Infrared identification of the Criegee intermediates syn- and anti-CH₃CHOO, and their distinct conformation-dependent reactivity

Hui-Yu Lin¹, Yu-Hsuan Huang¹, Xiaohong Wang², Joel M. Bowman², Yoshifumi Nishimura³, Henryk A. Witek¹ & Yuan-Pern Lee¹,³

The Criegee intermediates are carbonyl oxides that play critical roles in ozonolysis of alkenes in the atmosphere. So far, the mid-infrared spectrum of only the simplest Criegee intermediate CH₂OO has been reported. Methyl substitution of CH₂OO produces two conformers of CH₃CHOO and consequently complicates the infrared spectrum. Here we report the transient infrared spectrum of syn- and anti-CH₃CHOO, produced from CH₃CHI + O₂ in a flow reactor, using a step-scan Fourier-transform spectrometer. Guided and supported by high-level full-dimensional quantum calculations, rotational contours of the four observed bands are simulated successfully and provide definitive identification of both conformers. Furthermore, anti-CH₃CHOO shows a reactivity greater than syn-CH₃CHOO towards NO/NO₂; at the later period of reaction, the spectrum can be simulated with only syn-CH₃CHOO. Without NO/NO₂, anti-CH₃CHOO also decays much faster than syn-CH₃CHOO. The direct infrared detection of syn- and anti-CH₃CHOO should prove useful for field measurements and laboratory investigations of the Criegee mechanism.
Recent advances in the direct detection of the Criegee intermediates have stimulated active research on their structures, spectroscopy, reactions and implications for atmospheric chemistry. The Criegee intermediates are carbonyl oxides that are produced during the reactions of ozone (O$_3$) with unsaturated hydrocarbons; they play a central role in controlling the atmospheric budget of OH, organic acids and secondary organic aerosols, especially under low-light conditions.

These Criegee intermediates have eluded detection in the gaseous phase until recently because of their great reactivity and small concentration. Previous understanding of the reactivity of Criegee intermediates, including reaction mechanisms and rate coefficients, was hence subject to large uncertainties, because only indirect experimental evidence was available. Welz et al. produced the simplest Criegee intermediate, formaldehyde oxide (CH$_2$OO), in a flow cell and confirmed its identification with tunable vacuum-ultraviolet photoionization mass spectrometry. Following the reaction scheme of CH$_2$I + O$_2$ $\rightarrow$ I + CH$_2$OO initially developed by Welz et al., CH$_2$OO has now been detected with ultraviolet depletion, ultraviolet absorption, infrared absorption and microwave spectroscopy. The kinetic analysis of reactions of CH$_2$OO with various atmospheric species have been directly investigated with some of these detection methods.

In the atmosphere, O$_3$ reacts with larger alkenes and produces more complex Criegee intermediates RR'COO; the nature and location of the substituents RR' are predicted to affect their reactivity. For example, the OH yield increases from $\sim$10% for O$_3$ + C$_3$H$_6$ to $\sim$60% for O$_3$ + trans-2-butene. The methyl-substituted Criegee intermediate, acetaldehyde oxide (CH$_3$CHOO), is an intermediate of reactions O$_3$ + 2-alkenes (such as trans-2-butene) and serves as a prototype to understand various fundamental issues in larger Criegee intermediates. CH$_3$CHOO exists in two conformers, syn-CH$_3$CHOO and anti-CH$_3$CHOO (Supplementary Fig. 1), with the former more stable than the latter by $\sim$15 kJ mol$^{-1}$ (refs 19,20). Because of a large barrier $\sim$160 kJ mol$^{-1}$, the interconversion between syn-CH$_3$CHOO and anti-CH$_3$CHOO is unlikely. Taatjes et al. employed the reaction CH$_3$CHI + O$_2$ to produce CH$_3$CHOO and detected both conformers with photoionization. By employing photoionization at energies 9.37 and 10.5 eV to detect pre-dominantly anti-CH$_3$CHOO and syn-CH$_3$CHOO, respectively, these authors reported that anti-CH$_3$CHOO is significantly more reactive towards H$_2$O and SO$_2$ than is syn-CH$_3$CHOO.

