Abstract
In many applications, one is faced with an inverse problem, where the known signal depends in a bilinear way on two unknown input vectors. Often at least one of the input vectors is assumed to be sparse, i.e., to have only few non-zero entries. Sparse power factorization (SPF), proposed by Lee, Wu, and Bresler, aims to tackle this problem. They have established recovery guarantees for a somewhat restrictive class of signals under the assumption that the measurements are random. We generalize these recovery guarantees to a significantly enlarged and more realistic signal class at the expense of a moderately increased number of measurements.

1 Introduction

Many measurement operations in signal and image processing as well as in communication follow a bilinear model. Namely, in addition to the measurements depending linearly on the unknown signal, also certain parameters of the measurement procedure enter in a linear fashion. Hence, one cannot employ a linear model (for example, in connection compressed sensing techniques [7]) unless one has an accurate estimate of these parameters.

When such estimates are not available or too expensive to obtain, there are certain asymmetric scenarios when one of the inputs can be recovered even though the other one is out of reach (e.g., [21, 37], this scenario is sometimes referred to as passive imaging). In most cases, however, the natural aim will be to recover both the signal and the parameters, that is, to solve the associated bilinear inverse problem. Even when some estimates of the parameters are available, such a unified approach will be preferred in many situations, especially when information is limited. Consequently, the study of bilinear inverse problems, including but not limited to the important problem of blind deconvolution, has been an active area of research for many years [13].

Observing that bilinear maps admit a representation as a linear map in the rank-one outer product of the unknown signal and the parameter vector, one can approach such problems using tools from the theory of low-rank recovery (see, e.g., [1, 17, 26]). Under sparsity assumptions, that is, when the signals and/or parameter vectors admit an approximate representation using just a small (but unknown) subset of an appropriate basis (for more details regarding when such assumptions appear in bilinear inverse problems, see [25]), however, the direct applicability of these approaches is limited, as two competing objectives arise: one aims to simultaneously minimize rank and sparsity. As a consequence, the problem becomes considerably more difficult; Oymak et al., for example, have demonstrated that minimizing linear combinations of the nuclear norm (a standard convex proxy for the rank) and the $\ell_1$ norm (the corresponding quantity for sparsity) exhibits suboptimal scaling [31]. In fact, it is not even clear if without additional assumptions efficient recovery is at all possible for a near-linear number of measurements (as it would be predicted identifiability considerations [18]).

Recently, a number of non-convex algorithms for bilinear inverse problems have been proposed. For example, for such problems without sparsity constraints, several such algorithms have been analyzed for blind deconvolution and related problems [24, 27] with near-optimal recovery guarantees. In contrast, our understanding of bilinear inverse problems with sparsity constraints is only in its beginning. Recently, several algorithms have been analyzed for sparse phase retrieval [4, 33] or blind deconvolution with sparsity constraints [32]. The recovery guarantees for these algorithms, however, are either suboptimal in the number of necessary measurements or only local convergence guarantees are available, i.e., one relies on the existence of a good initialization. (A noteworthy exception is the two related papers [3, 14], where a two-stage approach for (sparsity) constrained bilinear inverse problems is proposed,
which achieves recovery at near-optimal rate. However, the algorithm relies on a special nested structure of the measurements, which is not feasible for many practical applications.)

In [23], Lee, Wu, and Bresler introduced the \textit{sparse power factorization} (SPF) method together with a tractable initialization procedure based on alternating minimization. They also provide a first performance analysis of their method for random bilinear measurements in the sense that their lifted representation is a matrix with independent Gaussian entries. That is, they work with linear operators \( A : \mathbb{C}^{n_1 \times n_2} \to \mathbb{C}^m \) that admit a representation as

\[
(A(X))(\ell) = \text{trace}\left( A_\ell^* X \right)
\]

for i. i. d. Gaussian matrices \( A_\ell \in \mathbb{C}^{n_1 \times n_2} \).

For such measurements, they show that with high probability, SPF converges locally to the right solution, i.e., one has convergence for initializations not too far from the signal to be recovered.

For signals that have a very large entry, they also devise a tractable initialization procedure—they call it thresholding initialization—such that one has global convergence to the right solution. Local convergence has also been shown for the multi-penalty approach \( A\text{-}T\text{-}LAS_{1,2} \) [10], but to our knowledge, comparable global recovery guarantees are not available to date. This is why we focus on SPF in this paper, using the results of [23] as our starting point.

The precise condition for their guarantee to hold is that both (normalized) input signals need to be larger than some \( c > \frac{1}{2} \) in supremum norm—more than one quarter of its mass needs to be located in just one entry, that is, the signals must have a very high peak-to-average power ratio.

In this paper, we considerably weaken this rather strong restriction in two ways. Firstly, we show that similar results hold for smaller lower bounds \( c \) at the expense of a moderately increased number of measurements. Secondly, we show that similar results can be obtained when the mass of one of the signals is concentrated in more than one, but still a small number of entries.

The SPF algorithm, the thresholding initialization, and the resulting recovery guarantees are reviewed in Section 2 before we discuss and prove our results in Sections 4 and 5.

1.1 Notation

Throughout the paper, we will use the following notation. By \([n]\), we will denote the set \(\{1; \ldots; n\}\). For any set \(J\), we will denote its cardinality by \(|J|\). For a vector \(v \in \mathbb{C}^m\), we will denote by \(\|v\|\) its \(\ell_2\)-norm and by \(\|v\|_\infty\) the modulus of its largest entry. If \(J \subset [n]\), we will by \(v_J\) denote the restriction of \(v\) to elements indexed by \(J\). For matrices \(A \in \mathbb{C}^{n_1 \times n_2}\), we will denote by \(\|A\|_F\) its Frobenius norm and by \(\|A\|\) its spectral norm, i.e., the largest singular value of \(A\).
2 Sparse power factorization: algorithm and initialization

