Abstract

An analytic model of the shear modulus applicable at temperatures up to melt and at all densities is presented. It is based in part on a relation between the melting temperature and the shear modulus at melt. Experimental data on argon are shown to agree with this relation to within 1%. The model of the shear modulus involves seven parameters, all of which can be determined from zero-pressure experimental data. We obtain the values of these parameters for 11 elemental solids. Both the experimental data on the room-temperature shear modulus of argon to compressions of ∼ 2.5, and theoretical calculations of the zero-temperature shear modulus of aluminum to compressions of ∼ 3.5 are in good agreement with the model. Electronic structure calculations of the shear moduli of copper and gold to compressions of 2, performed by us, agree with the model to within uncertainties.

Key words: dislocation, density, electronic structure, melting, pressure, shear modulus

1 Introduction

A reliable model of the adiabatic (isentropic) shear modulus, $G$, of a polycrystalline solid at temperatures to $T_m$, the melting temperature, and up to megabar pressures is needed for
many applications, including the modeling of plastic deformation at extremes of pressure and temperature, numerical calculations of elastic and shock wave propagation, and even calculations of the oscillations of low-mass astrophysical objects.

Adiabatic elastic properties are generally determined by ultrasonic wave-speed measurements, which are usually made in the low-pressure regime. Zero-pressure experimental data have been accumulated on single-crystal elastic constants, together with polycrystalline averages, at temperatures from $T = 0$ to nearly $T_m$ for Ag (to within 60 °K of $T_m$), Au (to within 60 °K of $T_m$), Ge (to within 90 °K of $T_m$), and V (to within 80 °K of $T_m$). The data run from $T = 0$ to $T_m$ for Al, Ar, Bi, Cd, Cs, Cu, In, K, Na, Nb, Ne, Pb, Sn, Ta, Te, Xe, and Zn.

On the theoretical side, it is possible to calculate single-crystal elastic constants as a function of compression at zero temperature from electronic-structure theory. Such calculations were done by Straub et al. for Cu, Christensen et al. for Mo and W, Söderlind et al. for Fe, and Söderlind and Moriarty for Ta. With known interatomic potentials it is possible to calculate the temperature dependence of the elastic constants by computer simulation techniques, as demonstrated by the calculations for Na, Mg, and Cu. Bounds on the shear modulus, $G$, can be calculated from the single-crystal elastic constants for any crystal class, and for a cubic crystal the polycrystalline shear modulus can be calculated exactly using the Kröner cubic equation.

Guinan and Steinberg modeled the zero-temperature shear modulus as $G = G_0 + G'_0 P (\rho_0/\rho)^{1/3}$, where $G'_0$ is the pressure derivative of $G$ at zero pressure and $\rho$ is density. This functional form was chosen so that $G \sim \rho^{4/3}$ as $\rho \to \infty$, the correct asymptotic behavior albeit with a prefactor which does not generally coincide with that given by the one-component plasma model for $G$. Preston and Wallace proposed a model for the temperature dependence of the shear modulus at any density, but left the density dependence itself arbitrary. The dependence of the shear modulus on both density and temperature has also been discussed by Anderson.

In this paper we develop an analytic model for the density and temperature dependence of the shear modulus by combining four key elements. First is a simple but accurate relation between the density, the melting temperature as a function of density, $T_m(\rho)$, and the shear modulus along the solidus. Second is the Preston-Wallace model for the shear modulus. Third is an analytic model for the Gruneisen parameter that is used in conjunction with the fourth ingredient, the Lindemann criterion, to generate an analytic expression for $T_m(\rho)$.

## 2 A relation between shear modulus and melting temperature

The melting temperature and shear modulus along the solidus approximately satisfy the relation

$$\frac{G(\rho, T_m(\rho))}{\rho T_m(\rho)} = \frac{G(\rho_{\text{ref}}, T_m(\rho_{\text{ref}}))}{\rho_{\text{ref}} T_m(\rho_{\text{ref}})},$$

(1)
where \( \rho_{\text{ref}} \) is a reference density. This relation is the foundation of our model for the shear modulus, so we provide theoretical justification for it following two approaches: the theory of dislocation-mediated melting \([32, 33]\), and the theory of a Debye solid (in which it derives as a consequence of the proportionality of \( G \) to the square of the Debye temperature). The relation is shown to agree very well with shear modulus data on argon, the only data available for such a comparison.

