Quantum materials that host a flatband, such as pseudospin-1 lattices and magic-angle twisted bilayer graphene, can exhibit drastically new physical phenomena including unconventional superconductivity, orbital ferromagnetism, and Chern insulating behaviors. We report a surprising class of electronic in-gap edge states in pseudospin-1 materials without the conventional need of band-inversion topological phase transitions or introducing magnetism via an external magnetic type of interactions. In particular, we find that, in two-dimensional gapped (insulating) Dirac systems of massive spin-1 quasiparticles, in-gap edge modes can emerge through only an electrostatic potential applied to a finite domain. Associated with these unconventional edge modes are spontaneous formation of pronounced domain-wall spin textures, which exhibit the feature of out-of-plane spin-angular momentum locking on both sides of the domain boundary and are quite robust against boundary deformations and impurities despite a lack of an explicit topological origin. The in-gap modes are formally three-component evanescent wave solutions, akin to the Jackiw-Rebbi type of bound states. Such modes belong to a distinct class due to the following physical reasons: three-component spinor wave function, unusual boundary conditions, and a shifted flatband induced by the external scalar potential. Not only is the finding of fundamental importance, but it also paves the way for generating highly controllable in-gap edge states with emergent spin textures using the traditional semiconductor gate technology. Results are validated using analytic calculations of a continuum Dirac-Weyl model and tight-binding simulations of realistic materials through characterizations of local density of state spectra and resonant tunneling conductance.

I. INTRODUCTION

The physics of quantum materials hosting a flatband, such as the magic-angle twisted bilayer graphene, has become a forefront area of research. These materials can generate surprising physical phenomena, such as unconventional superconductivity [1,2], orbital ferromagnetism [3,4], and the Chern insulating behavior with topological edge states. The purpose of this paper is to report the surprising emergence of a class of in-gap edge states in two-dimensional (2D) Dirac/Weyl pseudospin-1 materials, which cannot be fit into any of the known scenarios for producing such states. The uncovered states, at their birth, exhibit topologically nontrivial domain-wall-like pseudospin textures.

In modern physics, the emergence of low-dissipation or dissipationless topological surface or edge states in condensed-matter systems is a fascinating phenomenon [5–7] as exemplified by topological insulators (TIs) [8–16]. A TI has a bulk band gap, so its interior is insulating, but there are gapless surface states within the bulk band gap, which are protected by the time-reversal symmetry that renders the states robust against backscattering from nonmagnetic impurities. These topologically protected surface or edge states possess a perfect spin-momentum locking characterized by the invariance of spin orientation with respect to the direction of the momentum. Quite recently, high-order TIs hosting, e.g., robust in-gap excitations of zero-dimensional corner modes have been uncovered [17–19]. Topological states of matter, in addition to their importance to fundamental physics, have potential applications in electronics and spintronics [20]. For electronic systems, current understanding of the physical mechanisms behind the topological edge states requires a discontinuous change in the associated bulk topological invariants across the interface/edge rendered by, e.g., a strong external magnetic field in a two-dimensional electron gas [6], band inversion driven by spin-orbit coupling [8,21,22], introduction of ferromagnetism in topological insulators [23], presetting domain walls in gapped Dirac materials [24–27], stacking order in layered two-dimensional materials [28], and particular spatial crystalline symmetries [29]. There have been studies of defects and midgap formation in topological materials [30] and hybridization in metamaterials of midgap modes [31]. A general method based on Green’s function was developed to analyze the midgap modes [32].

Pseudospin-1 type of low-energy excitations beyond the Dirac-Weyl-Majorana paradigm have recently been realized in electronic lattice systems [33–38]. In a broader context, two-dimensional massive spin-1 bulk excitations can arise in
Our main finding is that, in pseudospin-1 systems with an energy gap, a surprising class of in-gap edge bound states can arise without band- or mass-inversion-based domain walls that separate the regions with different kinds of bulk band topology and any external magnetic interaction, but these states are remarkably robust against geometric deformations and impurities. In fact, they are generated through only a local electrostatic potential barrier of the repulsive type in the underlying insulating spin-1 systems. We uncover a number of remarkable quite unusual spectral properties of these modes. Unlike the topological edge states previously discovered and studied, the states reported here require no established topological restrictions, such as interfacing domains/systems of different bulk topological invariants and any particular type of discrete symmetries. In fact, through self-inducing topological spin textures, the uncovered states possess the degree of robustness enjoyed by conventional topological states, but classical nonlinear physical systems, such as rotating shallow water in a horizontally unbounded plane [39] and the wave system of magnetoplasmons where the corresponding Hamiltonian representations [40] can be effectively reduced to the Dirac-like equation for spin-1 particles. Applying the sign-changing Dirac mass scenario to the systems leads to an extension of the Jackiw-Rebbi mechanism that serves to ascertain the topological origin of, e.g., the equatorial waves [39], as well as rich topological phenomena in bosonic and classical systems [41–45].

