenvalue outside \( W \) cannot give a second-order contribution of lower order in \( \alpha \) than the almost-degenerate part.\(^{[10]}\) Note that the “degenerate window” \( W \) grows with \( N \). Therefore arbitrarily distant eigenvalues are considered almost degenerate in the limit \( N \to \infty \), which is justified because almost-degenerate perturbation theory is valid for any difference of eigenvalues.

Considering the first-order contribution, we have to deal with the matrix

\[
M_{kl} = (H_0)_{kl} + \alpha (H_{\beta'})_{kl} = \theta_k \delta_{kl} + \alpha (H_{\beta'})_{kl}, \tag{D6}
\]
where the indices \( k \) and \( l \) run over all values for which the eigenvalues \( \theta_k \) and \( \theta_l \) are localized in \( W \), which includes at least \( \theta_1 \) and \( \theta_2 \). This is a matrix taken from the Gaussian ensemble, but unlike \( H \) defined in Eq. (D1) it has a constant eigenvalue density in the limit \( N \to \infty \). To show this, we first consider the density at the lower end of the interval \( W \),

\[
\lim_{N \to \infty} N \hat{P}_0 (\theta_1 - C_W) = \lim_{N \to \infty} \hat{P}_0 \left( \frac{\theta_1}{N} - \frac{C_W}{N} \right) = \lim_{N \to \infty} \hat{P}_0 \left( \theta_1 - \frac{C_W^{(0)} N^{-1} \alpha}{N} \right) = \hat{P}_0 (\theta_1) = \rho_0 (\theta_1).
\]

This is the same as the eigenvalue density at the other end of \( W \),

\[
\lim_{N \to \infty} N \hat{P}_0 (\theta_2 + C_W) = \lim_{N \to \infty} \hat{P}_0 \left( \frac{\theta_2}{N} + \frac{S + C_W}{N} \right) = \lim_{N \to \infty} \hat{P}_0 \left( \frac{\theta_2}{N} + \frac{S + C_W^{(0)} N^{-1} \alpha}{N} \right) = \hat{P}_0 (\theta_2) = \rho_0 (\theta_2).
\]

Thus the spectrum of \( M \) can be unfolded by multiplying with the local eigenvalue density,

\[
\rho_0 (\theta_1) M_{kl} = \rho_0 (\theta_1) \theta_k \delta_{kl} + \alpha \rho_0 (\theta_1) (H_{\beta'})_{kl}. \tag{D9}
\]

Therefore we can define a new effective coupling parameter that solely determines the magnitude of the perturbation as in Sec. III A.

The second-order contribution to \( \Delta S \) in Eq. (D5) is a sum of at most \( N - 2 \) independent random numbers. As all of these random numbers have the same distribution we pick out one of them,

\[
x = \alpha^2 \left( \frac{b}{\theta_2 - \theta_1} - \frac{a}{\theta_1 - \theta_1} \right) \quad \text{with} \quad \theta_1 \notin W, \tag{D10}
\]

where we defined \( a = \left| (H_{\beta'})_{11} \right|^2 \) and \( b = \left| (H_{\beta'})_{2i} \right|^2 \). Its probability distribution is given by

\[
\mathcal{P}_x (x) = \left[ \int_{-\infty}^{\theta_1 - C_W} + \int_{\theta_2 + C_W}^{\infty} \right] d\theta \frac{1}{N} \hat{P}_0^{\text{out}} (\theta / N) \tag{D11}
\]

\[
\times \int_0^\infty da \int_0^\infty db \mathcal{P}_{\beta'}(a) \mathcal{P}_{\beta'}(b) \delta \left[ x - \alpha^2 \left( \frac{b}{\theta_2 - \theta_1} - \frac{a}{\theta_1 - \theta_1} \right) \right],
\]

where we renamed \( \theta_1 = \theta \) for convenience. The distribution \( \mathcal{P}_{\beta'} \) depends on the symmetry class of the perturbation ensemble (\( a \) and \( b \) are squared sums of \( \beta' \) Gaussian random variables). The moments of this distribution are

\[
p_m = \int_{-\infty}^\infty dx \mathcal{P}_x (x) x^m. \tag{D12}
\]