2.1 Problem formulation

Let \( b \in \mathbb{C}^m \) be given by

\[
b := B(u, v) + z,
\]

where \( B : \mathbb{C}^{n_1} \times \mathbb{C}^{n_2} \rightarrow \mathbb{C}^m \) is a bilinear map and \( z \in \mathbb{C}^m \) is noise. Recall that one can represent the bilinear map \( B : \mathbb{C}^{n_1} \times \mathbb{C}^{n_2} \rightarrow \mathbb{C}^m \) by a linear map \( A : \mathbb{C}^{n_1} \times \mathbb{C}^{n_2} \rightarrow \mathbb{C}^m \), which satisfies

\[
B(u, v) = A(uv^*).
\]

for all vectors \( u \in \mathbb{C}^{n_1} \) and all \( v \in \mathbb{C}^{n_2} \). Note that such a linear map \( A \) is characterized by a (unique) set of matrices \( \{A_\ell\}_{\ell=1}^m \subset \mathbb{C}^{n_1 \times n_2} \) such that the \( \ell \)th entry of \( A(X) \) is given by

\[
(A(X)) (\ell) = \text{trace} \left( A_\ell^* X \right).
\]

In this notation, our goal will be to reconstruct \( u \) and \( v \) from linear measurements given by

\[
b_\ell = \text{trace} \left( A_\ell^* uv^* \right)
\]

At the core of the Sparse Power Factorization Algorithm, as introduced in [23], are the linear operators \( F : \mathbb{C}^{n_2} \rightarrow \mathbb{C}^m \times \mathbb{C}^{n_1} \) and \( G : \mathbb{C}^{n_1} \rightarrow \mathbb{C}^m \times \mathbb{C}^{n_2} \) defined by

\[
F(y) := \begin{pmatrix}
y^* A_1^* \\
\vdots \\
y^* A_m^*
\end{pmatrix}, \quad G(x) := \begin{pmatrix}
x^* A_1 \\
\vdots \\
x^* A_m
\end{pmatrix}.
\]

A direct consequence of this definition is that

\[
A(xy^*) = [F(y)]x = [G(x)]y
\]

for all \( x \in \mathbb{C}^{n_1} \) and all \( y \in \mathbb{C}^{n_2} \).

2.2 Sparse power factorization

The idea of sparse power factorization is to iteratively update estimates \( u_\ell \) and \( v_\ell \) for \( u \) and \( v \) in an alternating fashion. That is, in each iteration, one keeps one of \( v_\ell \) and \( u_\ell \) fixed and updates the respective other one by solving a (underdetermined) linear system. Solving each of these linear systems then amounts to solving a linear inverse problem with sparsity constraints. Hence, many pursuit algorithms proposed in the context of compressed sensing can be applied such as CoSaMP [30], Hard Thresholding Pursuit [11], or Basis Pursuit. In [23], the authors used Hard Thresholding Pursuit (HTP) for their analysis and in this paper, we will also restrict ourselves to HTP. With this, the Sparse Power Factorization Algorithm reads as follows.
Algorithm 1 Algorithm 1 in [23].

Input: Operator \( \mathcal{A} \), Measurement \( b \), Sparsity Constraints \( s_1, s_2 \), Initialisation \( v_0 \).

Output: Estimate \( \tilde{X} \).

1: \( t \leftarrow 0 \)
2: while stop condition not satisfied do
3: \( t \leftarrow t + 1 \)
4: \( v_{t-1} \leftarrow \frac{v_{t-1}}{\|v_{t-1}\|} \)
5: if \( s_1 < n_1 \) then
6: \( u_t \leftarrow \text{HTP}(F(v_{t-1}), b, s_1) \)
7: else
8: \( u_t \leftarrow \arg \min_x \|b - [F(v_{t-1})]x\|^2 \)
9: end if
10: \( u_t \leftarrow \frac{u_t}{\|u_t\|} \)
11: if \( s_2 < n_2 \) then
12: \( v_t \leftarrow \text{HTP}(G(u_t), \tilde{b}, s_2) \)
13: else
14: \( v_t \leftarrow \arg \min_b \|\tilde{b} - [G(u_t)]b\|^2 \)
15: end if
16: end while
17: return \( \hat{X} \leftarrow u_tv_t^* \)

The Hard Thresholding Pursuit Algorithm is defined as follows:

Algorithm 2 HTP(A, b, s).

Input: Measurement matrix \( A \in \mathbb{C}^{m \times n} \), measurement \( b \in \mathbb{C}^m \), sparsity constraint \( s \in \mathbb{N} \).

Output: \( \hat{x} \in \mathbb{C}^n \).

1: \( t \leftarrow 0 \)
2: while stop condition not satisfied do
3: \( t \leftarrow t + 1 \)
4: \( w = x_{t-1} + A^* (b - Ax_{t-1}) \)
5: \( J \leftarrow \arg \max_{J \subseteq [n], |J| = s} \|w_J\| \)
6: \( x_t \leftarrow \arg \min_x \|Ax - b\| \quad \text{subject to} \quad \text{supp}(x) \subseteq J \)
7: end while
8: return \( \hat{x} \leftarrow x \)

2.3 Initialization

As for many other non-convex algorithms (e.g., [6, 15]), the convergence properties of sparse power factorization depend crucially on the choice of the starting
point. In [6, 15], the starting point is chosen via a spectral initialization. That is, one chooses the leading left- and right-singular vectors of $A^* (b)$ as the starting point, where $A^*$ denotes the adjoint of $A$. The general idea behind this approach is that, if the map $A$ is random, under appropriate assumptions, the leading eigenvectors of $E [A^* (y)]$ are given by $u$ and $v$. Indeed, under the assumptions in this manuscript (see Section 3), we have that $E [A^* A] = Id$. If $z = 0$, this implies that $E [A^* (y)] = E [A^* A (uv^*)] = uv^*$. However, spectral initialization requires that the number of measurements is at the order of $\max \{ n_1, n_2 \}$, as otherwise the matrix $A^* (y)$ will in general not concentrate around its expectation. Hence, spectral initialization will in general not be optimal as it does not take into account the sparsity of the vectors $u$ and $v$. One way to incorporate the sparsity assumption would be to solve the sparse principal component analysis (SparsePCA) problem.

