Minimum Relative Entropy for Quantum Estimation: Feasibility and General Solution

Mattia Zorzi, Francesco Ticozzi and Augusto Ferrante

Abstract—We propose a general framework for solving quantum state estimation problems using the minimum relative entropy criterion. A convex optimization approach allows us to decide the feasibility of the problem given the data and, whenever necessary, to relax the constraints in order to allow for a physically admissible solution. Building on these results, the variational analysis can be completed ensuring existence and uniqueness of the optimum. The latter can then be computed by standard, efficient standard algorithms for convex optimization, without resorting to approximate methods or restrictive assumptions on its rank.

I. INTRODUCTION

Quantum devices implementing information processing tasks promise potential advantages with respect to their classical counterparts in a remarkably wide spectrum of applications, ranging from secure communications to simulators of large scale physical systems [1], [2], [3].

In order to exploit quantum features to the advantage of a desired task, tremendous challenges are posed to experimentalists and engineers, and many of these have stimulated substantial theoretically-oriented research. Which particular problem is critical depends on the physical system under consideration: from optical integrated circuits to solid-state devices, the tasks in the device engineering, protection from noise and control are manifold [4], [5]. However, quantum estimation problems are ubiquitous in applications, be it in testing the output of a quantum algorithm, in reconstructing the behavior of a quantum channel or in retrieving information at the receiver of a communication system [3], [8], [9], [10], [11], [12]. In this paper we focus on state estimation problem for finite-dimensional quantum system, namely the reconstruction of a trace-one, positive semidefinite matrix given from data, and in particular on an estimation method that addresses two critical problems for most real-world situations. The first arises when only a small set of potentially noisy data is available, yielding no physically-acceptable solution; the second regards a situation in which the system dimension is large and the available measurement are insufficient to completely determine the state.

To address this second issue, a typical approach in both the classical and the quantum world is to resort to a MAX-ENT principle [13], [14], [15], [16], [7], [17], where one opts for a “maximum ignorance” criterion on the choice of parameters that are not uniquely determined by data. The MAXENT estimation can indeed be seen as a particular case of minimum relative entropy estimation, [18], where the information-theoretic pseudo-distance of the estimated state with respect to some a priori state is minimized subject to a set of constraints representing the available data [19], [20], [21], [22], [23]. This a priori information introduces a new ingredient with respect to typical maximum-likelihood methods for quantum estimation [7], [9].

A quantum minimum relative entropy method for state estimation has been discussed in [21], [24], where approximate solutions to minimum relative entropy problems are provided: the estimates are shown to be good approximation of the optimal solution when this is close enough to the prior. On the other hand, a way towards the computation of the exact optimal solution is indicated in [19]. Georgiou has analyzed the MAXENT problem for estimating positive definite matrices, providing a generic form for the optimal solution, parametric in the Lagrange multipliers. He has also observed that the results can be extended to the more general minimum relative entropy problem.

We shall here extend Georgiou’s approach, proving existence, uniqueness and continuity of the solution with respect to the measured data, when a generic prior is considered. The solution can then be computed by standard numerical methods. However, the approach returns a meaningful answer only when there is a full-rank admissible solution among the states compatible with the data. While this appears to be a reasonable assumption as quantum full-rank states are generic, this is no longer the case whenever the unknown state is pure or near the boundary of the physical state set. In fact, it is easy to picture realistic scenarios where the effect of noisy or biased measurements might actually force the solutions to be on the boundary, or even outside of the admissible set [25]. In the latter case the constrained optimization problem “as is” is not feasible, and one has to relax the constraints.

Our strategy to solve these issues is organized as follows: a general setting for posing the feasibility problem and quantum minimum relative entropy with data corresponding to linear constraints is presented in Section I. In Section III we propose a way to reformulate the feasibility analysis as a
convex optimization problem. The solution of this ancillary problem, for which we provide a numerical approach in Appendix A also indicates an optimal way to perturb, or relax the constraints in order to allow for admissible solutions to the estimation problem. We also show how the way in which the constraints are relaxed can be tailored to match the error distribution or the level of noisy we assume on the measurements. Once the feasibility analysis returns a positive answer, our approach directly leads to the construction of a reduced problem for which there exists a positive definite state satisfying the given constraints. In Section IV, we address the corresponding (reduced, if needed) minimum relative entropy problem, showing it admits a unique full-rank solution. The latter can be computed from the closed-form solution of the primal problem, and a standard numerical algorithm to find the corresponding Lagrange multipliers is suggested. Then, the solution to the non-reduced, original problem is immediately obtained. Some concluding remarks and future directions and applications are summarized in Section V.

II. Problem Setting

A. Quantum States and Measurement Data

Consider a quantum n-level system. Its state is described by a density operator, namely by a positive semidefinite unit-trace matrix

$$\rho \in \mathcal{D}_n = \left\{ \rho \in \mathbb{C}^{n \times n} | \rho = \rho^\dagger \geq 0, \quad \text{tr}(\rho) = 1 \right\},$$

which plays the role of probability distribution in the classical probability framework. Note that a density matrix depends on $n^2 - 1$ real parameters.

In this work we will be concerned on the problem of reconstructing an unknown $\rho$ from a set of repeated measurement data. This is of course an estimation problem in the statistical language, while in the physics community it is usually referred to as state tomography [7].

We assume that data are provided in one of the following forms:

1) Outcome frequencies for projective measurements: consider repeated measurements of a (Hermitian) observable [26]. $O = \sum_k \rho_k \Pi_k$, where $\{\Pi_k\}$ is the associated spectral family of orthogonal projections. The spectrum $\{\rho_k\}$ represents the possible outcomes at each measurement, and the frequency of the $k$-th outcome given a state $\rho$ can be computed as $p_k = \text{tr}(\rho \Pi_k)$. After $K$ measurements of $O$, we assume we are provided with some experimental estimates of $p_k$, i.e., the experimental relative frequencies of occurrences $\hat{p}_k = \frac{\#(O = \rho_k)}{\#(O = \rho_k)}$ of measurements that returned outcome $\rho_k$.

2) Observable averages: consider a set of no measured observables, represented by Hermitian matrices $O_i$, where now we only have access to the mean values of the outcomes, denoted by $\langle O_i \rangle$ (and with possible outcomes $\rho_{i,k}$), that can be theoretically computed as $\langle O_i \rangle := \text{tr}(\rho O_i)$ and experimentally estimated by $\langle O_i \rangle = \sum_k \rho_{i,k} \hat{p}_k$.