### 2.1 Two derivations of relation (1)

It follows from our model of melting as a dislocation-mediated phase transition that the relation

\[
k_B T_m = \frac{1 - \nu(T_m)/2}{1 - \nu(T_m)} \frac{G(T_m)v(T_m)}{\ln(z - 1)} \frac{\lambda}{8\pi} \ln \left( \frac{\alpha^2}{4b^2d(T_m)} \right).
\]

holds at any pressure. Here \( b \) is the magnitude of the Burgers vector, \( \nu \) is the Poisson ratio, \( v \) is the Wigner-Seitz volume, \( \lambda \equiv b^3/v \) is a geometric factor characterizing the lattice, \( z \) is the coordination number, and \( d(T_m) \) is the dislocation density at melt. Note that the factors \( \lambda \) and \( \ln(z - 1) \) explicitly account for the influence of crystal structure on melting. The value of \( \lambda \) is \( 3\sqrt{3}/4 \approx 1.30 \) for body-centered cubic (bcc), and \( \sqrt{2} \approx 1.41 \) for face-centered cubic (fcc) and ideal \( (c/a = \sqrt{8}/3) \) hexagonal close-packed (hcp) lattices \([33]\). The parameter \( \alpha \) is the ratio of \( b \) to the dislocation core radius, \( r_0 \); \( \alpha \approx 2.9 \) for both bcc and fcc crystals \([33]\). This melting relation plus experimental data on over half the elements in the periodic table give \( b^2d(T_m) = 0.61 \pm 0.20 \) (throughout this paper the error in such expressions is the corresponding standard deviation) with \( G(300^\circ\text{K}), v_{WS}(300^\circ\text{K}) \) used instead of \( G(T_m), v_{WS}(T_m) \), respectively \([32]\).

### Table 1. Numerical values of the ratio \( G(T_m)v(T_m)/(k_B T_m) \) for 11 elemental solids that melt from bcc crystalline structure at normal pressure.

| element | Ba | Cs | Cr | δ-Fe | K | Li | Na | Nb | Rb | β-Ti | V |
|---------|----|----|----|------|---|----|----|----|----|-------|---|
| \( T_m, ^\circ\text{K} \) | 1000 | 301.6 | 2130 | 1811 | 336.5 | 453.7 | 370.9 | 2750 | 312.5 | 1941 | 2183 |
| \( v(T_m), \lambda \phi^3 \) | 66.68 | 116.8 | 13.10 | 12.76 | 76.38 | 22.14 | 40.17 | 19.33 | 93.37 | 18.61 | 14.89 |
| \( G(T_m), \text{GPa} \) | 2.96 | 0.39 | 35.7 | 30.8 | 0.80 | 3.60 | 1.93 | 32.6 | 0.60 | 21.9 | 32.3 |
| \( G v/(k_B T_m) \) | 14.3 | 10.9 | 15.9 | 15.7 | 13.2 | 12.7 | 15.1 | 16.6 | 13.0 | 15.2 | 15.9 |

### Table 2. Numerical values of the ratio \( G(T_m)v(T_m)/(k_B T_m) \) for 11 elemental solids that melt from fcc crystalline structure at normal pressure.

| element | Ag | Al | Ar | Au | β-Co | Cu | Ni | Pb | Pd | Pt | Rh |
|---------|----|----|----|----|------|----|----|----|----|----|----|
| \( T_m, ^\circ\text{K} \) | 1235 | 933.5 | 83.8 | 1338 | 1768 | 1358 | 1728 | 600.6 | 1828 | 2041 | 2237 |
| \( v(T_m), \lambda \phi^3 \) | 18.19 | 17.55 | 40.90 | 17.88 | 11.96 | 12.61 | 11.85 | 31.14 | 15.65 | 16.04 | 14.87 |
| \( G(T_m), \text{GPa} \) | 17.2 | 15.6 | 0.60 | 15.2 | 34.7 | 27.1 | 38.6 | 5.60 | 35.0 | 32.0 | 35.0 |
| \( G v/(k_B T_m) \) | 18.4 | 21.2 | 21.2 | 14.7 | 17.0 | 18.2 | 19.2 | 21.0 | 21.7 | 18.2 | 26.5 |
From the compilation of data in Tables 1 and 2 we find that the product of $\lambda$ and the logarithm in Eq. (2) (with $\nu(T_m) = 0.42 \pm 0.02$ [36]) is a constant to 15% at zero pressure:

$$\frac{\lambda}{8\pi} \ln \left( \frac{\alpha^2}{4b^2d(T_m)} \right) = \begin{cases} 0.100 \pm 0.015, & \text{bcc,} \\ 0.091 \pm 0.014, & \text{fcc.} \end{cases} \quad (3)$$

We make the reasonable assumption that the mean interdislocation distance at the melting point, $2R \approx 1/\sqrt{d(T_m)}$, scales with $b$, which implies that $b^2d(T_m)$ is a compression-independent constant. It is also assumed that $\alpha^{-1} = r_0/b$ is unchanged under compression. Hence $\lambda\ln(\alpha^2/b^2d)$ is expected to be pressure-independent with approximately the same value for both bcc and fcc elements. It then follows from (2) that for a given element

$$\xi(P) \equiv \frac{1 - \nu(P, T_m(P))/2}{1 - \nu(P, T_m(P))} \frac{G(P, T_m(P))\nu(P, T_m(P))}{k_BT_m(P)\ln(\nu - 1)} = c, \quad (4)$$

where the constant $c$ has nearly the same value for both bcc and fcc elements. Experimental validation of this relation is not possible because of a lack of data from moderate to high compressions. However, the $P \rightarrow 0$ and $P \rightarrow \infty$ limits are consistent with Eq. (4), which we now demonstrate.