$$\max \quad \text{Re} \left( \tilde{u}^* A^* (b) \tilde{v} \right)$$
$$\text{subject to} \quad \| \tilde{u} \|_0 \leq s_1, \| \tilde{u} \| = 1$$
$$\| \tilde{v} \|_0 \leq s_2, \| \tilde{v} \| = 1,$$

where $\| \cdot \|_0$ denotes the number of non-zero entries. As it was shown in [23, Proposition 2], Algorithm 1, if initialized by a solution of (2) is able to recover the solution $u$ and $v$ from a number of measurements at the order of $(s_1 + s_2) \max \left\{ \frac{s_1}{n_1}, \frac{s_2}{n_2} \right\}$. However, the SparsePCA problem has been shown to be NP-hard [35]. Nevertheless, in the last 15 years, there has been a lot of research on the SparsePCA problem and, in particular, on tractable (i.e., polynomial time) algorithms, which yield good approximations to the true solution. Several computationally tractable algorithms have been proposed for solving (2), e.g., thresholdings algorithms [28], a general version of the power method [16] and semidefinite programs [8]. From the statistical perspective, a particular emphasis has been put for computationally efficient or at least tractable algorithms on the analysis of the single spike model [2, 9, 19]. These approaches, however, require that the number of samples scales with the square of the number of non-zero entries of the signal to estimate (up to log-factors). This raised the question whether there are fundamental barriers preventing the SparsePCA problem to be solved in polynomial time at a sampling rate close to the information theoretic limit. Indeed, it has been shown that an algorithm that achieves this would also allow for an algorithm which solves the $k$-clique problem in polynomial time [5, 36]. However, a widely believed conjecture in theoretical computer science states that this is not the case, which indicates that this approach will not be suited for initializing bilinear recovery problems either.

In this manuscript, we will analyze the following initialization algorithm, which is the one proposed in [23]. For a set $J_1 \subset [n]$, respectively $J_2 \subset [n_2]$ in the following, we will denote by $\Pi_{J_1}$, respectively $\Pi_{J_2}$, the matrix, which projects a vector onto the components which belong to $J_1$, respectively $J_2$. 
Algorithm 3 in [23].

**Input:** Operator \( \mathcal{A} \), Measurement \( b \), Sparsity Constraints \( s_1, s_2 \).

**Output:** Initial guess \( v_0 \) for \( v \in \mathbb{C}^{n_2} \).

1. For all \( i \in [n_1] \) let \( \xi_i \) be the \( \ell_2 \)-norm of the best \( s_2 \)-sparse approximation of the \( i \)th row of the matrix \( \mathcal{A}^* (b) \in \mathbb{C}^{n_1 \times n_2} \).
2. Let \( \hat{J}_1 \subset [n_1] \) be the set of the \( s_2 \) largest elements in \( \{ \xi_1; \xi_2; \ldots; \xi_{n_1} \} \).
3. Choose \( \hat{J}_2 \) to contain the indices of the \( s_2 \) columns of \( \Pi_{\hat{J}_1} \mathcal{A}^* (b) \) largest in \( \ell_2 \) norm, i.e.,
   \[
   \hat{J}_2 := \arg \max_{J \subset [n_2], |J| = s_2} \| \Pi_{\hat{J}_1} \mathcal{A}^* (b) \|_{F}. \tag{3}
   \]
4. \( \text{return} \ v_0 \), the leading right singular vector of \( \Pi_{\hat{J}_1} \mathcal{A}^* (b) \Pi_{\hat{J}_2} \).

### 3 Previous results

In the following, we will work with model (1), i.e., we observe

\[
\text{trace} \left( A_{\ell}^* uu^* \right) + z_{\ell}
\]

where \( u \in \mathbb{C}^{n_1} \) is \( s_1 \)-sparse, \( v \in \mathbb{C}^{n_2} \) is \( s_2 \)-sparse, and \( z \in \mathbb{C}^m \) is noise. As in [23], \( \nu (z) \) will quantify the noise-to-signal ratio by

\[
\nu (z) := \frac{\| z \|}{\| A (uv^*) \|} \tag{4}
\]

In our results, we will make no assumptions on the noise \( z \) except that \( \nu (z) \) needs to be smaller than a certain threshold. (Our results will hold for adversarial noise, i.e., the recovery guarantees will hold uniformly for all \( z \in \mathbb{C}^m \), such that \( \nu (z) \) satisfies this threshold.) For our analysis, \( \mathcal{A} \) will be a Gaussian linear operator, that is, all the entries of the matrices \( A_1, \ldots, A_m \) are independent with distribution \( \mathcal{CN} \left( 0, \frac{1}{m} \right) \).

(Here, a complex-valued random variable \( X \) has distribution \( \mathcal{CN} \left( 0, \frac{1}{m} \right) \) if its real and complex part are independent Gaussians with expectation 0 and variance \( \frac{\sigma^2}{2} \).)

In [23], the authors derived that Algorithm 1, if initialized by Algorithm 3, is able to recover both \( u \) and \( v \) (up to scale ambiguity), if both \( u \) and \( v \) belong to a certain restricted class of signals. More precisely, they proved the following result.

**Theorem 1** ([23, see Theorem 1 and 4]) Assume that \( \mathcal{A} : \mathbb{C}^{n_1 \times n_2} \rightarrow \mathbb{C}^m \) is a Gaussian linear operator as described above. Let \( b = \mathcal{A} (uv^*) + z \), where \( u \) is \( s_1 \)-sparse and \( v \) is \( s_2 \)-sparse. Suppose that \( \| u \|_\infty \geq 0.78 \| u \|, \| v \|_\infty \geq 0.78 \| v \| \), and that the noise level satisfies \( \nu (z) \leq 0.04 \). Then, with probability exceeding
1 − \exp (−c_1 m), the output of the Algorithm 1, initialized by Algorithm 3, converges linearly to \( uv^* \) provided that

\[
m \geq c_2 (s_1 + s_2) \log \left( \max \left\{ \frac{n_1}{s_1}, \frac{n_2}{s_2} \right\} \right),
\]

where \( c_1, c_2 > 0 \) are absolute constants.

Note that in order to apply Theorem 1 to signals \( u \) and \( v \), one needs to require that more than half of the mass of \( u \) and \( v \) are located in one single entry, which is a severe restriction, which can be prohibitive for many applications. Our goal in the following will be to considerably relax this assumption by slightly increasing the amount of required measurements. We will relax this assumption in two different ways: On the one hand, we will show that one can replace 0.78 by an arbitrary small constant that will then show up in the number of measurements. On the other hand, we generalize the result to the case that a significant portion of mass of \( u \) is concentrated on a small number of entries \( k \), rather than just one of them.