3) Outcome frequencies for general measurements: consider repeated measurements of a Positive-Operator Valued Measure (POVM), that is generalized measurements that can be used to describe indirect measurements on a system of interest [3]. A POVM with $M$ outcomes, say $k = 1, \ldots, M$, is associated to a set of non-negative operators $\{Q_k\}_{k=1}^M$ such that $\sum_k Q_k = I$, playing the role of resolution of the identity for projective measurements. The probability of obtaining the $k$-th outcome can be computed by $q_k = \text{tr}(\rho Q_k)$, and experimentally estimated by $\hat{q}_k$ after $K$ repeated measurements. This case in fact includes the first one, and the generalization to multiple POVM is straightforward.

In all these scenarios, data are provided as a set of real values representing estimates $\hat{f}_i$ of quantities $f_i$ (that can be either $p_i$, $\langle O_i \rangle$, or $q_k$), each associated to the state through a linear relation of the form $\hat{f}_i = \text{tr}(\rho Z_i)$, where $Z_i$ have the role of $\Pi_i$, $O_i$, or $Q_i$, described above. Clearly $\hat{f}_i \rightarrow f_i = \text{tr}(Z_i \rho)$ with probability one as $N \rightarrow \infty$. This framework is quite general, and can be adapted to include any case if the data are given as linear constraints. Another significant situation that fits in this framework is when reduced states of a multipartite systems are available as data [27], [28]. Finally, by the well-known Choi-Jamiołkowski isomorphism [29], the same setting, and methods for solution, can be adapted to include estimation of quantum channels, or quantum process tomography [7], [9].

From a theoretical viewpoint, $\rho$ can be in principle reconstructed exactly from at least $n^2 - 1$ averages $\hat{f}_i = \text{tr}(\rho Z_i)$ $i = 1 \ldots n^2 - 1$ when $Z_1 \ldots Z_{n^2-1}$ are observables which do not carry redundant information, namely they form a basis for the space of traceless Hermitian matrices. In any practical application, however, one has to face the following issues:

1) Accurate estimates $\hat{f}_i$ of $f_i$ are only obtained by averaging over a large quantity of trials; Often only a small set of trials is available, and/or the data are subject to significant errors;

2) The number of observables required for a unique reconstruction of $\rho$ grows quadratically with respect to the dimension of the quantum system, and exponentially in the number of subsystems. Typically only a small subset of these is available;

We here analyze the estimation problem when these two aspects are taken into account. The first one will lead us to consider the feasibility problem, that is, if the problem admits a physically admissible solution for the given data. Since errors may affect the $\hat{f}_i$, the reconstructed state may not be positive semidefinite, or a valid state that satisfies the constraints might not even exist. The second issue generally leads to a estimation problem where more than one state satisfy the constraints, and thus an additional criterion has to be introduced to arrive at a unique solution. As we said, a typical strategy in this setting is to introduce an entropic functional, e.g. relative entropy with respect to some reference state representing a priori information.

B. Statement of the Main Problems

Consider the setting described above, where we want to estimate the state of an $n$-dimensional quantum systems from
than one solution, and in principle any solution in between this aim, consider the (Umegaki’s) quantum relative entropy of the data. We focus on choosing a solution that has minimum \( \tau \) constraint of \( \rho \), \( \rho \in \mathcal{H}_n \), such that \( \rho \geq 0 \), \( \hat{f}_i = \text{tr}(\rho Z_i) \), \( i = 1, \ldots, p \).

Here, \( \mathcal{H}_n \) denotes the vector space of Hermitian matrices of dimension equal to \( n \). Notice that, if we remove the positivity constraint \( \rho \geq 0 \), all other constraints are linear and identify a hyperplane in \( \mathcal{H}_n \). To our aim it is convenient to first address a simpler problem: let

\[
S := \left\{ \rho \in \mathcal{H}_n \mid \rho \geq 0, \hat{f}_i = \text{tr}(\rho Z_i) \right\}
\]

be the set of the density matrices which solve Problem 1.

**Problem 2 (Feasibility):** Determine if \( S \) is not empty.

When the problem is feasible, in general \( S \) contains more than one solution, and in principle any solution in \( S \) fits the data. We focus on choosing a solution that has minimum distance with respect to an a priori state. In the same spirit of MAXENT problem, this corresponds to give maximum priority to fitting the data, and then choosing the admissible solution that is the closest (in the relative-entropy pseudo-distance) to our a priori knowledge on the systems. To this aim, consider the (Umegaki’s) quantum relative entropy between \( \rho \in \mathcal{D}_n \), and \( \tau \in \text{int} (\mathcal{D}_n) \) [30]:

\[
\mathcal{S}(\rho\|\tau) = \text{tr}(\rho \log \rho - \rho \log \tau).
\]

Assuming \( \tau \) in the interior and with the usual convention that \( 0 \log(0) = 0 \), we do not have to worry about unbounded values of \( \mathcal{S}(\rho\|\tau) \).

**Problem 3 (Minimum relative entropy estimation):** Given the observables \( Z_1, \ldots, Z_p \) and the corresponding estimates \( \hat{f}_1, \ldots, \hat{f}_p \), solve

\[
\text{minimize } \mathcal{S}(\rho\|\tau) \text{ subject to } \text{tr}(\rho Z_i) = \hat{f}_i, \ i = 1, \ldots, p.
\]

Here, \( \tau \) represents the a priori information on the considered quantum system. We set \( \sigma = I \) if no information is available. In this situation, \( \hat{f}_i \) is the opposite of the quantum entropy of \( \rho \), and we obtain a MAXENT problem. Note that, the solution to the Problem above may be singular.

### III. Feasibility Analysis

#### A. An auxiliary problem

We start by addressing the feasibility problem, i.e. to determine when \( S \) is not empty. In addition, whenever the problem is not feasible, we show how to determine a suitable perturbation of the \( \{\hat{f}_i\} \) that makes our problem feasible. We will show that the corresponding \( S \) only contains singular density matrices when the constraints are relaxed.

Note that, the constraints are linear in \( \hat{f}_i \) and \( Z_i \), and can be linearly combined: \( \alpha \hat{f}_i + \beta \hat{f}_k = \text{tr}(\rho (\alpha Z_i + \beta Z_k)) \) for each \( \alpha, \beta \in \mathbb{R} \setminus \{0\} \) and \( i, k = 1, \ldots, p \). Consider the vector space generated by the observed operators, \( \text{span} \{Z_1, \ldots, Z_p\} \).