The subject of our paper is pseudospin-1 relativistic quantum systems described by the generalized Dirac-Weyl equation which are fundamentally linear. Specifically, low-energy excitations in condensed-matter systems, such as graphene [46] and topological insulators [8–16], and in analogous physical systems of molecules, cold atoms, cavity polaritons, light, and even mechanical waves in judiciously designed lattices [41–45] are described by the Dirac-Weyl equation. In those circumstances, if the corresponding quasiparticles are massless, the energy band structure contains a pair of Dirac cones characteristic of the relativistic energy-momentum dispersion relation. A finite mass leads to a band gap, giving rise to unconventional topological phases in Dirac material systems [47] with unusual physical properties associated with tunneling, confinement, and transport, which have no analogies in quantum systems described by the Schrödinger equation. Among those, the physics of edge states and robust in-gap excitations are of fundamental interest. Jackiw and Rebbi [48] predicted a surprising zero-energy bound-state solution of the Dirac equation in the presence of a kink-shaped mass profile that generates a domain wall separating regions with sign-changing Dirac mass. The realization in polyacetylene [49,50] and the theoretical studies of narrow-gap semiconductors [51,52] led to the discovery of the phenomenon of band-gap inversion enabling topologically protected conducting interface states and localized subgap excitations in TIs [8–19]. In the description based on the massive Dirac equation, band-gap inversion is equivalent to a sign change in the mass. The topological edge states give rise to appealing physical properties and phenomena, such as robust low-power-dissipation wave transport [26], electrically tunable magnetism [53], and quasiparticles analogous to elementary fermionic particles in high-energy physics [54].

Our main finding is that, in pseudospin-1 systems with an energy gap, a surprising class of in-gap edge bound states can arise without band- or mass-inversion-based domain walls that separate the regions with different kinds of bulk band topology and any external magnetic interaction, but these states are remarkably robust against geometric deformations and impurities. In fact, they are generated through only a local electrostatic potential barrier of the repulsive type in the underlying insulating spin-1 systems. We uncover a number of remarkable quite unusual spectral properties of these modes. Unlike the topological edge states previously discovered and studied, the states reported here require no established topological restrictions, such as interfacing domains/systems of different bulk topological invariants and any particular type of discrete symmetries. In fact, through self-inducing topological spin textures, the uncovered states possess the degree of robustness enjoyed by conventional topological states, but they belong to a distinct class due to the following physical reasons: three-component spinor wave function, unusual boundary conditions, and a shifted flatband induced by the external electrical potential. Experimentally, these states can be generated readily through routine electrostatic gating within the same material (or within a single device), rendering them promising in applications, e.g., a gate-controlled spin-1 Dirac electron transistor of high on/off ratio.

II. RESULTS FROM A CONTINUUM DIRAC-WEYL HAMILTONIAN

A. Illustration of finding

Figure 1(a) presents a schematic of the system setting, whose effective Hamiltonian is $H_{\text{eff}} = \mathbf{v}_F \cdot \hat{\mathbf{S}} + \Delta \hat{S}_z + U(r)$ where the first term describes the bulk low-energy excitation of a massive spin-1 particle with quasimomentum $\hat{\mathbf{p}} = (p_x, p_y)$, the second term represents the generalization of the Dirac mass with $\hat{S}_z$ being a component of the spin-1 matrix vector $\hat{\mathbf{S}}$, and the last term is the locally applied electrostatic potential of height $V_g$ which defines a closed interface at the boundary. As we will establish, this magnetism-free configuration permits in-gap edge states, and the states with higher angular momenta possess highly organized domain-wall-like spin textures as illustrated in Fig. 1(b). In general, for the in-gap states to emerge and be stable, the perturbation in the form of the applied gate potential $V_g$ cannot be negligibly small in comparison with the pristine band-gap $\Delta$. Neither can the perturbation be too large to result in a substantially