At very high compressions a solid becomes a crystallized one-component plasma (OCP), i.e., a lattice of ions in a uniform neutralizing background of electrons [33]. The melting curve of a solid at ultrahigh pressures is described by the equation

$$\frac{Z^2e^2}{a(T_m)k_BT_m} = \Gamma_m, \quad (5)$$

where $Z$ is the atomic number, $a = (3\nu/4\pi)^{1/3}$ is the Wigner-Seitz radius, and $\Gamma_m$, a dimensionless constant, is the OCP coupling parameter at melt [33]. Numerous calculations of $\Gamma_m$ for a bcc OCP crystal (see ref. [37] for a review) converge on the value 175 [38, 39]. The value of $\Gamma_m$ for a fcc OCP crystal has been calculated to be 196 $\pm$ 1 [40] and 208.3 [41]; hence we take $\Gamma_m = 200$ for a fcc OCP crystal in the following analysis. The bcc OCP single-crystal elastic constants $(c_{11} - c_{12})/2$ and $c_{44}$ have been calculated by means of Monte-Carlo simulations [42]. A linear fit to the values of $G$ given by the formula of Sisodia et al. [43] (when $c_{11}$ and $c_{12}$ are not known separately, the value of $G$ given by this formula approximates Kröner’s shear modulus with high accuracy and, in fact, tends to the precise Kröner value in the limit $P \rightarrow \infty$) results in [37]

$$G_{\text{OCP}}^{\text{bcc}}(T) = g_{\text{bcc}} \left( \frac{4\pi}{3} \right)^{1/3} \frac{Z^2e^2}{v^{4/3}} \left( 1 - \frac{\beta_{\text{OCP}}}{\beta_{\text{OCP}}} T/T_m \right), \quad (6)$$

where $g_{\text{bcc}} = 0.09301$ and $\beta_{\text{OCP}} = 0.21 \pm 0.18$. We have calculated (unpublished) the coefficient $g_{\text{fcc}}$ to be 0.09011. The coefficient $\beta_{\text{OCP}}^{\text{fcc}}$ has not been calculated, so we assume $\beta_{\text{OCP}}^{\text{bcc}} = \beta_{\text{OCP}}^{\text{bcc}}$. We have also calculated the Voigt (V) and Reuss (R) bounds on the shear modulus of an ideal hcp OCP crystal: $g_{\text{hcp}}^{\text{V}} = 0.1194$, $g_{\text{hcp}}^{\text{R}} = 0.1045$, hence $g_{\text{hcp}} = 0.1120$ for the Voigt-Reuss-Hill average.

From Eqs. (4) and (6), and the ultrahigh pressure limit $\nu(T) = 1/2$ [44, 45], we obtain $\xi_{\text{bcc}} = 9.9 \pm 2.3$ and $\xi_{\text{OCP}} = 8.9 \pm 2.0$. Comparison of the OCP values of $\xi$ to their
zero-pressure counterparts (which follow from Eqs. (2) and (3)), $\xi_{bcc}(0) = 10.0 \pm 1.5$ and $\xi_{fcc}(0) = 11.0 \pm 1.7$, shows that the $P = 0$ and OCP values agree to within uncertainties, compelling evidence, though not a proof, that Eq. (4) is in fact valid, at least for bcc and fcc lattices. The uncertainty-weighted average of the four values is $10.0 \pm 1.8$.

Formula (1) now follows from Eq. (4) provided that the ratio \( (1 - \nu(T_m)/2)/(1 - \nu(T_m)) \) is (approximately) a constant; in fact this ratio varies between \( \approx 4/3 \) at $P = 0$ and $3/2$ as $P \to \infty$, i.e., it is $(17 \pm 1)/12 \approx 17/12$ to 94% accuracy.