### 4 Main result

In this section, we will state the main result of this article, Theorem 2. For that, we need to define the quantity

\[
\|x\|_{[k]} := \max_{I \subset [n_1], |I| = k} \left( \sum_{i \in I} |x_i|^2 \right)^{1/2} = \left( \sum_{i=1}^{k} (x_i^*)^2 \right)^{1/2},
\]

for any \( x \in \mathbb{C}^{n_1} \), where \( (x_i^*)_{i=1}^{n_1} \) denotes the non-increasing rearrangement of \( (|x_i|)_{i=1}^{n_1} \). (This is in fact a norm, cf. [29].) Our main requirement on the vector \( u \) will be that a significant amount of its mass is located in the largest \( k \) entries, i.e., that \( \|u\|_{[k]} / \|u\| \) is large enough.

**Theorem 2** Let \( k \in [n_1] \) and \( 0 < \xi < 1, 0 < \mu < 1 \). Then, there are absolute constants \( C_1, C_2, C_3 > 0 \) such that if

\[
m \geq C_1 \max \left\{ \frac{1}{\xi^4 \mu^4 \cdot \xi^2}, \frac{k}{\xi^2} \right\} (s_1 + s_2) \log \left( \max \left\{ \frac{n_1}{s_1}, \frac{n_2}{s_2} \right\} \right), \tag{5}
\]

then with probability at least \( 1 - \exp (−C_2 m) \), the following holds.

For all \( s_1 \)-sparse \( u \in \mathbb{C}^{n_1} \) with \( \|u\|_{[k]} \geq \xi \|u\| \), all \( s_2 \)-sparse \( v \in \mathbb{C}^{n_2} \) with \( \|v\|_{\infty} \geq \mu \|v\| \), and all \( z \in \mathbb{C}^{n} \) with \( v(z) \leq C_3 \min \left\{ \xi^2 \mu^2 ; \frac{\xi}{\sqrt{k}} \right\} \), the iterates \( \{X_t\}_{t \in \mathbb{N}} \) generated by applying Algorithm 1, initialized by Algorithm 3, satisfy

\[
\limsup_{t \to \infty} \frac{\|X_t - u v^*\|_F}{\|u v^*\|_F} \leq 8.3 v.
\]
Furthermore, the convergence is linear, i.e., for all \( t \gtrsim \log \left( \frac{1}{\epsilon} \right) \), we have that

\[
\frac{\|X_t - uv^*\|_F}{\|uv^*\|_F} \leq 8.3\nu + \epsilon. \tag{6}
\]

In the following, we will discuss some important special cases of Theorem 2.

- **Peaky signals:** In [23], the authors discuss recovery guarantees for signals \( u \) and \( v \) with \( \|u\|_\infty \) and \( \|v\|_\infty \), both bounded below by an absolute constant \( \mu \approx 0.78 \). The case \( k = 1 \) of our theorem yields a direct improvement of this result in the sense that \( \mu \) can be chosen arbitrarily small with the number of required measurements only increasing by a factor of order \( \mu^{-8} \). Hence, even when this constant decays logarithmically in the dimension, the required number of measurements will only increase by logarithmic factors.

- **Signals with multiple large entries:** When one of the input signals has multiple large entries, using the \( \|\cdot\|_k \) norm improves upon the resulting guarantee as compared to the scenario just discussed. As an example, assume that \( s_1 = s_2 = s \), that \( u \) and \( v \) are normalized with \( \|v\|_\infty \geq c_1s^{-1/8} \), and that \( k = c_2s^{1/2} \) of the entries of \( u \) are of absolute value at least \( c_3s^{-1/4} \). Then, \( \|u\|_k \geq \sqrt{c_2c_3} \). Using Theorem 2, we obtain that the vectors \( u \) and \( v \) can be recovered if the number of measurements is on the order of \( s^{3/2} \), thus below the order of \( s^2 \) that has been established for arbitrary sparse signals in [25] (cf. next item). In contrast, applying Theorem 2 with \( k = 1 \) would yield that the number of measurements would have to be on the order of \( s^{5/2} \), which is worse than the state-of-the-art.

- **Arbitrary sparse signals:** Applying Theorem 2 to non-peaky signals yields suboptimal results. Indeed, let \( u \in \mathbb{C}^{n_1} s_1\)-sparse and \( v \in \mathbb{C}^{n_2} s_2\)-sparse be generic vectors. Observe that \( \|v\|_\infty \asymp \frac{1}{\sqrt{s_2}} \|v\| \). Consequently, Theorem 2 applied with \( \xi = 1 \), \( k = s_1 \), and \( \mu = \frac{1}{\sqrt{s_2}} \) yields that with high probability a generic \( s_1\)-sparse \( u \) and a generic \( s_2\)-sparse \( v \) can be recovered from \( y = A(uv^*) + z \), if the number of measurements satisfies

\[
m \geq C \max \left\{ s_1; s_2^2 \right\} (s_1 + s_2) \log \left( \max \left\{ \frac{n_1}{s_1^2}, \frac{n_2}{s_2^2} \right\} \right),
\]

and if the noise level \( \nu \) is on the order of \( O \left( \max \left\{ \frac{1}{s_1^2}, \frac{1}{s_2^2} \right\} \right) \). Previous results (see, e.g., [25]), in contrast, require \( m \geq C \max \left\{ s_1^2; s_2^2 \right\} \log \left( \max \left\{ \frac{n_1}{s_1^2}, \frac{n_2}{s_2^2} \right\} \right) \) samples.

**Remark 1** The peakiness assumptions in Theorem 2 may seem arbitrary at first sight but in certain applications they are reasonable. Namely, when \( u \) is the signal transmitted via a wireless channel and \( v \) is the unknown vector of channel parameters, it is natural to assume that \( v \) has a large entry, as the direct path will always carry most of the energy. The signal \( u \) can be modified by the sender, so some large entries can be artificially introduced. In this regard, being able to consider multiple entries of comparable size is of advantage as adding a single very large entry will result in a dramatic increase of the peak-to-average power ratio.
5 Proofs

5.1 Technical tools

The goal of this section is to prove Theorem 2. We will start by recalling the following variant of the well-known restricted isometry property.