![Figure 1](attachment:image.png)
reduced effective band-gap size. In fact, the inequality $V_g < 2\Delta$ is required, and the reduced band-gap $(2\Delta - V_g)$ should be comparable to the pristine one. In terms of $\Delta$ and $V_g$ as defined in Fig. 1, the criterion for the stable emergence of the in-gap states is $|V_g - \Delta| \lesssim \Delta/2$. The case shown in Fig. 1 is for $V_g \approx \Delta$.

B. Emergence of in-gap edge states

For a circular domain of radius $R$, the electrostatic potential is given by $U(r) = V_g\Theta(R - r)$, where $\Theta$ is the Heavyside function. The system as governed by $H_0\psi = E\psi$ can be solved analytically in the polar coordinates $r = (r, \theta)$ to yield closed-form solutions of the form

$$
\psi^\mu_j(r, \theta) = \frac{1}{\sqrt{2}} \left( \frac{h v F_k \mu}{\bar{E}_\mu^2 - \Delta^2} Z^\mu_j(k_r r) e^{-i\delta_1}\right) e^{i\varphi_1},
$$

(1)

where $\mu = I, O$ labels the inner and outer regions as defined by the interface, $h v F_k \mu = \sqrt{E_\mu^2 - \Delta^2}$, and $F^I_j = J_j$ and $F^O_j = H^O_j$ are the Bessel and the Hankel functions of the first kind with $j$ being the integer angular momentum quantum number. As explained in Appendices A and B, the in-gap modes uncovered take the form of a three-component evanescent edge state. In comparison with known edge states, either topological or nontopological, the states uncovered here belong to a distinct class due to the following physical reasons: three-component spinor wave function, unusual boundary conditions, and a shifted flatband induced by the external scalar potential. Particularly, for $|j| \gg 1$, we calculate the eigenenergy $E \approx V_g/2$ and the resulting spin textures,

$$
S = [S_x, S_y, S_z]
$$

$$
\approx [\sin \theta \sin \Phi(r), -\cos \theta \sin \Phi(r), \cos \Phi(r)],
$$

(2)

where

$$
\cos \Phi(r) = j/\sqrt{j^2 + \xi^2}[2\Theta(R - r) - 1],
$$

with $\xi = (V_g + 2\Delta r)/(2h v F)$. Concretely, for a representative parameter setting, e.g., $V_g = \Delta = 6h v F/R$, we calculate the resulting energy spectra as a function of the angular momentum quantum number $j$ as shown in Fig. 2(a). We see that additional bounded eigenstates arise in the gap, i.e., those in the shaded area in Fig. 2(a). The striking feature is that these states emerge for $E_\mu < \Delta$ where the system is an insulator. In this case, without any change in the band topology (e.g., due to band inversion), conventional understanding of TIs stipulates that such states are impossible.

A feature of the spin textures is worth mentioning. If we calculate the topological number defined as

$$
N = \frac{1}{4\pi} \iint n \cdot \left( \frac{\partial n}{\partial x} \times \frac{\partial n}{\partial y} \right) dx dy,
$$

where $n = S/|S|$, we get

$$
N = -\text{sgn}(j)/2,
$$

signifying vortexlike spin textures that can arise from in-gap excitations of meronlike skyrmions [55]. Similar features have been predicted in chiral $p$-wave superconductors [56,57] that have the same symmetry class as the spin-1 Dirac Hamiltonian studied in this paper [Eq. (A1)].