Formula (1) can also be derived from the theory of a Debye solid. Ledbetter \[46\] derived the Debye-solid relation
\[
\Theta_D = \frac{\Lambda}{v^{1/3}} \sqrt{\frac{G}{\rho}},
\]
where $\Theta_D$ is the Debye temperature and $\Lambda$ is a constant. (Since $G \sim \rho^{4/3}$ as $\rho \to \infty$, $\Theta_D \sim \rho^{1/2}$, which is consistent with $\gamma$ (Grüneisen) $\to 1/2$ \[34, 44\]. Its widely used counterpart \[46\], $\Theta_D = \tilde{\Lambda} v^{-1/3} \sqrt{B/\rho}$, where $B$ is the bulk modulus, has the wrong asymptotic behavior, $\Theta_D \sim \rho^{2/3}$.) Siethoff and Ahlborn \[47\] demonstrated the validity of the Ledbetter formula at $P = 0$ for Debye-like cubic solids \[17, 48, 49\], non-Debye hexagonal and tetragonal solids \[50\], and intermetallic compounds \[51\]. Eq. (7), $v \sim 1/\rho$, and the Lindemann melting criterion \[35\]
\[
\frac{T_m(\rho) \rho^{2/3}}{\Theta_D(\rho)} = \text{constant},
\]
again yield relation (1).

Table 3. Numerical values of the ratio $G(P,T_m(P))v(P,T_m(P))/(k_BT_m(P))$ for Ar along its solidus. The last row of the table contains $P = 0$ values.

### 2.2 Experimental verification

Direct experimental validation of relation (1) over a restricted range of densities is possible for a single element, viz. argon. Ishizaki et al. \[52\] measured the transverse ultrasonic wave velocity, $u_t$, in compressed argon along its solidus as a function of temperature.
We calculate the shear modulus from the formula $u_t = \sqrt{G/\rho}$, and $v = V/N_A$ from the measured argon melting curve, $V = V(T_m)$, $V$ being the molar volume. Our results for the values of $G v/(k_B T_m)$ are shown in Table 3.

For the $P > 0$ data we find $G v/(k_B T_m) = 21.06 \pm 0.17$, in agreement with its $P = 0$ value (we get $G v/(k_B T_m) = 21.08 \pm 0.17$ for all of the data). Thus, $G v/(k_B T_m)$ for Ar deviates from a constant by less than 1%.

3 Model of the shear modulus at all temperatures and densities

Preston and Wallace [30] constructed a model of the temperature dependence of the shear modulus ($0 \leq T \leq T_m$) for arbitrary pressures. The $T$-dependence of $G$ involves two characteristic temperatures, namely the Debye temperature and the melting temperature. The shear modulus is always monotonically decreasing with $T$, and is nonlinear for $T < \sim \Theta_D$ and linear from $\Theta_D$ to $T_m$ for most elements. An accurate representation of $G(T)$ at fixed density is achieved by ignoring the low-temperature non-linearity and approximating $G(T)$ as a linear function of the reduced temperature $T/T_m$ with the correct value $G(\rho, 0)$ at $T = 0$ [30]:

$$G(\rho, T) = G(\rho, 0) \left(1 - \beta \frac{T}{T_m(\rho)}\right), \tag{9}$$

In general, the parameter $\beta$ may be density dependent. A fit to shear-modulus data spanning temperatures from $T = 0$ to $T/T_m \approx 0.4$ at zero pressure gave $\beta_0 = 0.23 \pm 0.08$ [30]. (For the 11 fcc elements in Table 4 below $\beta_0 = 0.27 \pm 0.10$.) On the other hand, $\beta_{\text{OCP}} = 0.21 \pm 0.18$ (as discussed above), which equals $\beta_0$ to within uncertainties, so we assume that $\beta$ is independent of density. At $\rho = \rho_{\text{ref}}$ and $T = T_m(\rho_{\text{ref}})$, Eq. (9) reduces to

$$\beta = 1 - \frac{G(\rho_{\text{ref}}, T_m(\rho_{\text{ref}}))}{G(\rho_{\text{ref}}, 0)}. \tag{10}$$

The linear temperature dependence is suggested by available $P = 0$ experimental data on $G$ over the temperature range $0 \leq T \leq T_m$ [1–19]. This straight-line representation turns out to be quite accurate: the maximum deviation of the data from the corresponding fitted lines is $\sim 5\%$ for 21 of the 22 metals analyzed in [30]. The exception is uranium, for which $G(T)$ is nonlinear throughout the $\alpha$ phase at $P = 0$. As mentioned above, $G(T)$ is is nonlinear below $\Theta_D$, thus $G(T)$ is nonlinear for low-melting-point solids from $T = 0$ to $T_m$. Despite the nonlinearity of $G(T)$ in these cases, the model uncertainty is only of order 10%.

At any given pressure, the introduction of the temperature dependence of the density, $\rho = \rho(T)$, into Eq. (9) gives the temperature dependence of $G$ at that pressure. In Fig. 1 we compare $G(\rho(T), T)$ for $0 \leq T \leq T_m$ at $P = 0$ for Au and Cu to experimental data [2, 10]. The temperature dependence of the density was taken from ref. [24], and $G(\rho, 0)$ and $T_m(\rho)$ are described by Eqs. (13) and (14) below with parameter values from Tables 2 and 4.
Fig. 1. The $P = 0$ shear moduli of Cu and Au: Eq. (9) with $\rho = \rho(T)$ from ref. [54] and $G(\rho(T), 0)$ and $T_m(\rho(T))$ described by Eqs. (13) and (14) with the parameters from Tables 2 and 4 vs. the experimental data on Cu [10] (smaller points) and Au [2] (larger points).