Thus, by applying the Gram-Schmidt process, starting with \( X_1 = \frac{1}{\sqrt{n}} Z_1 = \frac{1}{\sqrt{n}} I \), we can compute an orthonormal basis for it:

\[
X_i := \alpha_i^1 Z_i + \sum_{i=1}^{i-1} \alpha_i^1 X_i, \ i = 2, \ldots, m.
\]

By linearity, by associating these basis elements to the estimates

\[
\hat{f}_i := \frac{1}{\sqrt{n}} X_i, \ i = 1, \ldots, m.
\]

we obtain a new yet equivalent set of constraints:

\[
\hat{f}_i = \text{tr}(\rho X_i), \ i = 1, \ldots, m.
\]

Note that, \( I \in \text{span} \{X_1, \ldots, X_m\} \).

Let \( Y_1, \ldots, Y_{n^2-m} \) be an orthonormal completion of \( X_1, \ldots, X_m \) to a basis of \( \mathcal{H}_n \). Accordingly, all the Hermitian matrices, and in particular density operators, can be expressed as

\[
\rho = \sum_{i=1}^{m} \alpha_i X_i + \sum_{i=1}^{n^2-m} \beta_i Y_i,
\]

with \( \text{tr}(\rho X_i) = \alpha_i \). In particular, all the Hermitian matrices satisfying the linear constraints in (7) depend on \( n^2 - m \) parameters \( \beta = [\beta_1, \ldots, \beta_{n^2-m}] \):

\[
\rho = \tilde{\rho}_0 + \sum_{i=1}^{m} \beta_i Y_i
\]

where we have defined the (not necessarily positive) pseudo-state associated to the constraints:

\[
\tilde{\rho}_0 = \sum_{i=1}^{m} \hat{f}_i X_i.
\]

In the light of this observation, the feasibility problem consists in checking if there exists at least one vector \( \tilde{\rho}_0 \), there always exists a real \( \mu \) such that \( \tilde{\rho}_0 + \mu I \) is positive definite. More precisely, if \( \tilde{\rho}_0 \) is not positive definite already, it is easy to see that such a \( \mu \) will need to be positive. On the other hand, if \( \tilde{\rho}_0 \) is already positive, the perturbed matrix remains positive semi-definite for some small, negative \( \mu \). Studying the minimal \( \mu \) that correspond to a positive semidefinite matrix offers us a way to understand whether our constraints allow for physically admissible solutions.

Let us formalize these idea: we define \( c := \begin{bmatrix} 0 & \ldots & 0 & 1 \end{bmatrix}^T \in \mathbb{R}^{n^2-m+1} \), and

\[
H(c) := \tilde{\rho}_0 + \sum_{i=1}^{n^2-m} v_i Y_i + v_{n^2-m+1} X_1
\]

with \( v = [v_1, \ldots, v_{n^2-m+1}] \) and we consider the following minimum eigenvalue problem.
\textbf{Problem 4:} Given $\rho_0$ as in (10) and $Y_1, \ldots, Y_{n^2-m}$ an orthonormal completion of $\text{span} \{X_1 \ldots X_m\}$, solve

$$\text{minimize } c^T \mathbf{u} \text{ subject to } \mathbf{u} \in I := \{ \mathbf{u} \mid H(\mathbf{u}) \geq 0 \}. \quad (11)$$

Lemma 3.1: Problem 4 always admits solution.

\textbf{Proof:} First of all, notice that Problem 4 is a convex optimization problem, and the objective function $c^T \mathbf{u}$ is linear and continuous over the set $I$. Then, the proof is divided in three steps.

\textbf{Step 1:} We show that $c^T \mathbf{u} = v_{n^2-m+1}$ is bounded from below on $I$: since $X_1, \ldots, X_m, Y_1, \ldots, Y_{n^2-m}$ forms an orthonormal basis and $I \in \text{span} \{X_1, \ldots, X_m\}$, the matrices $\{Y_i\}$ are traceless. Thus,

$$\text{tr}[H(\mathbf{u})] = \text{tr}[\rho_0 + \sum_{i=1}^{n^2-m} v_i Y_i + v_{n^2-m+1} X_1] = \text{tr}(\rho_0) + \sqrt{n} v_{n^2-m+1} = 1 + \sqrt{n} v_{n^2-m+1}$$

and $\text{tr}[H(\mathbf{u})] \geq 0$ for each $\mathbf{u} \in I$. Hence, $c^T \mathbf{u} = v_{n^2-m+1} \geq -\frac{1}{\sqrt{n}}$ for each $\mathbf{u} \in I$.

\textbf{Step 2:} Let us consider $\bar{\mathbf{u}}_0 = [0 \ldots 0 \sqrt{\mu(\rho_0)} + 1] \in I$ where $\mu(\rho_0)$ denotes the minimum eigenvalue of $\rho_0$. Accordingly, $c^T \bar{\mathbf{u}}_0 = \sqrt{\mu(\rho_0)} + 1$ and Problem 4 is equivalent to minimize $c^T \mathbf{u}$ over the closed sublevel set $I_0 = \{ \mathbf{u} \mid H(\mathbf{u}) \geq 0, -\frac{1}{\sqrt{n}} \leq v_{n^2-m+1} \leq \sqrt{\mu(\rho_0) + 1} \} \subseteq I$. We want to show that $I_0$ is bounded and accordingly compact (recall that we are working in a finite dimensional space).

This can be done by proving that a sequence $\{\mathbf{u}^k\}_{k \geq 0}$ such that $\|\mathbf{u}^k\| \to \infty$ cannot belong to $I_0$. It is therefore sufficient to show that the minimum eigenvalue of the associated Hermitian matrix $H(\mathbf{u}^k)$ tends to $-\infty$ as $\|\mathbf{u}^k\| \to \infty$ with $v_{n^2-m+1}$ bounded. Note that the affine map $\mathbf{u} \mapsto H(\mathbf{u})$ is injective, since $Y_1, \ldots, Y_{n^2-m}, X_1$ are linearly independent. Accordingly $\text{tr}[H(\mathbf{u}^k)] = \text{tr}[H(\mathbf{u})] = 1 + \sqrt{\mu(\rho_0) + 1}$. By construction $\text{tr}[H(\mathbf{u}^k)] = 1 + \sqrt{\mu(\rho_0) + 1}$ and $v_{n^2-m+1}$ is bounded in $I_0$. Thus $\text{tr}[H(\mathbf{u}^k)] < \infty$, namely the sum of its eigenvalues is always bounded. Thus, there exists an eigenvalue of $H(\mathbf{u}^k)$ which approaches $-\infty$ as $k \to \infty$. So, $I_0$ is bounded.

\textbf{Step 3:} Since $c^T \mathbf{u}$ is continuous over the compact set $I_0$, by Weierstrass’ theorem we conclude that $c^T \mathbf{u}$ admits a minimum point over $I_0$.

