ABSTRACT

We present a five-band (u', g', r', i', z') optical photometry catalog of the sources in the north ecliptic pole (NEP) region based on deep observations made with MegaCam at CFHT. The source catalog covers about 2 square degree area centered at the NEP and reaches depths of about 26 mag for u', g', r' bands, about 25 mag for i' band, and about 24 mag for z' band (4σ detection over a 1″ aperture). The total number of cataloged sources brighter than r' = 23 mag is about 56,000 including both point sources and extended sources. From the investigation of photometric properties using the color-magnitude diagrams and color-color diagrams, we have found that the colors of extended sources are mostly (u' - r') < 3.0 and (g' - z') > 0.5. This can be used to separate the extended sources from the point sources reliably, even for the faint source domain where typical morphological classification schemes hardly work efficiently. We have derived an empirical color-redshift relation of the red sequence galaxies using the Sloan Digital Sky Survey data. By applying this relation to our photometry catalog and searching for any spatial overdensities, we have found two galaxy clusters and one nearby galaxy group.

Online material: color figures, machine-readable table

1. INTRODUCTION

The north ecliptic pole (NEP) is an undistinguished region in the sky, located at α = 18°00′00″, δ = +66°33′38″. It is, however, a very special region since many astronomical satellites have accumulated a large number of exposures over this location since Earth-orbiting satellites must point their fixed solar panels to the Sun and be in their orbits over the ecliptic poles. Unlike the south ecliptic pole (SEP) region where the South Atlantic Anomaly and the LMC prevent the clear view of the extragalactic sky at certain wavelengths, the NEP region suffers very little or no obscuration by foreground Galactic sources. The Galactic coordinates of the NEP are l ≈ 96.4°, b ≈ +29.8°, and the foreground extinction in this direction is E(B−V) = 0.047 (Schlegel et al. 1998). Therefore, the NEP is a good target for deep, unbiased, contiguous surveys for extragalactic objects such as galaxies, galaxy clusters, and AGNs.

The ROSAT All-Sky Survey (RASS) is one of the most representative surveys of the NEP region (Voges et al. 1999). The ROSAT was the first X-ray imaging satellite to survey the entire sky. A source catalog of X-ray sources that were extracted from a large area surrounding the NEP was constructed from this RASS data (Henry et al. 2001, 2006). From the follow-up observations and optical counterpart investigations, Gioia et al. (2003) reported that most X-ray sources in the NEP region are AGNs (~49%), stars (~34%), and galaxy groups/clusters (~14%). Mullis et al. (2001) also found a supercluster of galaxies in the NEP region using the RASS data and suggested that some galaxy clusters in this region are part of the supercluster at z = 0.087. The NEP region was also observed in the 1.5 GHz band by Kollgaard et al. (1994). Using this radio source catalog, Brinkmann et al. (1999) investigated the correlation between the radio sources and the RASS X-ray sources, and identified optical counterparts of the radio X-ray sources. They found that a significant number of radio-loud sources are also bright in the X-ray band, and that X-ray selection is an effective way to search for galaxy clusters and groups.

While the X-ray luminosity is an efficient measure of the hot ionized gas in the galaxy clusters, the star formation activities and the resulting stellar mass in galaxies can be estimated from the optical and infrared flux. A new infrared space telescope, named AKARI, was launched in 2006 February. AKARI is expected to give exceedingly higher quality data than the previous infrared space missions such as Infrared Astronomical Satellite (Neugebauer et al. 1984) and Infrared Space Observatory (Kessler et al. 1996). The AKARI data will also complement the successful Spitzer Space Telescope (Werner et al. 2004) data by providing better wavelength coverage over the 8–24 μm band, which is not available from Spitzer. As one of its major science programs, AKARI is currently carrying out deep near-to-mid-infrared surveys over the wide area around the NEP through two major survey programs, NEP-Deep and NEP-Wide. The key scientific objectives of these NEP
surveys are to unveil the dusty star formation history of the universe, the mass assembly and large-scale structure evolution, and the nature of the cosmic infrared background (CIRB). For further information on these NEP programs, please refer to Matsuhara et al. (2006).