After a short calculation, we obtain

\[
p_m = \int_{-\infty}^0 d\theta \int_0^\infty da \int_0^\infty db \frac{1}{N} \left[ \hat{P}_0^{\text{out}} \left( \frac{\theta - C_W^{(0)} \alpha}{N} + \hat{\theta}_1 \right) \right. \\
+ \left. \hat{P}_0^{\text{out}} \left( \frac{S - \theta - C_W^{(0)} \alpha}{N} + \hat{\theta}_1 \right) \right] \mathcal{P}_{\beta'} (a) \mathcal{P}_{\beta'} (b) \times \left[ \alpha^2 \left( \frac{b}{S + C_W^{(0)} N \varepsilon \alpha - \theta} - \frac{a}{C_W^{(0)} N \varepsilon \alpha - \theta} \right) \right]^m. \tag{D13}
\]

In the limit \( N \to \infty \), all terms that are divided by \( N \) in the arguments of \( \hat{P}_0^{\text{out}} \) can be neglected. This can be done in spite of \( \theta \) being integrated to \( \infty \), because the last part of the integrand (in square brackets) suppresses the large-\( \theta \) region and because \( \hat{P}_0^{\text{out}} \) is a probability density that has to converge to 0 for large argument. Also, \( \lim_{N \to \infty} \hat{P}_0^{\text{out}} (\theta_1) = \hat{P}_0 (\theta_1) = \rho_0 (\theta_1) \). We thus obtain

\[
p_m = \frac{2 \rho_0 (\theta_1)}{N} \int_{-\infty}^0 d\theta \int_0^\infty da \int_0^\infty db \mathcal{P}_{\beta'} (a) \mathcal{P}_{\beta'} (b) \times \left[ \alpha^2 \left( \frac{b}{S + C_W^{(0)} N \varepsilon \alpha - \theta} - \frac{a}{C_W^{(0)} N \varepsilon \alpha - \theta} \right) \right]^m. \tag{D14}
\]

Let us denote the second line of Eq. (D5) by \( \Delta S^{(2)} \). It is \( O(N P_1) \), and therefore its mean value becomes zero for \( N \to \infty \), as it is suppressed by \( N^{-\varepsilon} \). The same holds for the second moment of \( \Delta S^{(2)} \), which goes like \( N^{-2\varepsilon} \). Thus the distribution of \( \Delta S^{(2)} \) is a delta function at zero, and we can neglect its contribution to the perturbation of the spacing. The linear relation between eigenvalue density and coupling parameter could hence be shown up to second-order perturbation theory.

Appendix E: Method for fits to the surmises

Since most of the analytical formulas for the small matrices contain integrals, it takes some time to compute
them numerically. In order to get good fits to data in a reasonable time, a list of 1000 \( \lambda \)-values in the interval \((0.01, 10)\) was created, with

\[
\lambda_i = 0.01 \cdot 1000 \cdot \frac{m}{i}; \quad i = 1, \ldots, 1000.
\]  

(E1)

For each \( \lambda_i \) and each surprise, the corresponding spacing distribution was stored. The pure cases \( \lambda = 0 \) and \( \lambda = \infty \) were included as well.

As a measure of the fit quality, we use the \( L_2 \)-distance

\[
\Delta_2 = \left\{ \int dx \left[ f(x) - g(x) \right]^2 \right\}^{1/2}
\]  

(E2)

between the fit and the numerical data. The fitting was done by calculating the \( \Delta_2 \)-value of each spacing distribution in the list. From the one resulting in the smallest \( \Delta_2 \), we read off the coupling \( \lambda \). Note that the largest \( \Delta_2 \) we encounter in all the fits is 0.019. For comparison, the \( L_2 \)-norms of the pure Wigner surmises \( P_\beta(s) \) range from 0.71 for \( \beta = 0 \) to 0.94 for \( \beta = 4 \). We give no error bars, because the statistical errors of \( \lambda \) obtained by methods such as Jackknife were negligibly small. This is also the reason why we use \( \Delta_2 \) instead of a statistical quantity like chi-squared as a measure of the fit quality.

**Appendix F: Construction of a self-dual GUE**

In the following we construct a Hermitian, self-dual \( 2N \times 2N \) matrix whose eigenvalues are twofold degenerate and whose non-degenerate eigenvalues correspond to those of a matrix from the GUE. We start with a matrix \( M \) that contains an \( N \times N \) GUE matrix \( H \) and its complex conjugate (equal to the transpose),

\[
M = \begin{pmatrix} H & 0_N \\ 0_N & H^* \end{pmatrix}.
\]  

(F1)