Although photoionization can distinguish these two conformers of CH$_3$CHOO via distinct ionization energies, a small contribution from the other conformer is unavoidable. The ultraviolet depletion and ultraviolet absorption experiments yielded a broad feature without structure and provided no information about the conformation of the CH$_3$CHOO carrier. Recently Sheps et al. separated the ultraviolet spectra of two possible conformers based on their distinct reactivity towards H$_2$O and SO$_2$, but the two spectra were broad and overlapping with each other. Although microwave spectroscopy was successful in providing structural information, to employ it for monitoring these species in laboratory kinetic experiments is difficult. Liu et al. employed infrared activation of cold CH$_3$CHOO to produce OH, which was detected with laser-induced fluorescence, and assigned several absorption features in the region 5,600–6,100 cm$^{-1}$ to be the CH- overtone and combination bands of syn-CH$_3$CHOO; no bands of anti-CH$_3$CHOO were identified. It is thus desirable to develop an alternative spectral method that can be applied conveniently and can distinguish clearly these two conformers of CH$_3$CHOO.

We have demonstrated that coupling a step-scan Fourier-transform infrared (FTIR) spectrometer with a multipass absorption cell enables the recording of temporally resolved infrared absorption spectra of the simplest Criegee intermediate, CH$_2$OO (ref. 7); five distinct absorption bands of CH$_3$OO were clearly identified to provide a simple and direct detection method. Here we report a further application of this technique to characterize the infrared absorption of methyl-substituted Criegee intermediate CH$_3$CHOO in two conformations and to demonstrate the conformation-dependent reactivity towards its self-reaction and reaction with NO/NO$_2$. 

Results

Spectral analysis of CH$_3$CHOO. Even though only one H atom of CH$_3$OO was replaced with a methyl group to form CH$_3$CHOO, the infrared spectrum of the latter is expected to be much more complicated, because both syn- and anti-conformers contribute to the infrared absorption. In addition, the methyl group introduces low-energy vibrational modes such as the CH$_3$ torsion (internal rotation), which are populated with several vibrational quanta even at ambient temperatures; hot bands might consequently play important roles in the observed spectrum, as it was demonstrated in the spectrum of CH$_3$BrOO (ref. 26). Furthermore, the internal rotation of the methyl moiety may introduce torsional splitting in vibrational bands. Consequently, spectral identification and simulation of observed bands of CH$_3$CHOO are expected to be difficult. In this respect, sophisticated quantum-chemical calculations are essential to assist the spectral simulation and assignments.

We employed a step-scan FTIR spectrometer coupled with a multi-reflection White cell to record time-resolved infrared spectra. The laser beam at 308 nm photodissociated a flowing mixture of 1,1-diodoethane (CH$_3$CHI$_2$) and O$_2$ to produce CH$_3$CHI, which subsequently reacted with O$_2$ to form CH$_3$CHOO. The partial infrared absorption spectrum (830–1,550 cm$^{-1}$) of a flowing mixture of CH$_3$CHI$_2$/N$_2$/O$_2$ (1/13/288, 84 Torr) at 328 K exhibits an intense absorption line of CH$_3$CHI near 1,108 cm$^{-1}$ and some much weaker ones near 985, 1054, 1061, 1106, 1,190, 1,236, 1,383 and 1,447 cm$^{-1}$ (Fig. 1a). On irradiation with light at 308 nm, the absorption of CH$_3$CHI decreased because of photolysis, whereas new bands marked A$_2$ appeared in the difference spectrum recorded 0–2 µs after laser irradiation (Fig. 1b). The A$_2$ band was partially interfered with by the absorption of the precursor and the product acetaldehyde, but its sharp Q-branch is quite characteristic and can be readily recognized. These new lines decreased in intensity, as shown in Fig. 1c where 6–8 µs was recorded after ultraviolet irradiation and disappeared after $\sim$25 µs. To minimize interference from other products, we subtracted the spectrum recorded during 16.0–19.8 µs from these two spectra and stripped the contributions from the precursor and acetaldehyde, as shown in Fig. 1d,e.