We need to take into account that the vector which minimizes $c^T \mathbf{u}$ over $I$ may not be in general unique. However, to our aim we are more interested in the sign of the minimum.

\textbf{Proposition 3.1:} Let $\mu = \min_{\mathbf{u} \in I} c^T \mathbf{u}$. Then, the following facts hold:

1) If $\mu > 0$, then Problem 4 is feasible and there exists at least one positive definite matrix satisfying constraints in (7).

2) If $\mu < 0$, then Problem 4 is not feasible and there exists a reduced problem with a full-rank solution for which the data $\{f_i\}$ of a factor $1/(1 + \sqrt{n} \mu)$ and, in light of the fact that $\mu$ is a solution to

$$\mu := 1 + \sqrt{n} \mu.$$ 

\textbf{Proof:} Note that $G(v_1, \ldots, v_{n^2-m}) := \rho_0 + \sum_{i=1}^{n^2-m} v_i Y_i$ represents the parametric family of Hermitian matrices (not necessary positive semidefinite) satisfying constraints in (7). Define $\varepsilon := -v_{n^2-m+1}$, thus Problem 4 can be rewritten in the following way:

$$\text{maximize } \varepsilon \text{ subject to } G(v_1, \ldots, v_{n^2-m}) \geq \varepsilon I. \quad (12)$$

Let $\varepsilon^0 = -\mu$ be the solution of the above problem. If $\varepsilon^0 < 0$, the parametric family $G(v_1, \ldots, v_{n^2-m})$ does not contain positive semidefinite matrices, accordingly Problem 4 does not admit solution. If $\varepsilon^0 \geq 0$, the parametric family contains at least one matrix $\rho \geq \varepsilon^0 I > 0$ which is positive definite. On the contrary, for $\varepsilon^0 = 0$ there only exist positive semidefinite matrices which are singular.

An effective numerical approach for the solution to the problem is described in Appendix A.

In the light of the previous result, if $\mu < 0$ Problem 4 is feasible and $S$ contains at least one positive definite solution. As we will see in Section IV, this condition ensures that a minimum relative entropy criterion will lead to an admissible solution in $S$. The remaining cases need to be studied more carefully. We start by showing how to make Problem 4 feasible when it is not be so for the given constraints. It turns out that a minimally relaxed problem is feasible and $S$ only contains singular density matrices. Next, we deal with the case in which Problem 4 is feasible and all its solutions are singular, showing how they all share a minimal kernel and how to construct a reduced problem with a full-rank solution for which the minimum relative entropy methods work.

\textbf{B. Forcing the feasibility condition (case $\mu > 0$)}

The parameter $\mu$ given by the auxiliary problem described above reveals if the original problem is feasible, but also suggests an “optimal” way to relax unfeasible constraints so that they make Problem 4 feasible. In fact, from the definition of $\mu$, we know that there exist $v_1 \ldots v_{n^2-m} \in \mathbb{R}$ such that

$$\hat{\rho}_\mu := \rho_0 + \sum_{i=1}^{n^2-m} v_i Y_i + \mu X_1 \geq 0,$$

and:

$$\text{tr}(\hat{\rho}_\mu) = 1 + \sqrt{n} \mu.$$ 

From this positive operator, in order to obtain a density operator, we only need to normalize the trace by defining:

$$\rho := \frac{1}{1 + \sqrt{n} \mu} \hat{\rho}_\mu \quad (13)$$

This implies that the original problem can be made feasible by uniformly, “isotropically” contracting the data $\{f_i\}$ of a factor $1/(1 + \sqrt{n} \mu)$ and, in light of the fact that $\mu$ is a solution to
of a factor most noisy estimates. It is easy to see that if the original problem was unfeasible, since all the \( T \) multiplied for a factor \( \mu_1 \), \( \cdots \), \( \mu_m \) the new pseudo-state: the corresponding set \( S \) only contains singular solutions.

However, the entries in the data set \( \{ f_1 \} \) may differ in their reliability, and one would like to be able to relax the corresponding constraints accordingly. This is complicated by the fact that the original \( \{ Z_i \} \) may not be orthogonal, and the data we are contracting are in fact the linearly transformed output of the Gram-Schmidt orthonormalization described above.

This weighed relaxation can be realized as follows: consider the initial setting of Section II, where we have \( S \) associated to each observable \( \rho_0 \) corresponding to the normalized data we are contracting are in fact the linearly transformed results of the previous subsection and (13) above, we consider the perturbed constraints

\[
\begin{align*}
\tilde{f}_1 & = \frac{1}{\sqrt{n}} \\
\tilde{f}_i & = \frac{1}{1 + \sqrt{\mu_i}} f_m', \ i = 2 \ldots m.
\end{align*}
\]

Thus, the corresponding Problem \( \Pi \) is feasible and \( S \) only contains singular solutions.

C. Case \( \mu = 0 \)

In the limit case \( \mu = 0 \), not only all solutions are singular, but they share a key property.

**Proposition 3.2:** Assume that, with the definition above, \( \mu = 0 \). Then there exists a kernel \( K \) which is common for all \( \rho \in S \).

**Proof:** Let us assume \( \mu = 0 \), accordingly Problem 1 does only admit singular solutions, with \( \dim \ker(\rho) > 0 \) \( \forall \rho \in S \). Pick a solution \( \rho^o \in S \) with kernel of minimal dimension, suppose by contradiction that there exists \( \rho \in S \) such that \( \ker(\rho^o) \not\subset \ker(\rho) \). Taking into account \( p \in (0, 1) \), we define \( \rho := p\rho^o + (1 - p)\rho = \rho \in S \). Accordingly \( \dim \ker(\rho) < \dim \ker(\rho^o) \) which is a contradiction, since \( \rho^o \) has kernel with minimal dimension on \( S \). We conclude that \( K = \ker(\rho^o) \subseteq \ker(\rho) \forall \rho \in S \). \( \blacksquare \)

This directly implies the following block-form for all the solutions to Problem 1.

**Corollary 3.1:** Let \( \rho^o \in S \) be a solution with minimal kernel \( K \) and consider its block-diagonal form

\[
\rho^o = U \begin{bmatrix} \rho_1^o & 0 \\ 0 & 0 \end{bmatrix} U^T,
\]

where \( U \) is a unitary change of basis consistent with the Hilbert space decomposition \( H = \mathcal{K}^\perp \oplus K \) so that \( \rho_1^o > 0 \). Then, the set of all the solutions of Problem \( \Pi \) is

\[
S = \left\{ \rho = U \begin{bmatrix} \rho_1 \ & 0 \\ 0 & 0 \end{bmatrix} U^\perp \mid \rho_1 \geq 0, \ \tilde{f}_i = \text{tr}(\rho X_i) \right\}.
\]

As consequence of Corollary 3.1 we can focus on a reduced version of Problem \( \Pi \) by considering optimization only on the support of \( \rho^o \), for which the minimum relative entropy is applicable since \( \rho_1^o \) is positive definite, see Section V.