Combined with these space-borne infrared surveys, the optical survey of the NEP region constitutes the multifrequency data set that is essential for the studies of cosmic star formation history. Many researchers have investigated optical counterparts of radio and X-ray sources in this region, but, for the imaging data, they mostly relied on the COSMOS scan (e.g., Brinkmann et al. 1999) or Digitized Sky Survey images of the second Palomar Observatory Sky Survey (POSS-II) plates, only complemented by some independent but patchy observations (e.g., Gioia et al. 2003). Although the POSS-II data are excellent in complete coverage of the whole sky, the usefulness of the data are still limited by the low resolution with ~1.0′′ per pixel scale and the shallow depth with the limiting magnitude of $r_p \sim 21.0$ mag (Gal et al. 2004). In this study, therefore, we provide the first optical catalog of sources in the NEP region based on deep observations in $u'$, $g'$, $r'$, $i'$, $z'$ bands obtained with MegaCam at CFHT. This optical catalog will be an important part of multifrequency data sets of Galactic and extragalactic sources in the NEP region. It will also serve as a basis of the AKARI/NEP survey mission by providing the information on the optical counterparts of the infrared sources. This paper is composed as follows: We describe our observations in § 2 and data reduction procedures in § 3. We present a bright source catalog in § 4.1, photometric properties of the sources in the NEP region in § 4.2, and galaxy number counts in § 4.3. The result of galaxy cluster search using the color of red sequence galaxies is given in §§ 4.4 and 4.5. Some photometric properties of other X-ray sources are presented in § 4.6, and our primary results are summarized in the last section.

2. OBSERVATION

The observation of the north ecliptic pole (NEP) region was carried out over nine photometric nights between 2004 August 22 and September 22 using the 3.6 m CFHT telescope located at Mauna Kea, Hawaii. We used a wide field imager MegaCam at the telescope primary focus MegaPrime. The MegaCam is composed of 36, 2048 × 4612 CCDs covering about 1′′ × 1′′ area with 0.185′′ resolution per pixel (Boulade et al. 2003). The $u'$, $g'$, $r'$, $i'$, $z'$ filter system provided with MegaCam is basically the same as that used by the Sloan Digital Sky Survey (SDSS; York et al. 2000) except for the $u'$ filter, which is designed to take advantage of the improved UV extinction condition at the CFHT site. Therefore, the photometric data generated from this observation are presented in the CFHT unique $u'$ and the SDSS $g'$, $r'$, $i'$, $z'$ system.

As shown in Figure 1, the observed fields are composed of two fields separated by about 1° away from each other in the east-west direction, covering about 2 square degrees in total. The NEP-E (east) field was observed with five filters, $u'$, $g'$, $r'$, $i'$, $z'$ and the other field, NEP-W (west), was observed with only four filters, $g'$, $r'$, $i'$, $z'$. Each field was covered twice with a 15° offset for dithering in each filter with total exposure times of 3600 s for $u'$ (1800 × 2), 2400 s for $g'$ (1200 × 2), 3000 s for $r'$ (1500 × 2), 3000 s for $i'$ (1500 × 2), and 3600 s for $z'$ (1800 × 2). The raw images were processed using Elixir system by CFHT staff. The Elixir is a collection of programs, databases, and other tools specialized in processing and evaluation of the large mosaic data (Magnier & Cuillandre 2004). The overall quality of the preprocessed images is good, with a typical seeing of 0.7′′–1.1′′. Detailed information on the observation is listed in Table 1.

3. DATA REDUCTION

3.1. Prephotometry Processing

For the reliable source detection and photometry, it is essential to prepare a master image that satisfies the following two factors: (1) to obtain the required photometric depth and (2) to give the complete areal coverage. We used a software package SWarp12 written by E. Bertin at Terapix to transform each Multi Extension Fits (MEF) file containing 36 individual CCD frames into a single fits image data. SWarp also corrects different distortion effects between input data through the resampling process, and then combines the resampled images to create a deep output image after flux scaling and background subtraction.

To make a master image, we combined the $g'$, $r'$, $i'$, and $z'$ four-band data using SWarp for the NEP-E and the NEP-W field, respectively. During the SWarp run, BILINEAR resampling method was used since this method was found to be effective in suppressing the discontinuity effects around the chip boundaries, while other methods such as LANCZOS3 produced more noticeable discontinuities. We also used weighted images during SWarp run to enhance the quality of the output image. In the weight maps we assigned zero weights to pixels with negative values. We excluded the $u'$ band data from the master image construction since we do not have the $u'$ band data for the NEP-W and the signal-to-noise ratio (S/N) is lower than in other bands. Finally, we created two master detection images with high S/N, one for the NEP-E and the other for the NEP-W region.