As photolysis of CH$_3$CHI produces mainly CH$_3$CHI (ref. 27) and because this radical reacts readily with excessive O$_2$ in the system, possible carriers of the observed new bands include conformers of CH$_3$CHOO and vinyl hydroperoxide (C$_3$H$_4$OOH), methyldioxirane and the stabilized adduct CH$_3$CHOO. The structures of these species are shown in Supplementary Fig. 1. For all species except CH$_3$CHOO, MP2, B3LYP and NEVPT2(8,8) methods were employed to predict their vibrational wavenumbers and infrared intensities. For CH$_3$CHOO, the NEVPT2(1,1) method was used. Furthermore, the most sophisticated predictions were performed for syn- and anti-CH$_3$CHOO with high-level, full-dimensional quantum calculations, using the MULTIMODE method. The vibrational wavenumbers and infrared intensities of syn- and anti-CH$_3$CHOO calculated with these theoretical methods are given in Supplementary...
infrared intensities of CH₃CHOO. Possible ranges of vibrational anharmonicity for the spectrum recorded at 16.0–19.8 K are shown with thick lines.

A comparison of the observed new spectral features with those predicted with the MULTI.MODE method is depicted with thick lines in Fig. 1f,g, respectively, for CH₃CHOO and with the spectrum simulated according to slightly modified ratios of rotational constants for an improved fit. For details of simulation using the PGopher programme[23], see Supplementary Methods. This simulated feature consists of three bands: a dominant OO-stretching (ν₁) band of syn-CH₃CHOO at 871.2 cm⁻¹ and two smaller bands of OO-stretching (ν₃) and OO-stretching mixed with CH₂ wagging (ν₄) modes of anti-CH₃CHOO at 883.7 and 851.8 cm⁻¹, respectively, shown as thin lines in Fig. 2a,b; the fundamental Q-branches of these three modes correspond well with observed distinct peaks; hence, their vibrational wavenumbers can be determined accurately. It is found that several hot bands associated with the ν₁ (208 cm⁻¹) and ν₁₂ (314 cm⁻¹) low-energy vibrational modes of syn-CH₃CHOO and with the ν₁₈ (156 cm⁻¹) and ν₁₇ (255 cm⁻¹) low-energy vibrational modes of anti-CH₃CHOO contribute significantly to the observed spectral features. The individual contributions of fundamental and hot bands for these three vibrational modes are shown in Fig. 2c–e; the transitions of hot bands are expressed as ν’ in which ν is the vibrational mode number, and i and f are vibrational quantum numbers of the lower and upper states, respectively. Detailed positions and relative intensities are listed in Supplementary Table 6. This simulation implies that (1) the hot bands are all blue shifted from the fundamental; the unusual but necessary blue shifts of about 2 and 10 cm⁻¹ for the hot bands involving ν₁₈ and ν₁₂ of syn-CH₃CHOO, respectively, agree qualitatively with the theoretical predictions (Supplementary Table 6). The calculations also indicate that torsional splitting is small for all vibrational modes so that it has no consequence on our spectral simulation. (2) At 328 K, assuming a Boltzmann distribution and that the infrared intensities of hot bands are the same as that of the fundamental band (in qualitative accord with calculations), observed relative intensities of these hot bands imply energies of the first excited states of ν₁₈ and ν₁₂ of syn-CH₃CHOO and those of ν₁₈ and ν₁₂ of anti-CH₃CHOO to be ~193, 282, 149 and 239 cm⁻¹, respectively, which is consistent with theoretical predictions (Table 1 and Supplementary Tables 1 and 2). (3) The population fraction of anti-CH₃CHOO is 0.30 and 0.38 at 328 K, respectively, if infrared intensities predicted with the B3LYP and MULTI.MODE methods are used. This fraction is consistent with a value of ~0.30 derived from ultraviolet experiments[23], but greater than values ~0.20 from microwave experiments[24] and ~0.10 from photoionization experiments[21]. The weaker bands A₃ and A₄ can be simulated likewise with contributions of syn- and anti-CH₃CHOO, as presented in Fig. 3.