Definition 1 (see [23]) A linear operator $A$ has the $(s_1, s_2, r)$-restricted isometry property with constant $\delta > 0$ if

$$
(1 - \delta) \|X\|_F^2 \leq \|A(X)\|_F^2 \leq (1 + \delta) \|X\|_F^2
$$

(7)

for all matrices $X \in \mathbb{C}^{n_1 \times n_2}$ of rank at most $r$ with at most $s_1$ non-zero rows and at most $s_2$ non-zero columns.

The following lemma tells us that this property holds with high probability for a number of measurements close to the information-theoretic limit.

Lemma 1 (See, e.g., Theorem 2 in [23]) There are absolute constants $c_1, c_2 > 0$, such that if

$$
m \geq \frac{c_1}{\delta^2} r (s_1 + s_2) \log \left( \max \left\{ \frac{n_1}{s_1}, \frac{n_2}{s_2} \right\} \right),
$$

(8)

for some $\delta > 0$, then with probability at least $1 - \exp(-c_2 m)$ $A$ has the $(s_1, s_2, r)$-restricted isometry property with restricted isometry constant $\delta$.

As in [23, Lemma 6], we will need the following quantity, which depends on $\delta$ and $\nu$.

$$
\omega_{\sup} := \sup \left\{ \omega \in [0, \frac{\pi}{2}) : \sin(\omega) \geq C_\delta [\delta \tan(\omega) + (1 + \delta) \nu \sec(\omega)] \right\}
$$

(9)

Here, the constant $C_\delta$ is given by the expression

$$
C_\delta = 1.01 \sqrt{\frac{\frac{2}{1-\delta^2} + \frac{1}{1-\delta}}{1 - \sqrt{\frac{2}{1-\delta^2}} \delta}}
$$

as it can be seen by an inspection of the proof of Lemma 3 in [23]. The precise value of $C_\delta$ will not be important in the following, we will only use that $2 \leq C_\delta \leq 5$ for $\delta \leq 0.04$.

A simple estimate for $\omega_{\sup}$ is given by the following lemma.

Lemma 2 Assume that $0 < \delta \leq 0.04$ and $\nu \leq 0.04$. Then, it holds that

$$
\frac{1}{2} \leq \sin(\omega_{\sup}) \leq 1.
$$
Proof We observe that in order to show the claim, it is enough to verify that \( \omega = \arcsin \frac{1}{2} \) fulfills the inequality in (9). Indeed, using \( \cos \omega = \sqrt{\frac{3}{4}} \) and \( C_\delta \leq 5 \), we obtain that

\[
C_\delta \left[ \delta \tan \left( \arcsin \frac{1}{2} \right) + (1 + \delta) \nu \sec \left( \arcsin \frac{1}{2} \right) \right] \leq C_\delta \left[ 0.04 \frac{1/2}{\sqrt{3/4}} + 1.04 \cdot 0.04 \frac{1}{\sqrt{3/4}} \right] \leq \frac{1}{2}.
\]

The quantity \( \omega_{\text{sup}} \) controls the maximal angle between the initialization \( v_0 \) and the ground truth \( v \) such that the sparse power factorization is guaranteed to converge as captured by the following theorem.

**Theorem 3** (Theorem 3 in [23]) Assume that:
1) \( A \) has the \((3s_1, 3s_2, 2)\)-RIP with isometry constant \( \delta \leq 0.08 \).
2) \( \nu \leq 0.08 \).
3) The initialization \( v_0 \) satisfies \( \sin(\angle(v_0, v)) < \sin(\omega_{\text{sup}}) \).

Then, the iterates \( \{X_t\}_{t \in \mathbb{N}} \) generated by Algorithm 1, initialized via Algorithm 3, satisfy

\[
\limsup_{t \to \infty} \frac{\|X_t - uv^*\|_F}{\|uv^*\|_F} \leq 8.3 \nu.
\]

Furthermore, the convergence is linear in the sense of (6).

Thus, it remains to verify that the initialization satisfies \( \sin(\angle(v_0, v)) < \sin(\omega_{\text{sup}}) \). The following lemma gives an upper bound on \( \sin(\angle(v_0, v)) \).

**Lemma 3** (Lemma 8 in [23]) Assume that the \((3s_1, 3s_2, 2)\)-restricted isometry property holds for some constant \( \delta > 0 \). Furthermore, assume that \( \|u\| = \|v\| = 1 \). Let \( \hat{J}_1 \subseteq [n_1] \) and \( \hat{J}_2 \subseteq [n_2] \) denote the output resulting from Algorithm 3. Denote by \( v_0 \) the leading right-singular vector of \( \Pi_{\hat{J}_1} [A^* (b)] \Pi_{\hat{J}_2} \). Then, it holds that

\[
\sin(\angle(v_0, v)) \leq \frac{\|\Pi_{\hat{J}_1} u\| \|\Pi_{\hat{J}_2} v\| + (\delta + \nu + \delta \nu)}{\|\Pi_{\hat{J}_1} u\| - (\delta + \nu + \delta \nu)}.
\]

Furthermore, we will need the following two lemmas for our proof.

**Lemma 4** (Lemma 10 in [23]) Let \( u \) and \( v \) be as in Lemma 5 and assume that the measurement operator \( A \) satisfies the \((3s_1, 3s_2, 2)\)-restricted isometry property with constant \( \delta \). Recall that \( \hat{J}_1 \subseteq [n_1] \) is the support estimate for \( v_0 \) given by the initialization algorithm 3. Define

\[
\tilde{J}_1 := \left\{ j \in [n_1] : |u_j| \geq 2 (\delta + \nu + \delta \nu) \right\}.
\]

Then, we have that \( \tilde{J}_1 \subseteq \hat{J}_1 \).
**Lemma 5** Assume that $\mathcal{A}$ has the $(3s_1, 3s_2, 2)$-restricted isometry property with isometry constant $\delta > 0$ and assume that $u$, respectively $v$, are $s_1$-sparse, respectively $s_2$-sparse, and satisfy $\|u\| = \|v\| = 1$. Let $\tilde{J}_1$ be defined as in (11). Then, it holds that

$$\|\Pi_{\tilde{J}_1} u\| \geq \frac{\|\Pi_{\tilde{J}_1} u\| \|v\|_\infty - 2(\delta + v + \delta v)}{\sqrt{1 - \|\Pi_{\tilde{J}_2} v\|^2}}. $$

Lemma 5 is actually a slight generalization of what has been shown in [23, p. 1685]. For completeness, we have included a proof in the Appendix, which closely follows the proof in [23].