11 For further information on these filter systems used with MegaCam, see the “Filter System” section in the http://www.cfht.hawaii.edu/Instruments/Imaging/MegaPrime/specsinformation.html Web page.
12 See http://terapix.iap.fr/rubrique.php?id_rubrique=49 for further information.
Two MEF images for each band were processed using SWarp with the same parameters to generate a final photometry image for the corresponding filter. These $u^\prime$, $g^\prime$, $r^\prime$, $i^\prime$, $z^\prime$ band images were made to have the same dimension and coordinates with the master detection image of the corresponding field. The depth of photometry attained by combining two raw images was calculated as a $\sigma$ flux over a circular aperture with a diameter of 1$^\prime$. The magnitude error is estimated to be about 0.1 mag or less at $r^\prime < 16.5$ mag and stellarity $> 0.7$ are the results of the image saturation. Thus, the stellarity index is most reliable in the magnitude range of $17 < r^\prime < 22$ mag.

### 3.2. Source Detection and Photometry

We have used SExtractor (Bertin & Arnouts 1996) to detect sources from the master detection images of the NEP-E and NEP-W fields. A source is confirmed if it has more than five contiguous pixels above 4 times the background sky fluctuation. The signals from each source were measured in the $u^\prime$, $g^\prime$, $r^\prime$, $i^\prime$, $z^\prime$ band photometry images over the isophotal area previously defined during the source detection. The photometry was made using SExtractor in dual mode operation. This scheme enables the detection and photometry of any source that is registered at least once in any of the $g^\prime$, $r^\prime$, $i^\prime$, $z^\prime$ band images. The total number of sources detected in our two observed NEP fields is about 130,000.

The instrumental magnitudes were transformed into standard magnitudes using the transformation information provided and recorded in the header of the images by the CFHT staff. During this transformation, only the calibrated magnitudes of sources that have available color information required for the calibration are calculated and kept in the catalog. Otherwise, we assigned dummy values (99.000) to the magnitudes of sources in the final source catalog.

### 4. RESULTS

Figure 2 displays a source count histogram in the $u^\prime$, $g^\prime$, $r^\prime$, $i^\prime$, and $z^\prime$ bands along with the $r^\prime$ band error and stellarity distributions. This shows that the number of sources in our data increases up to $u^\prime \sim 24.3$, $g^\prime \sim 24.0$, $r^\prime \sim 23.5$, $i^\prime \sim 23.0$, and $z^\prime \sim 22.2$ mag before the incompleteness effect starts to take place and the number of the detected sources starts to decrease. The $r^\prime$ band magnitude error is estimated to be about 0.1 mag or less at $r^\prime \sim 23.5$ mag, where the source count reaches its maximum. The stellarity distribution shows how efficiently the star/galaxy classifier works in our data set. From this distribution, it is clearly seen that the stellarity index, which is calculated by SExtractor based on the isophotal areas, peak intensity, and seeing information, separates the point sources (stellarity $\sim 1$) and the extended sources (stellarity $\sim 0$) with high confidence for the sources with $r^\prime < 22$ mag. One more point to be noted in this stellarity distribution is that sources with $r^\prime < 16.5$ mag and stellarity $> 0.7$ are the results of the image saturation. Thus, the stellarity index is most reliable in the magnitude range of $17 < r^\prime < 22$ mag.

### 4.1. Source Catalog

Considering the source count and the stellarity distribution, we have decided the magnitude range of the most reliable sources for the final bright source catalog entry, which is $r^\prime \leq 23$ mag. The number of sources compiled in the final bright source catalog is about 56,000. Table 2 lists a sample of the bright source catalog...

**Notes.**—Table 2 is published in its entirety in the electronic edition of the *Astrophysical Journal Supplement*. A portion is shown here for guidance regarding its form and content.
for the reader’s guide. 14 Following are the short descriptions of data columns in the catalog.

Column (1) is the identification number of an optical source. Columns (2) and (3) list, respectively, the J2000.0 right ascension (R.A.) and declination (decl.) of a source in degrees. The uncertainties of the astrometric solution derived by Elixir are about ±0.5′.

Columns (4)–(13) are the AB magnitudes and magnitude errors of a source in the u′, g′, r′, i′, z′ bands. These are given by MAG_AUTO and MAGERR_AUTO parameters of SExtractor, which are Kron-like elliptical aperture magnitudes and their errors.

Column (14) is the extraction flag of a source given as a sum of powers of 2 by SExtractor. If a source has neighbors (flag = 1) and is blended with another source (flag = 2) and some pixels are saturated (flag = 4), then the final extraction flag given to the source is 7 (1 + 4 + 2). Generally, a source with the extraction flag 0 gives the most reliable photometry. For detailed information on this flag, see the SExtractor User’s Manual.

Column (15) is the stellarity index of a source calculated from several color-magnitude and color-color diagrams. The parameter PHOT__FLUXFRAC = 0.5 and is given by the output parameter FLUX__RADIUS.

Column (19) is the semimajor axis of a source in arcseconds. Column (20) is the detected isophotal area of a source. This parameter may be used as a measure of the object’s size for the case of extended sources.