The eigenvalues of \( M \) are obviously those of \( H \), but now twofold degenerate as desired. However, \( M \) is not self-dual. To transform \( M \) into a self-dual matrix without changing its eigenvalues, we apply an orthogonal transformation

\[
O = \begin{pmatrix} 1 & 0 & 0 & \cdots & 0 & 0 & \cdots & 0 & 0 & \cdots & 0 & 0 & \cdots & 0 \\
0 & 1 & 0 & \cdots & 0 & 0 & \cdots & 0 & 0 & \cdots & 0 & 0 & \cdots & 0 \\
0 & 0 & 1 & \cdots & 0 & 0 & \cdots & 0 & 0 & \cdots & 0 & 0 & \cdots & 0 \\
\vdots & \vdots & \vdots & \ddots & \vdots & \vdots & \ddots & \vdots & \vdots & \ddots & \vdots & \vdots & \ddots & \vdots \\
0 & 0 & 0 & \cdots & 1 & 0 & \cdots & 0 & 0 & \cdots & 0 & 0 & \cdots & 0 \\
0 & 0 & 0 & \cdots & 0 & 1 & \cdots & 0 & 0 & \cdots & 0 & 0 & \cdots & 0 \\
0 & 0 & 0 & \cdots & 0 & 0 & \cdots & 1 & 0 & \cdots & 0 & 0 & \cdots & 0 \\
\vdots & \vdots & \vdots & \ddots & \vdots & \vdots & \ddots & \vdots & \ddots & \ddots & \vdots & \vdots & \ddots & \vdots \\
0 & 0 & 0 & \cdots & 0 & 0 & \cdots & 0 & 1 & \cdots & 0 & 0 & \cdots & 0 \\
0 & 0 & 0 & \cdots & 0 & 0 & \cdots & 0 & 0 & \cdots & 1 & 0 & \cdots & 0 \\
\end{pmatrix} = O^T = O^{-1},
\]  

(F2)

which transforms a matrix by exchanging every \( 2n \)-th row and column with the \( (N + 2n - 1) \)-th one. Each of the four blocks is a square matrix of dimension \( N \). This is in complete analogy to the construction of a self-dual \( 4 \times 4 \) GUE matrix in Sec. II G.

We now show that the transformed matrix \( O^T M O \) is self-dual, the condition for which is

\[
O^T M O = \frac{1}{J} (O^T M O)^T J = JO^T M^T OJ^T \\
\rightarrow M = OJOM^T OJ^T O
\]  

(F3)

with

\[
J = I_N \otimes \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}.
\]  

(F4)

Multiplying \( J \) by \( O \) from the left and the right interchanges the second, forth, \ldots with the \((N + 1)\)-th, \((N + 3)\)-th, \ldots column and row. We thus obtain

\[
OJO = \begin{pmatrix} 0_N & -I_N \\ I_N & 0_N \end{pmatrix},
\]

\[
OJ^T O = -OJO = \begin{pmatrix} 0_N & I_N \\ -I_N & 0_N \end{pmatrix}
\]  

(F5)

and thus

\[
OJOM^T OJ^T O = \begin{pmatrix} 0_N & -I_N \\ I_N & 0_N \end{pmatrix} \begin{pmatrix} H^T & 0_N \\ 0_N & H \end{pmatrix} \begin{pmatrix} 0_N & I_N \\ -I_N & 0_N \end{pmatrix}
\]

\[
= \begin{pmatrix} H & 0_N \\ 0_N & H^T \end{pmatrix} = M,
\]  

(F6)

which proves Eq. (F3). \( O^T M O \) can therefore be written as a quaternion matrix with real quaternions and their conjugates at the transposed position. Each of these quaternions stands for a matrix of the form

\[
\begin{pmatrix} c_0 + ic_3 & c_1 + ic_2 \\ -c_1 + ic_2 & c_0 - ic_3 \end{pmatrix} = \begin{pmatrix} p & q^* \\ -p^* & q \end{pmatrix}
\]  

(F7)

with complex numbers \( p \) and \( q \). Evidently, \( p \) has to be zero for each quaternion in \( O^T M O \), because our original \( M \) generically contains no element which is the negative complex conjugate of any other, and we only exchanged elements by applying \( O \). This means that at least half of the matrix elements are zero. In the original \( M \), exactly half of the matrix elements were zero, while the other half were random numbers which depended on a total of \( N^2 \) real parameters, so the same has to hold for \( O^T M O \). From this and Hermiticity it follows that every off-diagonal \( q \) has to be an independent complex random number, while the \( q \) on the diagonal are real, so that there are again \( N^2 \) real degrees of freedom.

With this equivalence proven, one can construct a self-dual GUE matrix by taking a matrix from the GSE and set its \( c_1 \) and \( c_2 \) components to zero. This matrix has the same joint probability density of the eigenvalues as an \( N \times N \) matrix taken from the GUE, as it is related to a matrix of the form of \( M \) by a fixed basis transformation.