5.2 Proof of our main result

We will now piece together these ingredients to obtain a sufficient condition; in the remainder of the section, we will then show that the condition holds in our measurement setup. First note that in order to apply Theorem 3, we need to check that $\sin(\angle(v_0, v)) < \sin(\omega_{\text{sup}})$ is satisfied. By Lemma 3, it is sufficient to show that the right-hand side of inequality (10) is strictly smaller than $\sin(\omega_{\text{sup}})$. Combining this with the equality $\|\Pi_{\tilde{J}_2} v\| = \sqrt{1 - \|\Pi_{\tilde{J}_2} v\|^2}$, we obtain the sufficient condition

$$\|\Pi_{\tilde{J}_1} u\| \sqrt{1 - \|\Pi_{\tilde{J}_2} v\|^2} < \sin(\omega_{\text{sup}}) \left(\|\Pi_{\tilde{J}_1} u\| - (\delta + v + \delta v)\right) - (\delta + v + \delta v)$$

Further manipulations yield that this is equivalent to

$$\|\Pi_{\tilde{J}_1} u\|^2 < \left(\sin(\omega_{\text{sup}}) \|\Pi_{\tilde{J}_1} u\| - (1 + \sin(\omega_{\text{sup}}))(\delta + v + \delta v)\right)^2 + \|\Pi_{\tilde{J}_1} u\|^2 \|\Pi_{\tilde{J}_2} v\|^2. $$

(12)

Hence, in the following, our goal will be to verify (12). We already noticed that the angle $\omega_{\text{sup}}$ measures how much the vector $v_0$ given by the initialization has to be aligned with the ground truth $v$ in order for the sparse power factorization to converge. Consequently, it is natural to expect that the smaller the constant $\delta$ and the noise-to-signal ratio $v$, the less the initialization vector has to be aligned with the ground truth, i.e., the larger $\omega_{\text{sup}}$ can be. This fact is captured by the following lemma.

**Lemma 6** Let $0 < \delta \leq 0.04$ and $v \leq 0.04$. Then, it holds that

$$\sin(\omega_{\text{sup}}) \geq 1 - C_2^2 (\delta + 2\delta v + 2v)^2. $$

**Proof** We will first show that it holds that

$$\sin(\omega_{\text{sup}}) = C_\delta \left[\delta \tan(\omega_{\text{sup}}) + (1 + \delta) v \sec(\omega_{\text{sup}})\right]. $$

(13)

For that, we define the set

$$\Omega := \{\omega \in [0, \pi/2) : \sin(\omega) \geq C_\delta[\delta \tan(\omega) + (1 + \delta)v \sec(\omega)]\}$$
and note that \( \omega_{\text{sup}} = \sup \Omega \). (Note that from Lemma 2 and its proof, it follows that \( \Omega \) is nonempty.) We observe that

\[
\lim_{\omega \uparrow \pi/2} C_\delta \left[ \delta \tan(\omega) + (1 + \delta) \nu \sec(\omega) \right] = +\infty. \tag{14}
\]

Hence, \( \Omega \) is a compact set. In particular, \( \omega_{\text{sup}} \) is contained in this set. Now assume by contradiction that

\[
\sin(\omega_{\text{sup}}) > C_\delta [\delta \tan(\omega_{\text{sup}}) + (1 + \delta) \nu \sec(\omega_{\text{sup}})].
\]

Because of (14) and as the sine is bounded in \([0, \pi/2]\), this implies by continuity that there must be an \( \omega \in [0, \pi/2] \) such that \( \omega > \omega_{\text{sup}} \) and \( \sin(\omega) = C_\delta [\delta \tan(\omega) + (1 + \delta) \nu \sec(\omega)] \). Hence, \( \omega \in \Omega \), which is a contradiction to the definition of \( \omega_{\text{sup}} \). Hence, we have proven equation (13). Using trigonometric identities, we obtain from (13) that

\[
\sin(\omega_{\text{sup}}) = C_\delta \left[ \frac{\sin(\omega_{\text{sup}})}{\sqrt{1 - \sin^2(\omega_{\text{sup}})}} + (1 + \delta) \nu \frac{1}{\sqrt{1 - \sin^2(\omega_{\text{sup}})}} \right].
\]

Lemma 2 implies that

\[
\sin(\omega_{\text{sup}}) \leq \frac{\sin(\omega_{\text{sup}})}{\sqrt{1 - \sin^2(\omega_{\text{sup}})^2}} C_\delta (\delta + 2 (1 + \delta) \nu).
\]

Rearranging terms yields that

\[
\sin(\omega_{\text{sup}}) \geq \sqrt{1 - C_\delta^2 (\delta + 2 \delta \nu + 2 \nu)^2}.
\]

The claim follows then using the fact that \( \sqrt{x} \geq x \) for all \( x \in [0, 1] \). \( \square \)

With these preliminary lemmas, we can now prove the following proposition, which is a slightly more general form of Theorem 2.

**Proposition 1** There are absolute constants \( c_1, c_2, c_3 > 0 \) such that if

\[
m \geq c_1 \delta^{-2} (s_1 + s_2) \log \left( \max \left\{ \frac{n_1}{s_1}, \frac{n_2}{s_2} \right\} \right), \tag{15}
\]

for some \( 0 < \delta < 0.01 \), then with probability at least \( 1 - \exp(-c_2m) \), the following statement holds uniformly for all \( s_1 \)-sparse \( u \in \mathbb{C}^{n_1} \), \( s_2 \)-sparse \( v \in \mathbb{C}^{n_2} \), and \( z \in \mathbb{C}^m \) such that \( \|u\| = \|v\| = 1 \) and \( \nu(z) \leq 0.01 \):

Let the measurements be given by \( b = \mathcal{A}(uv^*) + z \) for a Gaussian as above and let \( \tilde{J}_1 \) be defined by

\[
\tilde{J}_1 := \left\{ j \in [n_1] : \ |u_j| \geq M_{\delta,v} \right\}, \tag{16}
\]

where

\[
M_{\delta,v} := 2 (\delta + \nu + \delta \nu).
\]

Then, whenever

\[
\|\Pi_{\tilde{J}_1} u\|_\infty > c_3 \sqrt{M_{\delta,v}}, \tag{17}
\]
the iterates \( \{X_t\}_{t \in \mathbb{N}} \) generated by Algorithm 1 initialized via Algorithm 3 satisfy
\[
\limsup_{t \to \infty} \|X_t - uv^*\|_F \leq 8.3\nu.
\]

Furthermore, the convergence is linear in the sense of (6).