IV. STATE ESTIMATION WITH MINIMUM RELATIVE ENTROPY CRITERION

A. Reduced Problem

In the previous part of the paper we showed how to check the feasibility of Problem \( \Pi \) given the constraints associated to the data and, if needed, how to relax the constraints in such a way that the corresponding Problem \( \Pi \) is feasible. In general, however, the set of solutions \( S \) is not constituted by only one element. In this section, we show how to choose, and then compute, a solution in \( S \) according the minimum quantum relative entropy criterion.

Given the results of the previous sections, we can assume that either Problem \( \Pi \) admits at least one (strictly) positive definite solution, or we can resort to a reduced problem for which a full rank solution exists. In fact, if \( S \) only contains
singular matrices (case $\mu = 0$, or after relaxation of the constraints), by Corollary 5.3.1 we have that the set of solution is

$$S = \left\{ \rho = U \begin{bmatrix} \rho_1 & 0 \\ 0 & 0 \end{bmatrix} U^\dagger \mid \rho_1 \geq 0, \bar{f}_i = \text{tr}(\rho X_i) \right\}$$

for some unitary change of basis $U$ consistent with the Hilbert space partition $\mathcal{H} = \mathcal{K}^{\perp} \oplus \mathcal{K}$. Accordingly for each $\rho \in S$, constraints in (7) can be rewritten in the following way

$$\bar{f}_i = \text{tr}(\rho X_i) = \text{tr} \left( U \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix} U^\dagger X_i \right) = \text{tr}(\rho X_i)$$

where $X_i := \begin{bmatrix} I & 0 \\ 0 & I \end{bmatrix} U^\dagger U \begin{bmatrix} I & 0 \\ 0 & I \end{bmatrix} \in \mathcal{H}_{n_1}$ with $n_1 < n$.

Accordingly Problem 1 is equivalent to the corresponding reduced problem with $X_1 \ldots X_m$ and $\bar{f}_1 \ldots \bar{f}_m$. The corresponding set of solutions is

$$S_1 = \left\{ \rho_1 \in \mathcal{H}_{n_1} \mid \rho_1 \geq 0, \bar{f}_i = \text{tr}(\rho_1 X_i) \right\}$$

which contains the positive definite solution $\rho_1^c$. Once chosen a solution $\rho_1^c \in S_1$, the corresponding original solution is

$$\hat{\rho} = U \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix} U^\dagger.$$

In the effort of keeping a simple notation, we will not distinguish between the reduced and the full problem in the following discussion, therefore using $\rho$ for either the full or the reduced state, $\{X_i\}$ for either the full or reduced observable, and $n$ for the dimension of the full Hilbert space or the reduced one as needed. We can consider the following simpler problem, restricted to strictly positive matrices:

**Problem 5:** Given the observables $X_1 \ldots X_m$ and the corresponding estimates $\bar{f}_1 \ldots \bar{f}_m$, solve

$$\text{minimize } S(\rho \| \tau) \text{ subject to } \text{tr}(\rho X_i) = \bar{f}_i, \; i = 1 \ldots m.$$  

(B. Lagrangian and Form of the Full-Rank Solution)

Now we are ready to derive a solution method for problem the entropic criterion. Consider the linear operator associated to the above constraints:

$$L : \mathcal{H}_n \to \mathbb{R}^m$$

$$\rho \mapsto \begin{bmatrix} \text{tr}(\rho X_1) \\ \vdots \\ \text{tr}(\rho X_m) \end{bmatrix}. \quad (24)$$

Given $\lambda = [\lambda_1 \ldots \lambda_m]^T \in \mathbb{R}^m$ and $\rho \in \mathcal{H}_n$,

$$\langle L(\rho), \lambda \rangle = \sum_{i=1}^m \lambda_i \text{tr}(\rho X_i) = \text{tr}(\rho \sum_{i=1}^m \lambda_i X_i) = \langle \rho, L^*(\lambda) \rangle$$

where

$$L^* : \mathbb{R}^m \to \mathcal{H}_n$$

$$\lambda \mapsto \sum_{i=1}^m \lambda_i X_i$$

is the adjoint operator of $L$. Define $\tilde{f} = [\tilde{f}_1 \ldots \tilde{f}_m]^T$.

Since Problem 5 is a constrained convex optimization problem, we take into account its Lagrangian

$$\mathcal{L}(\rho, \lambda) = \text{tr}(\rho \log \rho - \rho \log \tau) - \langle \lambda, \tilde{f} - L(\rho) \rangle$$

$$= \text{tr}(\rho \log \rho - \rho \log \tau + (L^*(\lambda), \rho) - \langle \lambda, \tilde{f} \rangle$$

$$= \text{tr}(\rho \log \rho - \rho \log \tau + L^*(\lambda)) \rangle - \langle \lambda, \tilde{f} \rangle$$

where $\lambda \in \mathbb{R}^m$ is the Lagrange multiplier. Note that $\mathcal{L}(\cdot, \lambda)$ is strongly convex over $\mathcal{H}_{n_+}$ where $\mathcal{H}_{n_+}$ denotes the cone of the positive definite matrices. Thus, its minimum point is given by annihilating its first variation

$$\delta \mathcal{L}(\rho, \lambda; \delta \rho) = \text{tr}[(\log \rho + I - \log \tau + L^*(\lambda))\delta \rho]$$

for each direction $\delta \rho \in \mathcal{H}_n$. Accordingly, the unique minimum point for $\mathcal{L}(\cdot, \lambda)$ is

$$\rho(\lambda) = e^{\log \tau - I - L^*(\lambda)}$$

and

$$\mathcal{L}(\rho(\lambda), \lambda) \leq \mathcal{L}(\rho, \lambda), \forall \rho \in \mathcal{H}_{n_+}. \quad (30)$$

If there exists $\lambda^0$ such that $\rho(\lambda^0) \in S$, i.e. $\tilde{f} = L(\rho(\lambda^0))$, then (30) implies

$$S(\rho(\lambda^0) \| \tau) \leq S(\rho \| \tau), \forall \rho \in S. \quad (31)$$

Thus, if we are able to find $\lambda^0 \in \mathbb{R}^m$ such that $\tilde{f} - L(\rho(\lambda^0)) = 0$, then $\rho(\lambda^0)$ is the unique solution to Problem 5. This issue is solved by considering the dual problem wherein $\lambda^0$ (if there exists) maximizes the following functional over $\mathbb{R}^m$

$$\inf_{\rho \in \mathcal{H}_{n_+}} \mathcal{L}(\rho, \lambda) = \mathcal{L}(\rho(\lambda), \lambda)$$

$$= - \text{tr}(e^{\log \tau - I - L^*(\lambda)}) \rangle - \langle \lambda, \tilde{f} \rangle. \quad (32)$$

The existence of such a $\lambda^0$ is proved in Section IV.C. Moreover, we suggest how to efficiently compute it.