Simulation of rotational contours. Further support for the presented assignment comes from analysis of the rotational contours of the observed bands. The rotational contour of the A₁ band near 871 cm⁻¹ recorded in the interval of 0–2 μs has several characteristic peaks; it cannot be simulated with a single band and was deconvoluted with guidance from calculations. The experimental data are presented with open circles and the resultant spectrum, simulated according to ratios of rotational constants of the excited and ground states predicted with the MULTI.MODE method and the experimental rotational constants of the ground state, is shown as a thick solid line in Fig. 2a; the agreement is satisfactory. Figure 2b presents a comparison of experimental data with the spectrum simulated according to slightly modified ratios of rotational constants for an improved fit. For details of simulation using the PGopher programme[23], see Supplementary Methods. This simulated feature consists of three bands: a dominant OO-stretching (ν₁₀) band of syn-CH₃CHOO at 871.2 cm⁻¹ and two smaller bands of OO-stretching (ν₃) and OO-stretching mixed with CH₂ wagging (ν₄) modes of anti-CH₃CHOO at 883.7 and 851.8 cm⁻¹, respectively, shown as thin lines in Fig. 2a,b; the fundamental Q-branches of these three modes correspond well with observed distinct peaks; hence, their vibrational wavenumbers can be determined accurately. It is found that several hot bands associated with the ν₁ (208 cm⁻¹) and ν₁₂ (314 cm⁻¹) low-energy vibrational modes of syn-CH₃CHOO and with the ν₁₈ (156 cm⁻¹) and ν₁₇ (255 cm⁻¹) low-energy vibrational modes of anti-CH₃CHOO contribute significantly to the observed spectral features. The individual contributions of fundamental and hot bands for these three vibrational modes are shown in Fig. 2c–e; the transitions of hot bands are expressed as ν’ in which ν is the vibrational mode number, and i and f are vibrational quantum numbers of the lower and upper states, respectively. Detailed positions and relative intensities are listed in Supplementary Table 6. This simulation implies that (1) the hot bands are all blue shifted from the fundamental; the unusual but necessary blue shifts of about 2 and 10 cm⁻¹ for the hot bands involving ν₁₈ and ν₁₂ of syn-CH₃CHOO, respectively, agree qualitatively with the theoretical predictions (Supplementary Table 6). The calculations also indicate that torsional splitting is small for all vibrational modes so that it has no consequence on our spectral simulation. (2) At 328 K, assuming a Boltzmann distribution and that the infrared intensities of hot bands are the same as that of the fundamental band (in qualitative accord with calculations), observed relative intensities of these hot bands imply energies of the first excited states of ν₁₈ and ν₁₂ of syn-CH₃CHOO and those of ν₁₈ and ν₁₂ of anti-CH₃CHOO to be ~193, 282, 149 and 239 cm⁻¹, respectively, which is consistent with theoretical predictions (Table 1 and Supplementary Tables 1 and 2). (3) The population fraction of anti-CH₃CHOO is 0.30 and 0.38 at 328 K, respectively, if infrared intensities predicted with the B3LYP and MULTI.MODE methods are used. This fraction is consistent with a value of ~0.30 derived from ultraviolet experiments[23], but greater than values ~0.20 from microwave experiments[24] and ~0.10 from photoionization experiments[21]. The weaker bands A₃ and A₄ can be simulated likewise with contributions of syn- and anti-CH₃CHOO, as presented in Fig. 3.

As shown in Fig. 1f and Supplementary Table 1, the more stable syn-CH₃CHOO conformer is predicted from the MULTI.MODE calculations to have more intense absorptions near 908 (100), 969 (5), 1,097 (6), 1,285 (19) and 1,494 (8) cm⁻¹; the numbers in parentheses give relative infrared intensity of each vibration. The observed new features near 871 (100), 956, 1,091 (10), 1,281 (40) and 1,477 (30) cm⁻¹ agree satisfactorily with these predicted values. The predicted pattern of intense lines of anti-CH₃CHOO near 894 (49), 944 (100), 1,295 (3) and 1,488 (10) cm⁻¹ agrees less satisfactorily with the observed spectrum.

We show below that the contribution from the anti-CH₃CHOO conformer, although less significant, is important for explaining the overall shape of the spectrum and is of primary importance for explaining some of the fine-structure spectral features of the spectrum.

Figure 1 | Comparison of observed spectra with predicted stick spectra.
(a) Absorption spectrum of a flowing mixture of CH₃CHI₂/N₂/O₂ (1/13/288, 84 Torr) before photolysis. (b) Difference spectra recorded 0–2 μs and (c) 6–8 μs after irradiation of the sample at 308 nm.
(d) Corrected spectra recorded 0–2 μs and (e) 6–8 μs after subtraction of the spectrum recorded at 16.0–19.8 K and removal of the contributions of the precursor CH₂=CH₂ and stable product acetaldehyde. Resolution of all spectra is 0.5 cm⁻¹. New features are marked with arrows and labelled as A₁–A₅. (f) Possible ranges of anharmonic vibrational wavenumbers and infrared intensities of syn-CH₃CHOO and (g) anti-CH₃CHOO predicted with various methods (Supplementary Tables 1 and 2) shown as filled boxes; those predicted with the MULTI.MODE method are shown with thick lines.