Column (21) is the field number that the photometric data of a source comes from. The field number 1 represents the NEP-E field and 2 represents the NEP-W field.

4.2. Color-Magnitude and Color-Color Diagrams

We have investigated the photometric properties of the NEP sources using several color-magnitude and color-color diagrams. In each diagram, we use the stellarity index given by SExtractor to distinguish between point sources and extended sources: stellarity >0.95 for point sources (mostly stars) and stellarity <0.2 for extended sources (mostly galaxies). They are found to be statistically very useful tools to separate stars and galaxies brighter than r = 23 mag from all kinds of sources in the catalog.

The r′ versus (g′ − r′) color-magnitude diagram (CMD) and (g′ − r′) color histogram in Figure 3 shows two prominent vertical sequences of point sources, i.e., stars at (g′ − r′) ≈ 0.3 (G dwarf stars) and 1.4 (M giant stars), respectively. The extended sources, presumably galaxies, are seen to be concentrated around (g′ − r′) ≈ 0.8 that corresponds to the (g′ − r′) color of early-type galaxies (Fukugita et al. 1995). The extended sources start to dominate at r′ ≈ 22 mag and fainter. Some of these sources may be faint stars that the SExtractor failed to classify as point sources. However, the different (g′ − r′) color histograms of the extended and the point sources suggest that the majority of these faint extended sources are galaxies.

Figure 4 displays the r′ versus (u′ − r′) CMD and (u′ − r′) color histogram of sources in the NEP-E field. The CMD shows that there are many galaxies distributed around (u′ − r′) ≈ 1.0 as shown in the (u′ − r′) color histogram of extended sources.
This value is consistent with the \((u' - r')\) color of Scd-type galaxies (Fukugita et al. 1995), whereas the \((g' - r')\) color of most galaxies in Figure 3 is that of early-type galaxies. It is also noted that there is a very long redward tail in the \((u' - r')\) color distribution of extended sources, reaching nearly \((u' - r') \approx 4\) or higher. The elliptical galaxies can be as red as \((u' - r') \sim 2.8\) (Fukugita et al. 1995). Therefore, some of those faint and red sources with \((u' - r') > 3.0\) could be distant galaxies with redshift \(z \geq 0.1\).

Figures 5 through 7 show the characteristic distribution of point sources and extended sources in three color-color diagrams (CCDs): \((r' - i')\) versus \((g' - r')\), \((i' - z')\) versus \((r' - i')\), and \((g' - z')\) versus \((u' - r')\). The most prominent feature in these CCDs is the stellar sequence of point sources, i.e., stars. In Figure 5, the stellar sequence in a flipped ‘L’ shape has a very narrow width of about 0.2 dex in the \((r' - i')\) versus \((g' - r')\) color space. This tight sequence is also well represented by a straight line in Figure 6. In these diagrams, extended sources are found to populate in a relatively well constrained color space centered at a certain color. It is still clear that we cannot possibly separate extended sources from point sources by simply constraining colors in the \((r' - i')\) versus \((g' - r')\) and the \((i' - z')\) versus \((r' - i')\) color-color space. However, Figure 7 shows that the \((g' - z')\) versus \((u' - r')\) color-color combination enables us to define the two exclusive spaces that are mostly populated by stars and galaxies, respectively. The boundary of these regions can be drawn by combination of three straight lines connecting \((u' - r', g' - z') = (-1.0, 0.5), (0.5, 0.5), (3.0, 1.7),\) and \((3.0, 5.0)\). This is a very useful tool for separating faint galaxies from stars to search for distant galaxy clusters or to compute the two-dimensional (2D) correlation function of galaxies.

4.3. Galaxy Number Counts

We have investigated the galaxy number counts using the NEP optical source catalog. To select galaxies efficiently from the photometry catalog, we adopted two different definitions of galaxies: (1) “galaxy I” sources with stellarity <0.2 and (2) “galaxy II” sources that belong to the designated area where the extended sources appeared to occupy in the \((u' - r')\) versus \((g' - z')\) CCD as denoted by the dashed line in Figure 7. The results of number counts for the galaxy I and galaxy II samples, as shown in Figure 8, show a consistent rise from \(r' = 17.5\) mag up to about \(r' = 23\) mag and then a steep down turn due to the incompleteness at \(r' \geq 23\) mag. From the bottom and middle panels of Figure 8, it
is clear that the galaxy II sample outnumbers the galaxy I sample in $r' > 23$ mag. This difference between number counts is mostly due to the deteriorating reliability of stellarity index in $r' \geq 23$ mag, as shown in the upper panel of Figure 2. Therefore, the galaxy I sample is likely to lose a large number of faint galaxies compared to the galaxy II sample.