**Remark 4.1:** When $\mu = 0$, $S$ only contains singular matrices. Instead of considering the reduced problem as we did, one could try to consider Problem 4 with relaxed constraint $\rho \geq 0$. In this situation the Slater’s condition [51 5.2.3], however, does not hold because $S$ does not contain positive definite matrices. Hence, we cannot conclude that $\rho(\lambda^0)$ is the desired solution of the primal problem. Moreover, for any $\lambda$, would be $\rho(\lambda^0) > 0$. This means that $\rho(\lambda^0)$ is not the solution to Problem 5.

(C. Dual Problem: Existence and Uniqueness of the Solution)

The dual problem consists in maximizing (32) over $\mathbb{R}^m$ which is equivalent to minimize

$$J(\lambda) = \text{tr}(e^{\log \tau - I - L^*(\lambda)}) + \langle \lambda, \tilde{f} \rangle. \quad (33)$$

This functional will be referred to as dual function throughout this Section. Before to prove the existence of $\lambda^0$ which minimizes $J$ we need to introduce the following technical results.

First of all, note that $\langle \lambda^\perp, \tilde{f} \rangle = 0$ for each $\lambda^\perp \in \text{Range} L^\perp$. In fact, if $\lambda^\perp \in \text{Range} L^\perp = \ker L^*$, then
Thus, 
\[
\langle \lambda^+, \bar{f} \rangle = \langle \lambda^+, L(\rho_f) \rangle = \langle L^*(\lambda^+), \rho_f \rangle = \text{tr}(L^*(\lambda^+)\rho_f) = 0. 
\] (34)

We conclude that \( \lambda^+ \) does not affect \( J \), i.e.
\[
J(\lambda + \lambda^+) = J(\lambda), \quad \forall \lambda^+ \in [\text{Range } L]^+. 
\] (35)

We may therefore restrict the search of the minimum point for \( J \) over Range \( L \).

**Proposition 4.1:** \( J \) is strictly convex over Range \( L \).

**Proof:** Since \( J \) is the opposite of \( \mathcal{L}(\rho(\lambda), \lambda) \), it is convex over \( \mathbb{R}^m \). The first and the second variation of \( J(\lambda) \) in direction \( \delta \lambda \) are:
\[
\delta J(\lambda; \delta \lambda) = - \text{tr} \int_0^1 e^{(1-t)(\log \tau - L^*(\lambda))} L^*(\delta \lambda) \, dt + \langle \delta \lambda, \bar{f} \rangle 
\] = \[- \text{tr} \int_0^1 e^{\log \tau - L^*(\lambda)} dt L^*(\delta \lambda) + \langle \delta \lambda, \bar{f} \rangle \]
\[
= - \text{tr} \int_0^1 e^{\log \tau - L^*(\lambda)} dt L^*(\delta \lambda) + \langle \delta \lambda, \bar{f} \rangle 
\] (37)
\[
\delta^2 J(\lambda; \delta \lambda) = \text{tr} \int_0^1 e^{(1-t)(\log \tau - L^*(\lambda))} L^*(\delta \lambda) \cdot e^{(\log \tau - L^*(\lambda))} L^*(\delta \lambda) dt]. \] (38)

Here, we exploited the expression for the differential of the matrix exponential (see [19] Appendix 1A). Define \( Q_t = e^{t(\log \tau - L^*(\lambda))} \) which is positive definite for each \( t \in \mathbb{R} \).

Thus,
\[
\delta^2 J(\lambda; \delta \lambda) = \int_0^1 \text{tr}(Q_{1-t} L^*(\delta \lambda) Q_t L^*(\delta \lambda)) dt 
\] = \[\int_0^1 \text{tr}(Q_t^2 L^*(\delta \lambda) Q_{1-t} L^*(\delta \lambda) Q_t^2) dt \geq 0. \] (39)

Assume now that \( \delta \lambda \in \text{Range } L \). If \( \delta^2 J(\lambda; \delta \lambda) = 0 \), then \( \text{tr}(Q_t^2 L^*(\delta \lambda) Q_{1-t} L^*(\delta \lambda) Q_t^2) = 0 \). Since \( Q_t > 0 \) for each \( t \in \mathbb{R} \), it follows that \( L^*(\delta \lambda) = 0 \). Since \( \delta \lambda \in \text{Range } L \), we get \( \delta \lambda = 0 \). We conclude that \( \delta^2 J(\lambda; \delta \lambda) > 0 \), for each \( \delta \lambda \neq 0 \), i.e. the statement holds.

In the light of the previous result, the dual problem admits at most one solution, say \( \lambda^0 \), over Range \( L \). If such a \( \lambda^0 \) does exist, then \( \delta J(\lambda; \delta \lambda) = 0 \) \( \forall \delta \lambda \in \text{Range } L \) which is equivalent to \( -L(e^{\log \tau - L^*(\lambda^0)}) + \bar{f} = 0 \). It means that \( \rho(\lambda^0) \) satisfies constraints in (28) and it is therefore the unique solution to Problem [5] it remains to show that such a \( \lambda^0 \) does exist.