Tables 1 and 2. Those of methyl dioxirane, trans- and cis-vinyl hydroperoxide and syn- and anti-CH₃CHOO are listed in Supplementary Tables 3–5, respectively. There is good consistency among these calculations, but there are significant variations in the calculated anharmonic vibrational wavenumbers and infrared intensities among these calculations. To indicate this, we show the ranges of values as filled rectangles, while the values predicted with the MULTI.MODE method are depicted with thick lines in Fig. 1f,g, respectively, for syn- and anti-CH₃CHOO.

Possible ranges of vibrational anharmonic wavenumbers and intensities of CH₃CHOO, methyl dioxirane and vinyl hydroperoxide predicted with various methods are compared with the observed spectrum in Supplementary Fig. 2. A comparison of the observed new spectral features with those predicted theoretically excludes the possibility of assigning the observed spectral features A₁–A₅ to the carriers other than CH₃CHOO.

As shown in Fig. 1f and Supplementary Table 1, the more stable syn-CH₃CHOO conformer is predicted from the MULTI.MODE calculations to have more intense absorptions near 908 (100), 969 (5), 1,097 (6), 1,285 (19) and 1,494 (8) cm⁻¹; the numbers in parentheses give relative infrared intensity of each vibration. The observed new features near 871 (100), 956, 1,091 (10), 1,281 (40) and 1,477 (30) cm⁻¹ agree satisfactorily with these predicted values. The predicted pattern of intense lines of anti-CH₃CHOO near 894 (49), 944 (100), 1,295 (3) and 1,488 (10) cm⁻¹ agrees less satisfactorily with the observed spectrum.
Band $A_3$ has a prominent Q-branch at 1,280.8 cm$^{-1}$, which is assigned to the HCO bending coupled with the CO-stretching ($v_2$) mode of syn-CH$_2$CHOO. A second feature with a weaker Q-branch at 1,279.4 cm$^{-1}$ is assigned to the corresponding $v_4$ mode of anti-CH$_2$CHOO. Band $A_4$ has prominent P- and R-branches; this band is assigned to the CO-stretching mode coupled with the HCO bending ($v_2$) mode of syn-CH$_2$CHOO. The observed weak Q-branch arises from a small contribution of the $v_5$ mode of anti-CH$_2$CHOO. The contributions of fundamental and hot bands to these features are presented in Supplementary Figs 3 and 4. The a- and b-type spectra of related vibrational modes of syn- and anti-CH$_2$CHOO are presented in Supplementary Figs 5 and 6, respectively. As band $A_2$ is rather weak and subject to interference from absorption of C$_2$H$_4$, we could only estimate its position to be $\sim$956 cm$^{-1}$ from the Q-branch and assign it to the $v_9$ mode of syn-CH$_2$CHO. Band $A_3$ suffers from partial interference due to the precursor, but the prominent Q-branch indicates that this band is due to syn-CH$_2$CHO and not anti-CH$_2$CHO. The observed position at 1,090.6 cm$^{-1}$ is much closer to the predicted anharmonic vibrational wavenumber of 1,097 cm$^{-1}$ for syn-CH$_2$CHO than the value 1,136 cm$^{-1}$ for anti-CH$_2$CHO.

As shown in Table 1, the agreement between observed vibrational wavenumbers of syn- and anti-CH$_2$CHOO, and those calculated with the MULTIMODE method is quite satisfactory with differences $<17$ cm$^{-1}$, except for the OO-stretching mode, which has differences of $37$ cm$^{-1}$ for syn-CH$_2$CHO and $60$ cm$^{-1}$ for anti-CH$_2$CHO. A similar shift between experiment and MULTIMODE calculations was reported previously for CH$_2$OO for an analogous band$^{33}$. Conceivably, the origin of the deviation is, as in CH$_2$OO, a slight deficiency in the level of electronic structure theory which is more sensitive to the OO-stretching mode.

Our observations also conform to an expectation that similar to CH$_2$OO, CH$_2$CHOO has a significant zwitterionic character with a strengthened C–O bond and a weakened O–O bond. The observed wavenumber of the OO-stretching mode of syn-CH$_2$CHOO near 871 cm$^{-1}$ is smaller than the corresponding value 908 cm$^{-1}$ of CH$_2$OO, consistent with theoretical predictions showing that the length of the O–O bond increases from 1.349Å in CH$_2$OO to 1.380Å in syn-CH$_2$CHOO.