To gain further insights, we characterize the energy spectra using two experimentally relevant quantities: the LDOS and spin LDOS defined as $D(E, r) = \sum_v \langle v|\delta(E - E_v)|v\rangle$ and $D_s(E, r) = \sum_v \langle S_v|\delta(E - E_v)|S_v\rangle$, respectively, where $v$ is the eigenstate label. As shown in Fig. 2(c), the in-gap modes are localized at the boundary and exhibit distinct domain-wall spin textures where the energy broadening effect (e.g., caused by measurement) has been taken into account by approximating the $\delta$ function as $\Gamma/\pi[(E - E_v)^2 + \Gamma^2]$ with $\Gamma = 0.2e\alpha$. Figure 2(d) shows the spatial distributions of the corresponding wave density and spin texture for a representative state (indicated by the red arrow in Fig. 2(a)). A calculation of the associated spin projection $(S_z)$ versus $j$ in the inner and outer regions reveals that the domain-wall spin ordering is more pronounced for states with higher angular momenta as shown in Fig. 2(b). Associated with the strengthening of the spin ordering, the energy flow tends to decrease as revealed by a nearly dispersionless dependence of the energy level on the angular momentum quantum number as shown in Fig. 2(a). Figure 2(b) demonstrates the emergence of spin angular momentum locking that depends on the side of the interface in which the state is located, suggesting that these states are robust.

C. Robustness

The robustness of the quantum spin Hall and quantum anomalous Hall edge states are known to be protected by the presetting discontinuous change in the associated bulk topological invariants across the interface, such as the $Z_2$ index and Chern number, all requiring some sort of magnetic interaction. However, for the edge modes demonstrated in Fig. 2, there is no such a priori topological origin/restriction. The question is whether the modes are protected or stable against irregular perturbations. To address this question, we consider a general type of perturbation: geometric deformation of the potential domain. A significant challenge is to obtain accurate eigensolutions of the massive spin-1 Dirac equation as with an irregular domain analytic solutions are no longer possible. We have developed an accurate and efficient numerical method to find solutions for arbitrarily shaped domain interfaces (Appendix C). As an illustration, we create deformed domains via the superformula in botany that can generate a great diversity of natural shapes with only a few parameters [58]. Figure 3(a) shows, for 13 deformed boundary shapes (insets), the corresponding energy spectra resolved by the total DOS. With respect to the eigenstates of the circular geometry, there are considerable shifts (up or down) in some eigenenergies of the strongly deformed domains but, importantly, there are stable states with virtually no changes in their energies despite the severe deformations.

To ascertain the nontrivial feature of the in-gap states, we examine the associated spin properties. In particular, we introduce an effective exchange energy penalty,

$$
E_w = -\langle S^I_j \cdot \langle S^O \rangle \rangle,
$$

to identify a domain-wall-like spin ordering structure between the inner and the outer regions. It can be seen from Fig. 3(b)
FIG. 2. Emergence of in-gap edge modes. (a) Eigenenergy $E$ (in units of $\hbar v_F/R$) as a function of the total angular momentum $j$ for $V_g = \Delta = 6\hbar v_F/R$. The light yellow shaded area represents the band gap. The inset shows the in-gap modes within the same energy range as that of Fig. 3(b). The light blue triangles denote the common eigenstates due to the induced quantum dot confinement of bulk valence-band carriers where all the corresponding wave functions are localized within the dot, see, e.g., complementary Fig. 7 in Appendix B. (b) Expectation values of $S_z$ versus $j$ for the in-gap modes marked by the purple dots in (a). The values are evaluated on both sides of the boundary, which are denoted by $\langle S_z \rangle_I$ (blue squares; inside the domain) and $\langle S_z \rangle_O$ (red dots; outside of the domain), respectively. (c) Local density of state (LDOS) and spin-resolved LDOS (spin LDOS) maps versus energy $E$ and the radial spatial position $r/R$ associated with the spectra in (a) where an empirical parameter value $\Gamma/\epsilon_s = 0.2$ is used to characterize the energy broadening effect as in an experimental situation. (d) Spatial profiles of wave (left panel) and spin texture (right panel) distributions of the in-gap mode indicated by the red arrow in (a).