The Grüneisen parameter was recently modeled as [34]

$$\gamma(\rho) = \frac{1}{2} + \frac{\gamma_1}{\rho^{1/3}} + \frac{\gamma_2}{\rho^q}, \quad \gamma_1, \gamma_2, q = \text{const}, \quad q > 1,$$

through consideration of its low- and ultrahigh-pressure limits. This analytic form for $\gamma$ was obtained under the assumptions that (i) $\gamma \to 1/2$ as $\rho \to \infty$, (ii) $\gamma$ is an analytic function of $x \equiv 1/\rho^{1/3}$, essentially the interatomic distance, and (iii) the coefficient of $x$ in the Taylor-Maclaurin series expansion for $\gamma$ is non-zero. The third term on the right-hand-side of Eq. (11) represents the contribution of the quadratic and higher-order terms in the power series. The procedure for calculating the values of $\gamma_1, \gamma_2,$ and $q$ is discussed below.

Eq. (11) and the Lindemmann criterion [35]

$$\frac{d \ln T_m(\rho)}{d \ln \rho} = 2 \left( \gamma(\rho) - \frac{1}{3} \right)$$

provide a model for the density dependence of the melting temperature,

$$T_m(\rho) = T_m(\rho_{\text{ref}}) \left( \frac{\rho}{\rho_{\text{ref}}} \right)^{1/3} \exp \left\{ 6\gamma_1 \left( \frac{1}{(\rho_{\text{ref}})^{1/3}} - \frac{1}{\rho^{1/3}} \right) + \frac{2\gamma_2}{q} \left( \frac{1}{(\rho_{\text{ref}})^q} - \frac{1}{\rho^q} \right) \right\}.$$
The natural choice for the reference density is \( \rho_m \), the zero-pressure density at melt, which is known experimentally in most cases (see, e.g., [54]).

Finally, Eqs. (1), (9), (10), and (13) result in

\[
G(\rho, 0) = G(\rho_{\text{ref}}, 0) \left( \frac{\rho}{\rho_{\text{ref}}} \right)^{4/3} \exp \left\{ 6\gamma_1 \left( \frac{1}{(\rho_{\text{ref}})^{1/3}} - \frac{1}{\rho^{1/3}} \right) + \frac{2\gamma_2}{\beta} \left( \frac{1}{(\rho_{\text{ref}})^{\beta}} - \frac{1}{\rho^{\beta}} \right) \right\}, \tag{14}
\]

where \( \rho_{\text{ref}} \) is most conveniently chosen to be either \( \rho_m \) or \( \rho_0 \), the density at zero pressure and temperature.

Eqs. (9), (13), and (14) constitute our analytic model for the shear modulus. It requires the determination of 7 parameters, namely \( \rho_{\text{ref}}, G(\rho_{\text{ref}}, 0), T_m(\rho_{\text{ref}}), \gamma_1, \gamma_2, q, \) and \( \beta \). The values of \( \gamma_1, \gamma_2 \) and \( q \) are obtained by simultaneous solution of Eq. (11) with \( \rho = \rho(T = 300 \, ^\circ\text{K}) \) and \( \rho = \rho_m \), and Eq. (5) with \( \Gamma_m = 180 \) [34] and \( T_m(\rho) \) given by the high-density limit of Eq. (13). The value of \( \gamma(\rho_m) \) is obtained from the Kraut-Kennedy relation [52] and low-pressure melting data. The remaining parameters are either zero-pressure experimental data themselves or can be determined from such data (for example, \( \beta \)). In Table 4 we present the values of \( \rho_{\text{ref}} \) (both \( \rho_0 \) and \( \rho_m \)), \( G(\rho_{\text{ref}}, 0), \gamma_1, \gamma_2 \), \( q \), and \( \beta \) for all of the fcc elements of Table 2. The values of \( G(\rho_{\text{ref}}, 0) \) can be calculated from the relation \( G(\rho_{\text{ref}}, 0) = G(\rho_m, T_m)/(1 - \beta) \) with \( G(\rho_m, T_m) \) from Table 2, which also contains the values of \( T_m(\rho_m) \). Since \( \beta\)-Co exists only above \( T \approx 700 \, ^\circ\text{K} \) at \( P = 0 \), its values of \( G(\rho_0, 0) \) and \( \beta \) were obtained from the conditions \( G(\rho_m, T_m) = 34.7 \) and \( G(\rho(T = 710 \, ^\circ\text{K}) = 8.62, T = 710 \, ^\circ\text{K}) = 57.1 \) [56].