Proof of Proposition 1  Assumption (15) and Lemma 1 yield that with probability at least \( 1 - \exp(-cm) \), the \((3s_1, 3s_2, 2)\)-restricted isometry property holds with constant \( \delta \). For the remainder of the proof, we will consider the event that the restricted isometry property holds for such \( \delta \). We obtain
\[
\|\Pi_{\tilde{J}_1} u\| \geq \left( \sqrt{C_\delta^2 + 1} \right) M_{\delta, v}
\]
from \( 2 \leq C_\delta \leq 5 \) and by choosing the constant \( c_3 \) in assumption (17) large enough. Combining this with Lemma 5, we obtain that
\[
\|\Pi_{\tilde{J}_1} u\| \geq \|\Pi_{\tilde{J}_1} u\| \geq \|\Pi_{\tilde{J}_1} u\| \geq \|\Pi_{\tilde{J}_1} u\| - M_{\delta, v},
\]
where we used that \( \sqrt{x} \geq x \) for all \( x \in [0, 1] \). This yields a lower bound for the second summand of the right-hand side of (12). To bound the first summand, we estimate
\[
\sin(\omega_{\text{sup}})\|\Pi_{\tilde{J}_1} u\| - (\sin(\omega_{\text{sup}}) + 1) (\delta + \nu + \delta\nu) \\
\geq (1 - C_\delta^2 (\delta + 2\nu + 2\delta\nu)^2) \|\Pi_{\tilde{J}_1} u\| - 2(\delta + \nu + \delta\nu) \\
\geq \|\Pi_{\tilde{J}_1} u\| - C_\delta^2 (\delta + 2\nu + 2\delta\nu)^2 - 2(\delta + \nu + \delta\nu) \\
\geq \|\Pi_{\tilde{J}_1} u\| - (C_\delta^2 + 1) M_{\delta, v} \\
\geq 0.
\]
In the first line, we used Lemma 6 and the fact that \( \sin(\omega_{\text{sup}}) \leq 1 \). The second line is due to \( \|\Pi_{\tilde{J}_1} u\| \leq 1 \) and the third inequality is due to \( \delta \geq 0, \nu \geq 0 \). In order to verify the last inequality, it is enough to observe that due to Lemma 4 and due to assumption (17) with \( c_3 \) large enough
\[
\|\Pi_{\tilde{J}_1} u\| \geq \|\Pi_{\tilde{J}_1} u\| \geq \|\Pi_{\tilde{J}_1} u\| \geq \left( C_\delta^2 + 1 \right) M_{\delta, v},
\]
where the last inequality uses that \( C_\delta \leq 5 \) and \( 0 \leq \delta, \nu \leq 0.01 \). Hence, by squaring (19), we obtain that
\[
\left( \sin(\omega_{\text{sup}})\|\Pi_{\tilde{J}_1} u\| - (\sin(\omega_{\text{sup}}) + 1) (\delta + \nu + \delta\nu) \right)^2 \\
\geq \|\Pi_{\tilde{J}_1} u\|^2 - \frac{1}{2} \left( C_\delta^2 + 1 \right) M_{\delta, v} \\
\geq \|\Pi_{\tilde{J}_1} u\|^2 - \left( C_\delta^2 + 1 \right) M_{\delta, v} \|\Pi_{\tilde{J}_1} u\| \\
\geq \|\Pi_{\tilde{J}_1} u\|^2 - \left( C_\delta^2 + 1 \right) M_{\delta, v},
\]
where in the last line, we again used that \( \|\Pi_{\tilde{J}_1} u\| \leq 1 \). Together with (18), this yields (12), as desired. \( \square \)

Finally, we will deduce Theorem 2 from Proposition 1.
Proof of Theorem 2  We will prove this result by applying Proposition 1 with
\[ \delta = \min \left\{ \frac{\xi}{\delta \sqrt{2k}}; \frac{\xi^2 \mu^2}{8c_3^2} \right\}. \] (21)

Let \( u \in \mathbb{C}^{n_1} s_1\)-sparse, \( v \in \mathbb{C}^{n_2} s_2\)-sparse, and \( z \in \mathbb{C}^m \) such that the assumptions of Theorem 2 are satisfied. Without loss of generality, we may assume in the following that \( \|u\| = \|v\| = 1 \). First, we note that invoking \( \delta, \nu < 0.01 \) and potentially decreasing the size of \( C_3 \), we have that
\[ 2(\delta + \nu(z) + \delta \nu(z)) < 2(\delta + 2\nu(z)) \leq \frac{\xi}{\sqrt{2k}}. \]

Hence, we obtain that
\[ \tilde{J}_1 := \left\{ j \in [n_1] : |u_j| \geq \frac{\xi}{\sqrt{2k}} \right\} \subset \tilde{J}_1, \] (22)
where \( \tilde{J}_1 \) is the set defined in (16). Note that
\[ \sum_{i \in [k] \setminus \tilde{J}_1} (u_i^*)^2 < \sum_{i \in [k] \setminus \tilde{J}_1} \frac{\xi^2}{2k} \leq \frac{\xi^2}{2}, \]
where in the first inequality, we have used that \( u_i^* < \frac{\xi}{\sqrt{2k}} \) for all \( i \in [k] \setminus \tilde{J}_1 \). By the assumption \( \|u\|_k \geq \xi \), this yields that \( \sum_{i \in [k] \setminus \tilde{J}_1} (u_i^*)^2 \geq \frac{\xi^2}{2} \), which in turn implies that \( \|\Pi_{\tilde{J}_1} u\| \geq \frac{\xi}{\sqrt{2}} \). By the inclusion (22), we obtain that \( \|\Pi_{\tilde{J}_1} u\| \geq \frac{\xi}{\sqrt{2}} \). Hence, using the assumption \( \|v\|_\infty \geq \mu \), our choice of \( \delta \), the assumption on the noise level \( \nu(z) \) and potentially again decreasing the value of the constant \( C_3 \), we obtain that
\[ \|\Pi_{\tilde{J}_1} u\| \|v\|_\infty \geq \frac{\xi \mu}{\sqrt{2}} \geq c_3 \sqrt{M \delta, \nu}. \]