that the stable modes insensitive to deformation attain large energy penalties, a strong indication of the emergence of domain-wall spin ordering, whereas the modes with small values of $E_w$ are sensitive to deformations. Figure 3(c) shows the real-space wave density and the corresponding spin texture patterns of three representative states as indicated in Fig. 3(b). The wave density topography associated with the strong domain-wall spin texture is mainly contributed by the high angular momentum states [those with distinctly more angular nodes—cf., middle panel of Fig. 3(c)]. This agrees with the prediction of the continuum theory that a nearly perfect out-of-plane spin angular momentum locking should emerge for the high orbital angular momentum states as shown in Fig. 2(b), providing the physical reason for the robustness. (Intuitively, this behavior can be understood that a faster spinning egg is able to stand upright in a more stable manner). The unambiguous signature of spin angular momentum locking can greatly circumvent mode coupling due to backscattering caused by the deformation. For those modes, the conventionally anticipated level repulsion/shifting effect due to geometric deformation is greatly suppressed, an unequivocal indication that the modes with spin angular momentum locking are robust with self-induced protection.
FIG. 3. Robustness of in-gap modes against geometric deformations of the domain. (a) DOS-based spectral lines for 14 boundary shapes (inset). (b) Dependence of the energies of the in-gap edge modes on the deformed shape as revealed by a color-coded map of the effective (exchange) energy penalty $E_w$ for forming a globally organized domain-wall spin texture, defined as the dot product of the spin expectation values inside and outside of the domain for each mode. The penalty attains large values for edge modes with a strong domain-wall ordering but has small values for ones with a dominant in-plane vortex spin texture. The yellow shaded region is for eye guidance of the approximately invariant energy range in which the in-gap modes arise in the presence of systematically varying geometric deformations. (c) Representative real-space wave (top panel) and spin texture (bottom panel) profiles of the categorized in-gap edge modes indicated by the corresponding color-filled markers in (b) for three distinct energy values.

As in most studies of TIs [8,59], we have employed a sharp potential boundary to demonstrate the findings. However, by performing calculations using a finite difference method for realistic and smoothly varying potential profiles, we find that the topological states as exemplified in Figs. 2 and 3 persist (Appendix C). We also find that these states can tolerate strong disorders.

III. RESULTS FROM TIGHT-BINDING CALCULATIONS OF AN EXPERIMENTALLY RELEVANT LATTICE MODEL

The in-gap excitations predicted have the striking physical properties of dispersionless spectral flow and spontaneous domain-wall spin ordering. They manifest themselves as distinct real-space topographies of LDOS and spin LDOS, which can be experimentally mapped out using the low-temperature scanning tunneling spectroscopy technique [60,61]. With advances in Dirac materials in recent years, realizing the spin-1 generalization of ordinary Dirac/Weyl fermions in the form of low-energy collective states or quasiparticles is experimentally possible in condensed-matter systems [34,36,62–65], such as a Lieb or a dice lattice, the generalized mass term can be induced via a staggered sublattice potential that breaks the inversion symmetry, which is an extension of the standard Dirac mass term in, e.g., graphene. As a way of an example, we consider the case of a Dice lattice model as illustrated in Fig. 4(a), which is relevant to emerging 2D Dirac materials, such as transition-metal dichalcogenide/dihalide monolayers [66], monolayer Mg$_2$C (MXene) [67], decorated graphene [68], etc. Its tight-binding Hamiltonian in real space is given by

$$H_{\text{Dice}} = -t \sum_{\langle i,j \rangle} (c_{i\nu}^\dagger c_{A_j} + c_{i\nu}^\dagger c_{C_j} + \text{H.c.}) + \Delta \sum_i (c_{C_i}^\dagger c_{C_i} - c_{A_i}^\dagger c_{A_i}),$$

where $c_{i\nu}^\dagger (c_{i\nu})$ with $\nu = A, B, C$ are creation (annihilation) operators of the localized states $|\nu i\rangle$ at site $i$ belonging to the sublattice $\nu$. $(i, j)$ denotes pairs of nearest-neighbor sites with the tunneling strength (hopping energy) of $t$. The last term represents a staggered sublattice potential that is responsible
FIG. 4. Tight-binding Dice lattice model of a 2D spin-1 Dirac insulator. (a) Left: schematic of a Dice lattice consisting of three sublattices denoted by A, B, and C with a nearest-neighbor hopping $t$ (between them) and primitive vectors $a_1 = (a, 0)$, $a_2 = (a/2, \sqrt{3}a/2)$, given $a$ the primitive lattice constant. Right: the corresponding first Brillouin zone. (b) Left: bulk band structure plotted along the lines connecting points of high symmetry indicated in the right panel of (a). Middle and right show the resulting LDOS and pseudospin-polarized LDOS (sLDOS) spectra, respectively.

for the Dirac-type mass-based gap opening. In the absence of any external field, we obtain the bulk energy band structure and corresponding LDOS spectra as shown in Fig. 4(b). We see that, near the $K$ point, the system behaves as a band insulator hosting Dirac-like quasiparticles of massive spin-1. Notably, the flatband leads to a sharp peak in the LDOS but has a vanishing group velocity as well as a vanishing out-of-plane pseudospin polarization/orientation [cf. right panel in Fig. 4], i.e., $sLDOS \equiv |D_B - D_C| = 0$ with $D_\mu$ as the LDOS occupied at sublattice $\mu$.