Table 4. Numerical values of the model parameters for 11 fcc elements. The corresponding values of \( T_m(\rho_m) \) and \( G(\rho_m, T_m(\rho_m)) \) are provided in Table 2.

In Figs. 2, 3, and 4 we compare the melting curves of Ar, Al and Cu as given by Eq. (13) with the corresponding parameters from Table 4 to experimental data.
Fig. 2. Melting curve of Ar: Eq. (13) with the Ar parameters from Table 4 vs. data. The smaller points are the experimental data of ref. [53], and the larger points are the results of calculations [57].

Fig. 3. Melting curve of Al: Eq. (13) with the Al parameters from Table 4 vs. data. The smaller points are the experimental data of ref. [58], and the larger points are the results of calculations [59].
Fig. 4. Melting curve of Cu: Eq. (13) with the Cu parameters from Table 4 vs. data. The smaller points are from a new SESAME melting curve table for Cu \[60\]. The larger points are the \( P = 0 \) reference point at \( \rho = 8.4 \), and the shock-melting points of ref. \[61\] at \( \rho = 10.2, 12.2 \) and 14.3, and of refs. \[62, 63\] at \( \rho = 14.0 \).

Only five of the seven shear modulus parameters are independent because four appear in the model as two ratios, namely \( \beta/T_m(\rho) \) in Eq. (9) and \( G(\rho_{\text{ref}}, 0)/(\rho_{\text{ref}})^{4/3} \) in Eq. (14); hence the shear modulus is of the form

\[
G(\rho, T) = a_1 \rho^{4/3} \exp\left\{-\frac{a_2}{\rho^{2/3}} - \frac{a_3}{\rho^{1/3}}\right\} - a_4 \rho T, \quad a_1, a_2, a_3, a_4, q = \text{const} > 0. \tag{15}
\]

As specific examples we provide the following formulas for the shear moduli of Ar, Al, Cu, and Au:

\[
G_{\text{Ar}}(\rho, T) = 687.4 \rho^{4/3} \exp\left\{-\frac{5.84}{\rho^{2/3}} - \frac{6.36}{\rho^{1/3}}\right\} - 1.32 \cdot 10^{-3} \rho T, \tag{16}
\]

\[
G_{\text{Al}}(\rho, T) = 611.8 \rho^{4/3} \exp\left\{-\frac{25.9}{\rho^{2/3}} - \frac{5.04}{\rho^{1/3}}\right\} - 1.85 \cdot 10^{-3} \rho T, \tag{17}
\]

\[
G_{\text{Cu}}(\rho, T) = 841.2 \rho^{4/3} \exp\left\{-\frac{9.83 \cdot 10^3}{\rho^{1/3}} - \frac{11.22}{\rho^{1/3}}\right\} - 7.96 \cdot 10^{-4} \rho T, \tag{18}
\]

\[
G_{\text{Au}}(\rho, T) = 1022.0 \rho^{4/3} \exp\left\{-\frac{4.19 \cdot 10^{11}}{\rho^{9/4}} - \frac{19.26}{\rho^{1/3}}\right\} - 1.37 \cdot 10^{-4} \rho T. \tag{19}
\]
Fig. 5. The $T = 300$ shear modulus of Ar: Eq. (16) vs. older [64] (smaller points) and more recent [65] (larger points) experimental data. The experimental technique used to obtain the older data has been criticized [65].

Fig. 6. The $T = 0$ shear modulus of Al: Eq. (17) vs. the electronic-structure calculations of ref. [66]. The small, medium, and large points represent the values of $G$ in fcc, hcp, and bcc phases of Al, respectively.
In Fig. 5 we compare the $T = 300\,^\circ K$ shear modulus of Ar as given by Eq. (16) to experimental data. The $T = 0$ shear modulus of Al from Eq. (17) is compared to the results of electronic structure calculations in Fig. 6. The $T = 0$ shear moduli of Cu and Au as given, respectively, by Eqs. (18) and (19) are compared to the results of the corresponding electronic-structure calculations in Figs. 7 and 8 in the next section.

4 Comparison of model to electronic-structure results for Cu and Au

With the exception of Ar, experimental data are not available to test the model to megabar pressures. We can, however, test the $T = 0$ version of the model by comparing it to the results of ab initio electronic-structure calculations of the shear modulus.

Electronic structure calculations based on approximate density functional theories have proven to give good predictions for a variety of material properties. A study of the elastic constants of several elements and compounds \[67\] covering a wide range of elastic properties, found errors with respect to experiment of generally less than 10% in the isotropic shear modulus. These results are obtained without empirical inputs. We expect such calculations to have similar accuracy under compression, thus providing a test of the new analytic model.