**Figure 2** Spectral simulation of band $A_4$. (a) Comparison of experimental data (open circles, recorded 0–2 μs) with spectrum simulated according to theoretical predictions (thick red solid line) and (b) the best simulated spectrum (thick red solid line) with slightly modified parameters; contributions of $v_{10}$ of syn-CH$_2$CHOO, and $v_9$ and $v_{10}$ of anti-CH$_2$CHOO are shown with thin lines. Resolution is 0.5 cm$^{-1}$. (c) Contributions of fundamental and hot bands of $v_{10}$ of syn-CH$_2$CHOO, (d) $v_9$ of anti-CH$_2$CHOO and (e) $v_{10}$ of anti-CH$_2$CHOO. Detailed positions and relative intensities are listed in Supplementary Table 6. Spectral width of simulation is 0.64 cm$^{-1}$. The transitions of hot bands are expressed with $v_i$ in which $v$ is the vibrational mode number, and $i$ and $f$ are vibrational quantum numbers of the lower and upper states, respectively.

**Conformation-dependent reactivity.** Further support for this assignment of the $A_1$ band comes from a comparison of low-resolution spectra recorded in experiments with and without NO/NO$_2$. Taatjes et al.$^{31}$ reported that anti-CH$_2$CHO is more reactive towards H$_2$O, SO$_2$ and NO than syn-CH$_2$CHO, with the effect much more significant for the former two. A direct test with H$_2$O in our system is difficult because of the intense infrared absorption of H$_2$O and the hygroscopic KBr windows we employed. A test with SO$_2$ is also infeasible, because the windows were contaminated by the products easily. Instead, we added NO/NO$_2$ to explore the differences. As shown in Fig. 4a, the difference between bands $A_1$ in the range 870–910 cm$^{-1}$ recorded in experiments with and without adding NO/NO$_2$ is significant during the interval 0–5μs and the difference in the range 830–870 cm$^{-1}$ is smaller but non-negligible. The differences in these two regions are consistent with the contributions of $v_9$ and $v_{10}$ bands of anti-CH$_2$CHOO shown in Fig. 2a. This difference in spectra recorded in experiments with and without NO/NO$_2$ diminished at a later period and the spectrum recorded 5–10μs after photolysis in the experiment with NO/NO$_2$ (Fig. 4b) agrees with that simulated for syn-CH$_2$CHOO only, as shown in Fig. 4d; this provides additional support that our simulation of these two conformers is reliable and most anti-CH$_2$CHO was consumed within 10 μs.

Further indication of the greater reactivity of anti-CH$_2$CHO compared to syn-CH$_2$CHOO comes from the observation of a more rapid decrease of peaks at 851.8 and 883.7 cm$^{-1}$ (assigned to anti-CH$_2$CHOO) relative to that at 871.2 cm$^{-1}$ (assigned to syn-CH$_2$CHOO) in the earlier stage of reaction. Without NO/NO$_2$, nearly all anti-CH$_2$CHOO diminished and only syn-CH$_2$CHOO survived after 10 μs; syn-CH$_2$CHO became nearly diminished after 25 μs. The decay of syn-CH$_2$CHO is likely to be mainly due to its self-reaction, similar to that observed for CH$_2$OO (refs 7,14,15). In Supplementary Fig. 7, we plotted the reciprocal absorbance ($1/\text{Abs}$) integrated from 850 to 900 cm$^{-1}$ for band $A_1$ as a function of reaction period; the integrated absorbance $f$ is proportional to concentration. The slope at the initial stage of reaction is twice that at a later stage of reaction.
Table 1 | Comparison of experimentally observed wavenumbers (cm$^{-1}$) and intensities with the vibrational wavenumbers and infrared intensities of representative vibrational modes of CH$_3$CHOO predicted with the MULTIMODE method.

| Symbol | Syn-CH$_3$CHOO | Anti-CH$_3$CHOO | Description$^*$ |
|--------|----------------|----------------|-----------------|

|        | $v_{17}$       | 449 (0)        | $v_{17}$       | 255 (0)$^i$    | ap deformation |
|        | $v_{18}$       | 208 (1)$^i$    | $v_{18}$       | 156 (0)$^i$    | CH$_3$ torsion |

$^i$ Relative infrared intensities normalized to the most intense line. The maximal intensities of syn- and anti-CH$_3$CHOO are predicted to be 44.4 and 43.6 km mol$^{-1}$, respectively, with the MULTIMODE method (18-mode coupling); values of 13-mode coupling for syn- and 14-mode coupling for anti-CH$_3$CHOO are 50.3 and 611 km mol$^{-1}$, respectively.