In Figure 8, we also plotted the $R$-band galaxy number count of Kümmler & Wagner (2001) for comparison after a simple transformation into $r'$ band. Kümmler & Wagner (2001) derived the number count of extended sources by modeling the number count distribution of pointlike sources (star) and then subtracting the extrapolated model count of pointlike sources from the detected source count. On the other hand, we defined galaxies as a certain part of all the detected sources that satisfy a given stellarity condition (galaxy I) or a given two-color criterion (galaxy II). Nonetheless, it is clear from the plot that the number count by Kümmler & Wagner (2001) data is generally consistent with our result except for the differences in the faint magnitude domain where the incompleteness becomes significant.

As shown in the middle panel of Figure 8, the logarithmic number counts defined as $\log \left( \text{counts} / 0.5 \text{ mag/deg}^2 \right)$ also display very similar slopes over the range of $r' = 18 \sim 22$ mag. Simple linear square fits over that magnitude range returned the slope $d(\log N)/dm = 0.387$ for Galaxy I, 0.408 for galaxy II, and 0.397 for Kümmler & Wagner (2001) data. The errors of the fitted slopes are about $\pm 0.010$ for all cases. Therefore, the slopes of logarithmic galaxy number counts are in good agreement with that of Kümmler & Wagner (2001) within the errors.

However, there are some differences in several minor features between the logarithmic profiles of galaxy number count. This is more clearly shown in the upper panel of Figure 8. It is apparent that there are two small dips in galaxy II data: one at $r' \approx 17.5$–18 mag and another smooth one at $r' \approx 19$–20 mag. The first dip also appears to exist in Kümmler & Wagner (2001) data but the second smooth and shallow dip could not be identified from Kümmler & Wagner (2001) data in this plot. However, the magnitude of the second dip is roughly coincident with the break point at $R \approx 19$–20 mag as shown in their Figure 4.15

Fig. 4 of Kümmler & Wagner (2001) is constructed using the galaxy number count made with 0.25 mag bin. But the number count data in a table published in the same paper, which we used for Fig. 8, is made with 0.5 mag bin. The use of 0.5 mag bin instead of 0.25 mag bin in the number count is thought to cause the smoothing out of the feature.
4.4. Galaxy Clusters

We have carried out a galaxy cluster search using our optical photometry catalog. Among numerous galaxy cluster finding methods available, we adopted a simplified version of the C4 cluster finding algorithm by Miller et al. (2005) that utilizes a seven-dimensional position and color space. In this study, we use only a three-dimensional color space constructed based on \((g_0/C_0, r_0/C_0, i_0/C_0)\) colors to select cluster member galaxies and then we investigate the spatial distribution of the selected galaxies to find any overdensity of these galaxies in small regions. Finally, the CMDs of any overdense region are consulted to check whether the red sequence of galaxies is apparent before we identify the region as a galaxy cluster.

4.4.1. Nearby Galaxy Clusters in SDSS

We have carried out a galaxy cluster search using our optical photometry catalog. Among numerous galaxy cluster finding methods available, we adopted a simplified version of the C4 cluster finding algorithm by Miller et al. (2005) that utilizes a seven-dimensional position and color space. In this study, we use only a three-dimensional color space constructed based on \((g_0/C_0, r_0/C_0, i_0/C_0)\) colors to select cluster member galaxies and then we investigate the spatial distribution of the selected galaxies to find any overdensity of these galaxies in small regions. Finally, the CMDs of any overdense region are consulted to check whether the red sequence of galaxies is apparent before we identify the region as a galaxy cluster.

This approach requires the definition of color ranges spanned by the cluster member galaxies with various redshifts and richness classes before the actual application to the photometric data. We have used the Sloan Digital Sky Survey (SDSS;York et al. 2000) data for this purpose. The SDSS project provides a huge amount of multiband photometric and spectroscopic data over a large sky area. This enables us to select cluster member galaxies using the spectroscopy information and to reduce the possible contamination by field galaxies and stars. One more advantage of using the SDSS data set to define color ranges occupied by cluster member galaxies is that the SDSS filter system is the same as the MegaCam filter system of CFHT except for the \(u'\) filter (see § 2 for details). Therefore, we have searched the SDSS database and retrieved photometric and spectroscopic data of nearby galaxy clusters for the calibration of the red sequence colors in the SDSS filter system.