For this reason, we have carried out electronic structure calculations to obtain the single crystal elastic constants $C' = (C_{11} - C_{12})/2$, $C_{44}$, and $B = \frac{1}{3} (C_{11} + 2C_{12})$ for the fcc metals Cu and Au from normal to twice normal density. From these an average polycrystalline shear modulus is calculated and compared to the model.

The method for the calculations was described by Söderlind et al. \[68\]. To evaluate $C'$, the lattice is deformed by the (volume conserving) transformation

$$
\begin{pmatrix}
1 + \delta & 0 & 0 \\
0 & 1 + \delta & 0 \\
0 & 0 & 1/(1 + \delta)^2
\end{pmatrix},
$$

(20)

The resulting energy change is

$$
\Delta E/V = 6C'\delta^2 + O(\delta^3).
$$

(21)

Similarly, $C_{44}$ is obtained by applying the (volume conserving) transformation

$$
\begin{pmatrix}
1 & \delta & 0 \\
\delta & 1 & 0 \\
0 & 0 & 1/(1 - \delta^2)
\end{pmatrix},
$$

(22)

resulting in an energy change

$$
\Delta E/V = 2C_{44}\delta^2 + O(\delta^4).
$$

(23)

In our calculations we have evaluated the energy as a function of $\delta$ at intervals of 0.01, up to $\delta = 0.04$. For the $C'$ case the energy is not an even function of $\delta$, and so negative
values of delta were used. The resulting $E(\delta)$ were fit to 4th degree polynomials and the quadratic coefficient was used to evaluate the elastic constant from Eq. (21) or Eq. (23).

The bulk modulus $B$ is obtained from the volume-dependent energy of the undistorted crystal by

$$B = V \frac{d^2E}{dV^2}. \tag{24}$$

The energy was evaluated at volume intervals of 5% of the normal volume, from 20% expanded to 50% contracted. Derivatives were evaluated by fitting the equation of state of Rose et al. [69] to the energies and differentiating the function. It was found that a single curve of this type did not accurately fit both the high density points and the points near the minimum, so separate overlapping fits were made for the 10 highest and lowest densities.

The electronic structure calculations were based on the linearized augmented plane-wave (LAPW) code WIEN97 [70]. The energy functional used was the generalized-gradient approximation as parameterized by Perdew, Burke, and Ernzerhof [71]. Some numerical parameters used in the calculations for Cu (Au) were, in atomic units: muffin tin radius $r_{MT} = 1.8 \ (2.0)$, plane wave cut-off $r_{MT}k_{\text{max}} = 9.0$, cut-off for expansion of density and potential $g_{\text{max}} = 16 \ (19)$; Brillouin zone integrals used special points corresponding to $16^3 \ (18^3)$ points in the full zone, with Gaussian smearing of the energies by 20 mRy.

Our results on $C'$, $C_{44}$ and $B$ for Cu and Au are shown in Tables 5 and 6, respectively. It is interesting to note the increasing anisotropy of Au under pressure. From Table 6 we see that, for Au, $C'$ does not increase nearly as rapidly as $C_{44}$ with compression. This is connected with the fact that the energy difference between the fcc and bcc structures is small at all pressures [72]. The distortion corresponding to $C'$ is along the Bain path connecting fcc to bcc, and it has been seen [68] that a small energy difference between these structures correlates with a small value of $C'$.

Let us now turn to the calculation of the shear moduli of Cu and Au. For a solid of cubic crystalline structure, as analysis by Kröner [28] shows, successively narrower bounds can be placed on the shear modulus as the degree of disorder in grain orientation increases. In the limit of perfect disorder, the value of the shear modulus is the single positive real root of a cubic equation with coefficients that depend on the single-crystal elastic constants $C'$, $C_{44}$, and $B$:

$$x^3 + \frac{9B + 4C'}{8} x^2 - \frac{3(B + 4C')C_{44}}{8} x - \frac{3BC'C_{44}}{4} = 0. \tag{25}$$

The values of the shear modulus calculated from Eq. (25) are shown in Tables 5 and 6 along with $C'$, $C_{44}$ and $B$.

As a by-product of our analysis, we obtain the interesting results that $G(2\rho_0, 0) \simeq 10 G(\rho_0, 0)$ for Cu, and $G(2\rho_0, 0) \simeq 20 G(\rho_0, 0)$ for Au.

In Figs. 7 and 8 we compare Eqs. (18) and (19) with $T = 0$, for Cu and Au, to the corresponding $G$ entries in Tables 5 and 6.
Table 5. The single-crystal elastic constants and shear modulus of Cu as functions of density from the electronic-structure calculations described in the text.

Fig. 7. The $T = 0$ shear modulus of Cu: Eq. (18) vs. electronic-structure calculations (larger points, Table 5). The smaller points, obtained from first-principles calculations [26], are shown for comparison.
Fig. 8. The \( T = 0 \) shear modulus of Au: Eq. (19) vs. electronic-structure calculations (larger points, Table 6). The smaller points, obtained from first-principles calculations [73] are shown for comparison.