$^j$ Harmonic vibrational wavenumbers, as the anharmonic treatment of this mode is problematic using the methods employed here. Anharmonic vibrational wavenumbers are $v_{12} = 290$ cm$^{-1}$ and $v_{18} = 241$ cm$^{-1}$ predicted with the VCI/NEVPT2(8,8)/aug-cc-pVDZ method.

A qualitative analysis indicates that the overall removal of anti-CH$_3$CHOO could be up to 30 times faster than that of syn-CH$_3$CHOO; this probably reflects the difference in reactivity of these two conformers associated with some reactions with themselves or with other species. We are unable to derive absolute concentration of CH$_3$CHOO, because the infrared probe volume does not follow the photolysis volume in our experiments$^{14}$; hence, accurate rate coefficient cannot be determined. In any case, it is clear that in the CH$_3$CHI + O$_2$ system the reactivity of anti-CH$_3$CHOO is much greater than that of syn-CH$_3$CHOO, so that most anti-CH$_3$CHOO was consumed within 10$^{-5}$ s under our experimental conditions. Future theoretical investigations on this...
distinct conformation-dependent reactivity will provide some insight on this important observation.

**Discussion**

We recorded the transient infrared spectrum of both syn- and anti-CH3CHO, produced from CH3CHI + O2 in a flow reactor, using a step-scan Fourier-transform spectrometer. The rotational contours, vibrational wavenumbers and relative infrared intensities of these observed bands provide definitive identification of both conformers; the rotational contours are critical in distinguishing these conformers. The assignments and spectral simulation are guided and supported by high-level full-dimensional quantum chemical calculations. We found that anti-CH3CHO is more reactive towards NO/NO2 than syn-CH3CHO. Without NO/NO2, anti-CH3CHO also decays much more rapidly than syn-CH3CHO. This feature shall enable one to prepare nearly pure syn-CH3CHO either by adding NO/NO2 or by waiting till a later reaction period. This distinct conformation-dependent reactivity is of fundamental interest and is also important in modelling reactions involving Criegee intermediates both in laboratory and in the atmosphere. Our infrared identification provides an alternative way to probe CH3CHO directly in the atmosphere or in laboratory experiments. Although nearly all observed bands of anti-CH3CHO overlapped with syn-CH3CHO, the Q-branch of ν8 near 1,090.6 cm⁻¹ is dominated solely by syn-CH3CHO, and the ν14 near 1,280 cm⁻¹ is also dominated by syn-CH3CHO; they can be unambiguously detected with a narrow-width infrared laser. This convenient detection scheme will be useful in providing information on the exact mechanism and detailed kinetics of reactions involving CH3CHO.

**Methods**

**Experimental.** The White cell of base path length 15 cm and effective absorbing path length 3.6 m was coupled with a step-scan FTIR spectrometer (Bruker, Vertex 80v) and served as a flow reactor. The flow reactor has volume ~1,370 cm³ and accommodates two rectangular quartz windows (3 x 12 cm) on opposite sides of the cell, to allow the photoysis beam to propagate through the cell. The photoysis laser was generated from a XeCl excimer laser (Coherent, CompexPro 102F, 11 Hz, ~170 mJ per pulse, beam size 2.9 x 1.2 cm²). In earlier experiments, light at 248 nm from a KrF excimer laser (Coherent, CompexPro 102F, 11 Hz, ~200 mJ per pulse, beam size 1.5 x 1.0 cm²) was used. The photoysis beam passed the White cell and was reflected five times with two external mirrors, to enhance the photoysis. With appropriate optical filters to allow passage of light in a narrow spectral region, we performed undersampling to decrease the size of the interferogram, hence the duration of data acquisition. The infrared probing light was detected with a HgGaTe detector from which dc- and ac-coupled signals were recorded at each scan step on irradiation with the photoysis laser. These signals were sent either directly to the external 16-bit digitizer with resolution of 4 or 10 ns. For the ac signal, 5,000 data points at 10 (4 ns) intervals were acquired to cover a period of 19.8 (40.0) μs afterwards. These signals were typically averaged over 15 laser shots at each scan step. For spectra in the range 753–1,304 cm⁻¹ at resolution 0.5 cm⁻¹, 3,046 scan steps were completed in ~1.5 h. For spectra in the range 1,089 – 1,633 cm⁻¹ at resolution 0.5 cm⁻¹, 2,206 scan steps were completed in ~1 h. The spectral width (full width half maximum) at this resolution after apodization is 0.64 cm⁻¹. Fourteen spectra recorded under similar conditions were averaged to yield a spectrum with a satisfactory ratio of signal to noise. For experiments with added NO/NO2, the resolution is 2.0 cm⁻¹ (full width half maximum 2.6 cm⁻¹) and one spectrum was recorded.