**Proposition 4.2:** \( J \) admits a minimum point over Range \( L \).

**Proof:** We have to show that the continuous function \( J \) takes minimum value over Range \( L \). Observing that \( J(0) = \frac{1}{\tau} \text{tr}(\tau) \), we can restrict our search over the closed set
\[
\mathcal{M} := \{ \lambda \in \mathbb{R}^m \mid J(\lambda) \leq J(0) \} \cap \text{Range } L. 
\]

We shall show that \( \mathcal{M} \) is bounded. To this aim, consider a sequence \( \{ \lambda_n \}_{n \in \mathbb{N}} \), \( \lambda_n \in \text{Range } L \) such that \( \| \lambda_n \| \to \infty \). It is therefore sufficient to show that \( J(\lambda_n) \to \infty \), as \( n \to \infty \). First of all note that the minimum singular value \( \alpha \) of \( L^* \) restricted to Range \( L = [\ker L^*] \) is strictly positive, accordingly
\[
\| L^*(\lambda) \| \geq \alpha \| \lambda \| \to \infty. \] (40)

This means that \( L^*(\lambda) \), which is an Hermitian matrix, has at least one eigenvalue \( \beta_i \) such that \( |\beta_i| \to \infty \). If \( \beta_i \to -\infty \), then the first term of \( J \) tends to infinity and dominates the second one, accordingly \( J(\lambda_i) \to \infty \). In the remaining possible case no eigenvalue of \( L(\lambda) \) approaches \( -\infty \) and \( \beta_i \to \infty \). Thus, \( L^*(\lambda_i) \geq M \) where \( M \in \mathbb{R} \) is a finite constant and the first term of \( J \) takes a finite value. Since \( \mathcal{M} \) is not empty, there exists \( \rho_f \in \mathcal{H}_{n,+} \) such that \( f = L(\rho_f) \) and
\[
\langle \lambda_i, \bar{f} \rangle = \langle L^*(\lambda_i), \rho_f \rangle = \text{tr}(\rho_f^2 L^*(\lambda_i)\rho_f^2) \geq M, \] (41)
where we exploited the fact that \( \text{tr}(\rho_f) = 1 \). This means that \( \langle \lambda_i, \bar{f} \rangle \) cannot approach \( -\infty \). Finally, \( ||\rho_f^2 L^*(\lambda_i)\rho_f^2|| \to \infty \), because \( \rho_f > 0 \). It follows that \( \rho_f^2 L^*(\lambda_i)\rho_f^2 \) and hence \( L^*(\lambda_i) \), have at least one eigenvalue tending to \( \infty \). Accordingly \( J(\lambda_i) \to \infty \) as \( i \to \infty \). We conclude that \( \mathcal{M} \) is bounded and accordingly compact. By Weierstrass’ theorem, \( J \) admits minimum point over \( \mathcal{M} \).

Finally, \( \lambda^0 \) may be computed by e.g. employing a Newton algorithm with backtracking, see Section VI in [22], which globally converges.

V. CONCLUSIONS

The proposed set of analytic results and algorithms provides a general method to find the exact minimum relative entropy estimate of a quantum state under general assumptions, that is, without requiring the constraints to include a full-rank solution to begin with. A general solution to the problem was missing for quantum estimation, and our feasibility analysis is of interest for the classical case as well. Summarizing, we have proposed: (i) A numerical method to decide the feasibility of Problem [1] which is of interest on his own, and compute the minimum necessary relaxation of the constraints whenever necessary to obtain at least one solution; (ii) As a side product, we are able to determine whether there is at least a full-rank solution. When this is not the case, we proved there exists, and devised a way to determine, the maximal common kernel of all the solution; (iii) We extended Georgiou’s approach to maximum entropy estimation to our setting, and analyzed in depth both the primal and the dual optimization problems. The general form of a full-rank solution of the reduced problem, namely the one we obtain by removing the common kernel, is given explicitly and depends on the solution of the dual problem. The latter is proven to be a convex optimization problem with a unique solution, \( \lambda^0 \), which can be obtained by standard numerical algorithms.

It is also possible to show, \( \lambda^0 \) is continuous with respect to the data set \( \bar{f} \) (see Appendix [3]). Since, in view of (28), \( \rho(\lambda^0) \) is continuous with respect to \( \lambda^0 \), we can conclude that the solution to Problem [5] is continuous with respect to the data \( f_1, \ldots, f_m \). This is of course a desirable property, and ensures that for a increasing accuracy of the estimates, the computed solution will converge to the actual state.
Possible extensions of the present framework include applications to state reconstruction from local marginals and its connection to entanglement generation [21, 28], as well as comparison with the existing approximate results [21] in physically meaningful situations. Lastly, the advantage offered by the introduction of an a priori state in the estimation problem can be exploited to devise recursive algorithms, that update existing estimate in an optimal way relying only on partial data.

Appendix

A. Numerical solution for the feasibility problem

We propose a Newton-type algorithm with logarithmic barrier for numerically find one solution \( w^0 \) to Problem \( \text{B} \). Using the same approach of [9] Section 4, we resort to the approximate problem

\[
\min_{w \in \text{int}(I)} g_q(w)
\]

(42)

where \( q > 0 \), and

\[
g_q(w) := qe^T w - \log \det(H(w)).
\]

(43)

Recall that we defined

\[ I = \{ w \mid H(w) \geq 0 \}, \]

and notice that \( g_q \) is continuous and strictly convex over the set \( \text{int}(I) \). Moreover \( \lim_{w \to \partial I} g_q(w) = +\infty \) and the component \( v_{n^2-m+1} \) can be restricted to belong to a closed and bounded interval. Accordingly the approximated problem admits a unique solution, denoted by \( w^q \), which is numerically computed by employing the Newton algorithm with backtracking, [31, 9.5]. Here, we can choose as initial guess the vector \( w^0 = [0 \ldots 0 \sqrt{n(-\lambda_{\min}(\rho_0) + 1)}]^T \in \text{int}(I) \). Concerning the \( l \)-th Newton step, we have to solve

\[
\Delta w^q = -H^{-1}_{w^q} \nabla G_{w^q}
\]

(44)

where

\[
\nabla G_{w^q} = qe - \begin{bmatrix}
\text{tr}(H(w^q)^{-1}Y_1) \\
\vdots \\
\text{tr}(H(w^q)^{-1}Y_{n^2-m}) \\
\text{tr}(H(w^q)^{-1}X_1)
\end{bmatrix}
\]

\[
H_{w^q} = \begin{bmatrix}
\text{tr}(H(w^q)^{-1}Y_1H(w^q)^{-1}Y_1) & \text{tr}(H(w^q)^{-1}Y_1H(w^q)^{-1}Y_2) & \cdots \\
\text{tr}(H(w^q)^{-1}Y_1H(w^q)^{-1}Y_2) & \text{tr}(H(w^q)^{-1}Y_2H(w^q)^{-1}Y_2) & \cdots \\
\vdots & \vdots & \ddots
\end{bmatrix}
\]

(45)

are the gradient and the Hessian computed at \( w^q \), respectively. Note that, it is not difficult to prove that

1) The sequence \( \{w^q\}_{q \geq 0} \) generated by the algorithm is contained in the compact set \( \mathcal{N} = \{ w \in \text{int}(I) \mid -\frac{1}{n^2} \leq c^T w \leq c^T w^0 \} \);
2) \( g_q \) is twice differentiable and strongly convex on \( \mathcal{N} \); 3) The Hessian of \( g_q \) is Lipschitz continuous on \( \mathcal{N} \).