We have searched the SDSS DR5 database (Adelman-McCarthy et al. 2007) and found 101 nearby Abell galaxy clusters whose \(u', g', r', i', z'\) photometric and spectroscopic data of member galaxies are available.\(^{16}\) Figure 9 displays the redshift distribution of these cluster galaxies. The redshift of the selected galaxy clusters runs from 0 to 0.2 with a peak at \(z \sim 0.07\). After the data retrieval from the SDSS data archive, we have selected member galaxies of each cluster based on the velocity distribution and the spatial separation from the cluster center. The total number of the selected member galaxies for the 101 clusters is about 5700.

\(^{16}\) Please note that the \(u'\) filter is the Sloan system, which is different from the CFHT \(u'\) system. See § 2 for details.
From the cluster member galaxies, only the early-type galaxies were selected using the fracDev and eclass parameters provided by the SDSS archive: fracDev > 0.8 and eclass < 0 (for further information on these constraints, see Bernardi et al. 2005). Application of these parameters finally returned about 1700 early-type galaxies in 88 clusters and the number of early-type galaxies in each cluster runs from 4 (A2192) to 73 (A2199) depending on the redshift and the richness class.

Figure 10 displays the CMDs of the cluster galaxies in the SDSS color system. From these diagrams, it is seen that most early-type galaxies in the clusters lie within a well-defined and narrow color range with a width of \( \Delta r' < 0.2 \) dex in \( (g' - r')_0, (r' - i')_0, \) and \( (i' - z')_0 \). Although the \( (u' - r')_0 \) versus \( r'_0 \) CMD shows a rather large dispersion, it still shows a strong concentration at \( 2.0 < (u' - r')_0 < 3.0 \). The colors of these narrow sequences of early-type galaxies have been used as indicators of the clusters’ redshifts (Gladders & Yee 2000). We used the SDSS photometry data of member galaxies in four clusters (A2199, A1166, A1349, and A775) to derive the relation between the clusters’ redshift and the \( (g' - r')_0 \) color of the sequence as shown in Figure 11. From the linear fit after repeating one sigma clipping twice, we derived a linear and empirical relation between the redshift and the \( (g' - r')_0 \) color of the fitted sequences at \( r'_0 = 18 \) mag [hereafter \( (g' - r')_{18,0} \)] as follows:

\[
    z = (0.415 \pm 0.044) \times (g' - r')_{18,0} - (0.286 \pm 0.039).
\]

Therefore, the galaxies in nearby clusters occupy a certain space in a multicolor parameter space, which can be used to separate galaxies in the clusters from field galaxies and to estimate the approximate redshift of the cluster using the \( (g' - r')_{18,0} \) color of the sequence.

4.4.2. Galaxy Cluster Search in the NEP Field

To find galaxy clusters based on the results shown in Figure 10 and to estimate the redshift using equation (1), the Galactic foreground reddening was corrected for our photometry data using Schlegel et al. (1998) assuming \( A_r \approx 2.751E(B - V), E(g' - r') \approx 1.042E(B - V), E(r' - i') \approx 0.665E(B - V), \) and \( E(i' - z') \approx 0.607E(B - V) \). After some tests on the CFHT data, we have defined color ranges for the cluster galaxies as follows: \( 0.6 < (g' - r')_0 < 1.1, 0.1 < (r' - i')_0 < 0.4, 0.0 < (i' - z')_0 < 0.4 \). We did not use \( (u' - r')_0 \) color for this color space definition because of the unavailability of \( u' \) band data for the NEP-W field and the general low S/N in the \( u' \) band in the NEP-E field. According to a test performed after adopting the range \( 2.0 < (u' - r')_0 < 3.0 \) as the fourth constraining color, the efficiency of finding the cluster galaxies turned out to be comparable to that of another test run using the three-color combination of \( (g' - r')_0, (r' - i')_0, \) and \( (i' - z')_0 \). This three-color combination approach also enables a homogeneous search of cluster galaxies over our two data fields.

Possible cluster galaxies were selected by constraining the colors of galaxies with the predefined parameters of \( (g' - r')_0, (r' - i')_0, \) and \( (i' - z')_0 \). Using their R.A. and decl. information, we constructed spatial number density maps of the selected galaxies. Then we identified 13 possibly overdense regions in the NEP field. Over these 13 regions, CMDs of galaxies in \( (g' - r')_0, (r' - i')_0, \) and \( (i' - z')_0 \) colors were constructed using the source catalog to find any feature that resembles the red sequence of galaxies in a cluster. From this investigation, we have identified two galaxy clusters and one nearby galaxy group, and estimated their redshifts using the \( (g' - r')_0 \) colors of the red sequences. The CMDs of those galaxy clusters and the group are presented in Figures 12, 13, and 14. More details about them are discussed below.