Fig. 9. Comparison of the two models for the \( T = 0 \) shear modulus: Eqs. (16) and (17) vs. the corresponding Guinan-Steinberg values for Ar (smaller points) and Al (larger points).
Finally, it is interesting to compare our model at $T = 0$ to the Guinan-Steinberg model mentioned in the Introduction. The equation of state, $P = P(\rho)$, is needed to make this comparison. In Fig. 9 the models are compared to each other for Ar and Al. The corresponding equations of state are taken from ref. [74]. For Al, $G'_0 = 1.8$ comes from ref. [75]. For Ar, $G'_0 = 1.6$ is obtained from the relation $\gamma_0 = B_0 / 2G'_0/G_0 - 1/6$ with $\gamma_0 = \gamma(\rho_0)$ from Eq. (11) and $B_0$ taken from ref. [74]. The values of $\rho_0$ and $G_0 = G(\rho_0, 0)$ can be found in Table 4.

It is seen that agreement between the two models is good at low densities, but it gradually deteriorates with increasing compression. The reason for this must be that the Guinan-Steinberg model generally provides only the correct functional form $G \sim \rho^{4/3}$ in the limit of infinite compression, not the precise numerical value of $G$ in that limit, in contrast to our model which provides both.

5 Concluding remarks

We have constructed an analytic model of the shear modulus applicable at all densities greater than or of order ambient ($G(\rho, 0) \to 0$ as $\rho \to 0$, as required, but the model may not be quantitatively correct for expanded states), and temperatures from 0 to $T_m$. All of the model parameters can be obtained from low-pressure experimental data. The model has the proper low-pressure and high-pressure limits, by construction, and to within uncertainties it agrees with electronic-structure values of $G$ for Cu and Au to compressions of 2, which roughly corresponds to pressures of 5 Mbar for Cu and 9 Mbar for Au.

The above comparisons of our shear modulus model, which includes a model for $T_m(\rho)$, to electronic structure calculations and experimental data on Ar, Al, Cu, and Au show very good agreement. This suggests that our model accurately represents the density and temperature dependence of the shear moduli of monatomic solids in general. There is, however, no theoretical justification for applying our model to alloys or compounds, although in practice it may work reasonably well in these cases. Its generalization to more complex materials would involve generalizing our model for the Grüneisen parameter. A functional form for $\gamma(\rho)$ depends critically on the asymptotic ($\rho \to \infty$) form of the equation of state [34], and it has been suggested that the asymptotic forms of the equations of state of more complex materials, e.g., ionic, covalent, or molecular crystals, are different from that of a metal [76]. If so, the limiting value of $\gamma$ is unknown (not necessarily 1/2) for such materials. In that case, an analytic model for the Grüneisen parameter cannot be constructed, hence analytic forms for the melting curve and shear modulus cannot be obtained.

We now briefly discuss three potential applications of our model.

1. Plastic deformation of metals at high pressure. It is generally assumed that the ratio of the plastic flow stress (shear stress necessary to induce plastic deformation at a given strain rate) to the shear modulus is approximately independent of pressure. In other words, the predominant pressure dependence of the plastic flow stress is contained in the shear modulus. An accurate, simple analytic (for fast evaluation) model of the shear modulus is therefore essential for numerical simulations of material deformation over extremes in pressure.
(2) Numerical simulations of elastic wave propagation, including pressure release waves in shocked solids. The differential stress deviator, $ds_{ij}$, is equal to $2G(\rho, T)(d\epsilon_{ij} - \delta_{ij}d\epsilon_{kk}/3)$ plus material rotation terms ($d\epsilon_{ij}$ is the differential elastic strain), thus a model of the shear modulus is required for calculations of elastic wave propagation in materials with sufficiently high yield stresses that the stress deviators are not negligible. The speed of a release wave in a shocked solid depends on $G(\rho_H, T_H)$, where $\rho_H$ and $T_H$ are the density and temperature of the shocked state.

(3) Pulsations and quakes of dense stars. Hansen and Van Horn [77] have done a preliminary analysis of the effects of crystalline cores on the oscillations of white dwarfs and found that the $g$-like spheroidal mode frequencies are increased by approximately a factor of two, concluding that the elastic shear strength of the core must be taken into account in the computation of cool white dwarf oscillations. The inclusion of elastic shear strength in the neutron star pulsation equations of McDermott et al. [78] resulted in the appearance of two classes of oscillation modes not present in a fluid neutron star. The change in the shape of the surface following a neutron star quake is proportional to the shear modulus of the crust [79].

Further tests of our model for the shear modulus should be made as high-pressure experimental data and electronic structure results become available for elements other than argon, aluminum, copper and gold. New zero-pressure data are also needed to generate additional sets of model parameters.