This shows that (17) is satisfied. Hence, we can apply Proposition 1 and by inserting our choice of \( \delta \) into (15), so choosing the constant \( C_1 \) large enough, we obtain the main result. \( \square \)

6 Outlook

We see many interesting directions for follow-up work. Most importantly, it remains to explore whether additional constraints on the signals to be recovered are truly necessary (cf. our discussion on to SparsePCA in Section 2.3). Even if this is the case, there is substantial room for improvement with respect to the noise-dependence of the recovery results. A direction to proceed could be to consider stochastic noise models instead of adversarial noise. Also in this work, we exclusively considered operators \( \mathcal{A} \) constructed using Gaussian matrices. However, in many applications of interest, the
measurement matrices possess a significantly reduced amount of randomness. For example, in blind deconvolution, one typically encounters rank-one measurements. That is, the restricted isometry property as used in this paper does not hold. Thus, one needs additional insight to study whether there exists a computationally tractable initialization procedure at a near-optimal sampling rate. First steps in this direction were taken in [20, 22], but a lot of questions remain open.

Acknowledgements The authors want to thank Yoram Bresler and Kiryung Lee for helpful discussions. Furthermore, we would like to thank the referees for the careful reading and their helpful suggestions, which improved the manuscript.

Appendix: Proof of Lemma 5

For the proof of Lemma 5, we will use the following result.

Lemma 7 (Lemma 17 and Lemma 18 in [23]) Assume that the \((3s_1, 3s_2, 2)\)-restricted isometry property is fulfilled for some restricted isometry constant \(\delta > 0\). Assume that the cardinality of \(\tilde{J}_1 \subseteq [n_1]\), respectively \(\tilde{J}_2 \subseteq [n_2]\) is at most \(2s_1\), respectively \(2s_2\). Then, whenever \(u \in \mathbb{C}^{n_1}\) is at most \(2s_1\)-sparse and \(v \in \mathbb{C}^{n_2}\) is at most \(2s_2\)-sparse, we have that

\[
\|\Pi_{\tilde{J}_1}[(A^*A - I)(uv^*)]\Pi_{\tilde{J}_2}\| \leq \delta\|uv^*\|_F.
\]

Furthermore for all \(z \in \mathbb{C}^n\) and for all \(\tilde{J}_1 \subseteq [n_1]\), respectively \(\tilde{J}_2 \subseteq [n_2]\), with cardinality at most \(s_1\), respectively \(s_2\), we have that

\[
\|\Pi_{\tilde{J}_1}[A^*(z)]\Pi_{\tilde{J}_2}\| \leq \sqrt{1 + \delta}\|z\|_{\ell_2}.
\]

Proof of Lemma 5 Recall that \(b = A(X) + z\) and define \(k_1\) and \(k_2\) by

\[
k_1 := \arg \max_{k \in [n_2]} |v_k|
\]

\[
k_2 := \arg \max_{k \in [n_2]} \|\Pi_{\tilde{J}_1}[A^*(b)]\Pi_{\{k\}}\|_F.
\] (23)

The starting point of our proof is the observation that

\[
\|\Pi_{\tilde{J}_1}[A^*(b)]\Pi_{\{k_1\}}\|_F \geq \|\Pi_{\tilde{J}_1}[A^*(b)]\Pi_{\{k_1\}}\|_F \geq \|\Pi_{\tilde{J}_1}[A^*(b)]\Pi_{\{k_1\}}\|_F,
\]

where the first inequality is due to the definition of \(k_2\) and the second one follows from \(\tilde{J}_1 \subseteq \tilde{J}_1\), which is due to Lemma 4. The right-hand side of the inequality chain can be estimated from below by

\[
\geq \|\Pi_{\tilde{J}_1}[A^*(b)]\Pi_{\{k_1\}}\|_F
\]

\[
\geq \|\Pi_{\tilde{J}_1}[A^*(b)]\Pi_{\{k_1\}}\|_F - \|\Pi_{\tilde{J}_1}[A^*(b)]\Pi_{\{k_1\}}\|_F - \|\Pi_{\tilde{J}_1}[A^*(b)]\Pi_{\{k_1\}}\|_F
\]

\[
\geq \|\Pi_{\tilde{J}_1}[A^*(b)]\Pi_{\{k_1\}}\|_F - (\delta\|uv^*\|_F + \sqrt{1 + \delta}\|z\|)
\]

\[
\geq \|\Pi_{\tilde{J}_1}[A^*(b)]\Pi_{\{k_1\}}\|_F - (\delta + \nu + \nu).\] (25)
In the first inequality, we used \( b = A(uv^*) + z \) and the triangle inequality. The second inequality follows from Lemma 7. The last line follows from \( \|uv^*\|_F = 1 \) and \( \|z\| = \nu \). Next, we will estimate the left-hand side of (24) by

\[
\begin{align*}
\|\prod_{\hat{J}_1} [A^*(b)] \prod_{\{k_2\}} \|_F \\
\leq \|\prod_{\hat{J}_1} uv^* \prod_{\{k_2\}} \|_F + (\delta \|uv^*\|_F + \sqrt{1 + \delta} \|z\|) \\
\leq \|\prod_{\hat{J}_1} u \prod_{\{k_2\}} v \|_F + (\delta + \nu + \delta \nu) \\
\leq \|\prod_{\hat{J}_1} u \prod_{\hat{J}_2} v \|_F + (\delta + \nu + \delta \nu).
\end{align*}
\]

(26)

The first two lines are obtained by an analogous reasoning as for (25). The last line is due to \( \{k_2\} \subset \hat{J}_2 \), which is a consequence of the definition of \( \hat{J}_2 \) (3) and the definition of \( \{k_2\} \) (23). We finish the proof by combining the inequality chains (24), (25), and (26).