4.5. Galaxy Clusters and Groups in X-Ray/Radio Source Catalogs

Some galaxy clusters or groups were found and reported in the previous studies made by using the X-ray and the radio band data.
Fig. 10.—CMDs of galaxies in 101 nearby ($z < 0.2$) galaxy clusters in the SDSS data archive. All the photometric data used in these diagrams are foreground-reddening–corrected. Early-type galaxies are plotted with crosses. Please note the relatively narrow and well-defined red sequence of early-type galaxies in each CMD. [See the electronic edition of the Supplement for a color version of this figure.]
4.5.2. RX J1754.7+6623

Henry et al. (2006) classified this source as a galaxy cluster with redshift \( z = 0.0879 \). However, the CMDs shown in Figure 13 suggest that there are two kinds of galaxies: (1) several bright galaxies that form the red sequence running from \( r^0 \approx 16 \) to 18 mag and (2) many faint galaxies in the background. The second component of galaxies are not brighter than \( r^0 = 19 \) mag, which is about 1 mag fainter than the faintest galaxy of the brighter component. This indicates that those bright galaxies may happen to be located in front of the faint background galaxies by chance. Therefore, we suggest that these galaxies are members of a galaxy group rather than a galaxy cluster. The red sequence’s \((g'-r')_0\) color is about 0.793, corresponding to an estimated redshift of 0.043 \pm 0.048. The relatively large error may be due to the poorly determined slope of red sequence depends sensitively on several bright galaxies with \( r^0 < 18 \) mag.

4.5.3. RX J1757.9+6609

There is a known X-ray source RX J1757.9+6609 at a similar position. It is listed as a type 2 AGN with redshift \( z = 0.4865 \) in the catalog of Henry et al. (2006). A type 2 AGN is a narrow emission line (FWHM < 2000 km s\(^{-1}\)) object, while a type 1 AGN is a broad emission line (FWHM \( \geq 2000 \) km s\(^{-1}\)) object (Gioia et al. 2003). The spatial number density plot in Figure 14 shows some clustering in the 2D projected space. This point was also noted by Gal et al. (2003), who carried out a cluster search using the Digitized Second Palomar Observatory Sky Survey (DPOSS) data. They detected an overdensity of galaxies at this location and listed it as a galaxy cluster candidate under the name of NSC J175751+660924, and also estimated its redshift to be \( z \approx 0.1663 \) from their photometric redshift analysis. Our photometric data shows well developed red sequences running from \( r^0 \approx 17.5 \) mag in \((g'-r')_0\), \((r'-i')_0\), and \((i'-z')_0\) colors, confirming that it is a genuine galaxy cluster. The red sequence’s \((g'-r')_0\) color is about 0.811, and this leads to the estimated redshift of \( z = 0.043 \pm 0.025 \). Therefore, there appears to be a galaxy cluster with redshift \( z < 0.2 \) and a type 2 AGN with redshift \( z = 0.4875 \) in the background of the same projected area.

4.5.4. Other Galaxy Clusters

We have identified two galaxy clusters and one galaxy group by applying the simple color cut method to our photometry catalog. However, there are two more galaxy clusters that are listed in the literature in our observation field that we failed to confirm. One is RX J1801.7+6637 (\( z = 0.57 \)) reported by Bower et al. (1996), and the other is RX J1757.3+6631 (\( z = 0.6909 \)) from the catalog of Henry et al. (2006). There appear to be some weak hints of clustering among these clusters on the images. But our photometry is not deep enough to identify any red sequence of galaxies in the CMD of the galaxies.