A small stream of O2 from a main stream at flow rate of F0 = 23 STP cm⁻³ is passed through a sample of CH3CHO. The samples and the flow reactor were heated to 328 K with heated water circulated from a thermostated bath through the jacket of the reactor. CH3CHO (99.99%), N2 (99.9995%) and Ar (99.99%) were used as gases.

**Computational.** The harmonic and anharmonic vibrational wavenumbers have been computed using quadratic force field obtained with the MP2 (ref. 34) and the NDDO-PT2 methods35 implemented inGAMESS quantum chemistry software36 using a complete active space defined by four highest occupied orbitals and four lowest unoccupied orbitals; no symmetry has been used in these calculations to avoid problems during numerical determination of force-field coefficients. The anharmonic wavenumbers9 have only an approximate character, as the effects of three and four mode couplings have been neglected due to great computational complexity.

For CH3CHO, we also employed the MULTIMODE method. See Supplementary Methods for more details. The MULTIMODE calculations employ full-dimensional potential energy surfaces (PESs) for syn-CH3CHO and anti-CH3CHO conformers. Most geometries are determined from classical dynamical trajectories with density functional theory (B3LYP). More points are chosen randomly around the equilibrium geometry and the torsion saddle point to further increase the accuracy of the PESs, additional points are chosen along the grids of normal mode along the fully relaxed torsion path for both syn- and anti-CH3-CHO. Finally, we get about 39,000 ab initio energies, which are computed with the CCSD(T)-F12b method38,39 and aug-cc-pVQZ basis for carbon and oxygen atoms, and cc-pV QZ basis for hydrogen atoms.

The PESs are fitted with permutationally invariant method, which has been described in detail somewhere else40,41. The Morse variable is applied in the PES function, in which yp = exp(-r²/2) and x is fixed at 2 bohr. The maximum polynomial order is 5 for both PES and the number of coefficients is 5,801. The fitting root mean squares of the PESs are 0.076 and 0.068 cm⁻¹ for syn- and anti-CH3CHO, respectively. The comparisons of energies and harmonic frequencies between the PES and CCSD(T)-F12b calculation for syn- and anti-conformer are given in Supplementary Tables 9 and 10. As seen, great agreement is achieved between the PES and direct ab initio calculation. In addition, the dipole moment surfaces, which are computed with MP2 methods, are fitted as well for the infrared intensity calculation.

The infrared intensities are calculated using the dipole transition matrix and each element is determined by integrating the ground and vibrationally excited-state wave functions and the dipole moment components. The calculated energies and intensities of fundamental states for syn- and anti-CH3CHO are listed in Supplementary Tables 1 and 2. Several fundamental states, especially the CH-stretching modes, are difficult to assign due to their strong coupling with other modes.

Rotation constants of the ground vibrational state and fundamental vibrational states are determined rigorously from calculated energy difference of J = 1 and 0. The rotation constants of syn-CH3CHO ground vibrational state agree with those determined experimentally.24 The computed rotation constants for syn- and anti-CH3CHO are shown in Supplementary Tables 7 and 8, respectively. These small energy differences are sensitive to the treatment of the torsion degree of freedom, and so several sets of calculations, including ones that eliminated that degree of freedom, were performed. The rotation constants that appear to be most consistent with the simulation of experimental bands are from the smaller set of calculation with 13 modes coupling for syn-CH3CHO (14 modes for anti) and these are given in the tables.