Accordingly, the Newton algorithm with backtracking globally converges, [31, 9.5]. Moreover, the rate of convergence is quadratic in the last stage. Finally, note that the found solution \( w^q \) satisfies the following inequalities, [31, p. 566],

\[
c^T w^q \leq c^T w^q \leq c^T w^0 + \frac{n}{q}
\]

(47)

where \( w^0 \) is a solution to Problem \( \text{B} \) and \( w^q \) the accuracy of \( c^T w^q \) with respect to the optimal value \( c^T w^0 \).

This method works well only setting a moderate accuracy. To improve the accuracy, we can iterate the above Newton algorithm and in each iteration we gradually increase \( q \) in order to find a solution \( w^\xi \) with a specified accuracy \( \xi > 0 \) [31, p. 569]:

1) Set the initial conditions \( q_0 > 0 \) and \( w^{q_0} = [0 \ldots 0 \sqrt{n(-\lambda_{\min}(\rho_0) + 1)}]^T \in \text{int}(I) \).
2) At the \( k \)-th iteration compute \( w^{q_k} \in \text{int}(I) \) by minimizing \( g_q \) with starting point \( w^{q_{k-1}} \) by using the Newton method previously presented.
3) Set \( q_{k+1} = \beta q_k \) with \( \beta > 1 \) close to one.
4) Repeat steps 2 and 3 until the condition \( \frac{n}{q_k} < \xi \) is satisfied.

Finally, we deal with the problem to compute a solution to Problem \( \text{B} \) with kernel \( \mathcal{K} \) when \( \mu = 0 \). In this situation, consider the non-empty convex set

\[
\mathcal{I}_* = \left\{ w \mid \rho_0 + \sum_{i=1}^{n^2-m} w_i Y_i \geq 0 \right\},
\]

(48)

where \( w = [w_1 \ldots w_{n^2-m}]^T \in \mathbb{R}^{n^2-m} \). Thus, the set of solutions to Problem \( \text{B} \) is

\[
\mathcal{S} = \left\{ \rho_0 + \sum_{i=1}^{n^2-m} w_i Y_i \mid w \in \mathcal{I}_* \right\}.
\]

(49)

We wish to compute a matrix \( \rho^* \in \mathcal{S} \) having kernel corresponding to the minimum common kernel \( \mathcal{K} \). To this aim consider the following problem.

Problem 6: Pick \( w \in \mathbb{R}^{n^2-m} \) at random and solve:

\[
w^* = \arg \min_{w \in \mathcal{I}_*} (w - w)^T (w - w).
\]

(50)

Note that:

- \( \mathcal{I}_* \) is compact (i.e. closed and bounded)
- \( (w - w)^T (w - w) \) is continuous and strictly convex on \( \mathcal{I}_* \).

By Weiestrass’ theorem, the above problem admits a unique solution \( w^* \).

Let us define \( \rho_{w^*} := \rho_0 + \sum_{k=1}^{n^2-m} w^*_i Y_i \in \mathcal{S} \) and \( \rho^* := \rho_0 + \sum_{k=1}^{n^2-m} w_i Y_i \in \mathcal{S} \). It is easy to see that Problem \( \text{B} \) can be rewritten in terms of the matrix \( \rho_{w^*} \) as follows:

\[
\rho_{w^*} = \arg \min_{\rho \in \mathcal{S}} ||\rho - \rho||^2_F,
\]

(51)

where \( || \cdot ||_F \) denotes the Frobenius matrix norm. Thus, \( \rho_{w^*} \) is the closest matrix in \( \mathcal{S} \) (with respect to the Frobenius norm) to the matrix \( \rho^* \) belonging to the hyperplane characterized by the constraints \( \mathcal{Q} \). Hence, randomly generating a finite sequence \( \{w_1, \ldots, w_k\} \) of elements in \( \mathbb{R}^{n^2-m} \) we obtain a subset
where we make the dependence of

\[ J \]

on the boundary of \( S \) becomes small as \( \ell \) grows.

Concerning the computation of \( w^T \), we can resort to a Newton-type algorithm with logarithmic barrier named exterior-point method, [33, Chapter 4].

**B. Continuity of \( \lambda^c \) with respect to \( \bar{f} \)**

We show that the solution \( \lambda^c \) is continuous with respect to the data set \( \bar{f} \). To this aim we take into account the following result, see [34, Theorem 3.1].

**Theorem A.1:** Let \( A \) be an open and convex subset of a finite-dimensional euclidean space \( V \). Let \( h : A \to \mathbb{R} \) be a strictly convex function, and suppose that a minimum point \( \bar{x} \) of \( h \) exists. Then, for all \( \varepsilon > 0 \), there exists \( \delta > 0 \) such that, for \( p \in \mathbb{R}^n \), \( \| p \| \leq \delta \), the function \( h_p : A \to \mathbb{R} \) defined as

\[ h_p(x) := h(x) - \langle p, x \rangle \]

admits a unique minimum point \( \bar{x}_p \), and moreover

\[ \| \bar{x}_p - \bar{x} \| < \varepsilon. \]

Consider

\[ J(\lambda, \bar{f}) = \text{tr}(\text{e}^{\lambda \bar{f}} - I - L^*(\lambda)) + \langle \lambda, \bar{f} \rangle \]

where we make the dependence of \( J \) upon \( \bar{f} \). Then, the unique minimum point is

\[ \lambda(\bar{f}) = \arg \min_{\lambda \in \mathbb{R}^m} J(\lambda, \bar{f}). \]

Let \( \delta f \in \mathbb{R}^m \) be a perturbation of \( \bar{f} \). We have

\[ J(\lambda, \bar{f} + \delta f) = J(\lambda, \bar{f}) + \lambda^T \delta f. \]

Applying the previous theorem, where \( \delta f \) is \(-p\), we have: \( \forall \varepsilon > 0 \exists \delta > 0 \) s.t. if \( \| \delta f \| < \delta \) then \( J(\lambda, \bar{f} + \delta f) \) admits a unique minimum point

\[ \lambda(\bar{f} + \delta f) = \arg \min_{\lambda \in \mathbb{R}^m} J(\lambda, \bar{f} + \delta f) \]

and

\[ \| \lambda(\bar{f} + \delta f) - \lambda(\bar{f}) \| < \varepsilon. \]

Accordingly, the map \( \bar{f} \mapsto \lambda(\bar{f}) \) is continuous.