4.6. The Photometric Properties of Other X-Ray Sources

The photometric properties of various X-ray sources such as stars, AGNs, BL Lac objects could provide valuable information regarding their stellar populations and evolution. Comparison of our photometry catalog with the X-ray source catalog of Henry et al. (2006) returned about 25 possible matches. Based on the classification information of the X-ray sources by Henry et al.
Fig. 12.—CMDs (three top panels), the spatial distribution (bottom left), and the number density plot (bottom right) of galaxies of NEPX1. In each CMD, only the extended sources are plotted and the magnitude limit adopted for the analysis is indicated with an arrow. The color ranges used to find the cluster galaxies are shown in short dashed lines and the red sequence line fitted in each color is displayed in long dashed lines. The estimated redshift from the \((g'-r')_0\) color of the red sequence is indicated in the head as \(Z_{\text{CMR}}\). The galaxies satisfying the color cut criteria and being located within a solid circle in the bottom left panel are represented by filled circles in the CMDs and the spatial distribution plot. The size of the circles in the spatial distribution plot are proportional to luminosity: the larger, the brighter. Galaxies that satisfy only the color cut criteria are plotted in open circles while other galaxies are in open squares. The dashed line in the density plot displays the number density profile of all galaxies around the selected area and the solid line shows the profile of 10 times the number density of those selected galaxies and the corresponding errors. [See the electronic edition of the Supplement for a color version of this figure.]
Fig. 13.—CMDs (three top panels), the spatial distribution (bottom left), and the number density plot (bottom right) of galaxies of RX J1754.7+6623. There are several bright galaxies in the foreground over the many faint background galaxies in this region. See Fig. 12 for the legend. [See the electronic edition of the Supplement for a color version of this figure.]
Fig. 14.—CMDs (three top panels), the spatial distribution (bottom left), and the number density plot (bottom right) of galaxies of RX J1757.9+6609. See Fig. 12 for the legend. [See the electronic edition of the Supplement for a color version of this figure.]
we have investigated the photometric property of each object class using several CMDs and CCDs. Figure 15 shows a \((g'-r')\) versus \(r'\) CMD and the three different CCDs of various optical counterparts of X-ray sources. For a guideline in each diagram, the distribution of point sources, which are mostly stars, is also plotted.

In Figure 15, it is easily seen that (1) generally, X-ray bright stars do not belong to the well-defined stellar sequence in each diagram, and (2) AGNs and BL Lac objects are not readily separated from stars or other kind of objects in these CMDs and CCDs. Most X-ray bright stars that are used in this comparison are very bright \(r' < 15\) mag and are mostly saturated except for one faint giant star as shown in the top left panel of Figure 15. This may explain why these X-ray bright stars appear to be in different color domains from other generic stars. Even one faint star (marked by a star with a circle in Fig. 15) is bluer in \((u'-r')\) color than normal stars. Although AGNs and BL Lac objects as a whole do not show any distinct pattern in each color, the AGN1s with stellarity >0.9, which are relatively free from wrong identification, are found only in the blue domains of \((g'-r'), (r'-i')\), and \((u'-r')\). The \((g'-r')\) CMD also shows that any sources with \((g'-r') < 0.0\) and \(r' > 15-16\) mag are very likely to be AGNs or BL Lac objects.

5. SUMMARY AND CONCLUSION

We have obtained \(u', g', r', i',\) and \(z'\) optical band high-resolution images of the 2 square degree area centered at the NEP with MegaCam/MegaPrime at CFHT. From the source detection and the photometry using SExtractor, we have compiled about 56,000 sources with \(r' \leq 23\) mag, including point and extended sources, into the final optical photometry catalog as listed in Table 2. The use of the color-magnitude diagrams and color-color diagrams revealed strikingly different photometric characteristics of stars and galaxies. We have found that the use of \((u' - r')\) versus \((g' - z')\) color enables us to clearly separate galaxies from stars, and this separation does not suffer from the uncertainties involved in the morphological classification of faint sources. The galaxy number counts constructed from the galaxies selected based on the \((u' - r')\) versus \((g' - z')\) color show a nearly monotonic increase up to about \(r' = 23\) mag with a slope \(d(\log N)/dm \approx 0.40 \pm 0.01\), which is in agreement with the literature. However, there are some changes in the slope at
$r' = 17.5$–$18$ mag and $r' = 19$–$20$ mag, which needs further studies.

Using the SDSS DR5 data of the 101 nearby Abell galaxy clusters with redshift $z < 0.2$, we have derived a relation between the redshift and the color of the red sequences in the SDSS filter system that is compatible with the CFHT MegaCam filter system. Utilizing the information derived from the nearby galaxy clusters, we have applied a simple color cut method to find galaxy clusters in our data field, which returned two galaxy clusters and one galaxy group. These galaxy clusters and group are also radio and X-ray sources, which were reported by previous studies. We have also estimated the redshift of these galaxy clusters and group using the linear relation between the $(g' - r')_{18.0}$ color and the redshift. The estimated redshift is in agreement with the known value of 0.09 for galaxies in NEPX1 but it is lower than the spectroscopic redshift in the literature for galaxies in RX J1754.7+6623 and the photometrically derived redshift for RX J1757.9+6609. For RX J1754.7+6623, this underestimate of redshift may be due to the poorly determined slope of red sequence since there are only a few bright galaxies. For RX J1757.9+6609, the galaxy cluster seems to be overlaid on the background type 2 AGN with redshift of 0.4875.

We have compared our photometry catalog with an X-ray source catalog in the literature to investigate the photometric properties of other X-ray sources. The result of comparison implies that the sources with $(g' - r') < 0.0$ could be classified as candidates of AGNs or BL Lac objects.