An electrostatic potential of height $V_0/t$ is locally applied to a small region of an undoped Dice lattice sheet to realize the gate-controlled quantum dot structures. Concretely, for $\Delta/t = 0.439$ and $V_0/t = \Delta/t (< 2\Delta/t)$, we calculate the sLDOS measured at the boundary of the gated region for three different domain shapes with a characteristic size parameter $R = 5$ nm as depicted in the insets of Figs. 5(a)–5(c). The results are displayed by red curves, whereas those for the (ungated) case of $V_0/t = 0$ (black curves) are also shown for comparison. Signified by dramatic changes in the sLDOS spectra with large amplitudes, a number of in-gap states emerges. As displayed in the middle panel of Fig. 5, they are highly localized edge modes. This result agrees with that obtained from the analytic continuum spin-1 Dirac model in Sec. II.

We also consider a lead-contacted Dice lattice flake with a circular gate-defined quantum dot as schematically illustrated in the top panel of Fig. 5(d) for a possible experimental detection via transport measurements. One typical simulation result is given in the bottom panel of Fig. 5(d). Remarkably, the

FIG. 5. In-gap edge modes in the Dice lattice-based material system. sLDOS at the position of the domain boundary (marked by the cyan dot) as a function of energy for a uniformly gated region with a shape of (a) a disk, (b) a rectangle and (c) a stadium via an electrostatic gate potential $V_0/t$. Middle panels display typical real-space patterns of associated in-gap states. (d) Top: schematic of a gate-controlled spin-1 Dirac electron transistor setup. Bottom: the simulation result of transport conductance versus energy.
emerging in-gap modes acting as “doorway” states can actuate resonant tunneling through the device with large conductance. Because of the ease of realizing control with an electrostatic gate potential, the setup can act as a novel quantum switch or transistor of high on/off ratio with spin-1 Dirac electrons.

Alternatively, associated with triple point semimetals of bulk massless spin-1 excitations described by a three-band extension of the Weyl Hamiltonian [37], i.e., $H_3 \propto k_x S_x + k_y S_y + k_z S_z$, a thin-film structure of thickness $L$ in the $z$ direction can host the two-dimensional spin-1 quasiparticles with an analogous finite mass $\propto \pi/L$ due to the confinement effect. This provides another potential experimental platform. In addition, the massive spin-1 physics turns out to be accessible in a dimerized quantum magnet [34] and is even relevant to classical systems of a two-dimensional magneto-plasmon [40] where the mass term is induced by an applied magnetic field.

We have also solved a gapped Dice lattice in a semi-infinite geometry in the presence or absence of a locally applied gate potential, which represents a trivial bulk band insulator with low-energy massive pseudospin-1 excitations. For comparison, we have also included the known case of gapped graphene. The results are shown in Fig. 6. It can be seen that, in contrast to the well-studied graphene case [(c) and (d)], in the Dice lattice with massive pseudospin-1 quasiparticles, the in-gap states emerge as the result of simply applying an electrostatic potential to a trivial bulk band insulator. As shown in (e), they are localized edge states that are distinct from the dispersionless flatband states [top panel in (e)] and from the typical quantum well bound states [bottom panel in (e)] as well. These results agree with the prediction from the general continuum model.

IV. CONCLUSION AND DISCUSSION

To summarize, we have predicted a class of in-gap edge excitations with spontaneous domain-wall spin textures in insulating Dirac-type systems of massive spin-1 particles with only a locally applied electrostatic potential. Despite the absence of magnetism and any a priori topological origin, these states are extremely robust against boundary deformation and disorders. The remarkable property of these states is the self-induced emergence of domain-wall spin ordering that renders distinct spin angular momentum locking on different sides of the domain interface. Consequently, the states are stable against impurities and/or geometric deformation. The in-gap modes are formally three-component evanescent wave solutions, bearing certain resemblance with the Jackiw-Rebbi type of bound states. The modes belong to a distinct class due to the following physical reasons: three-component spinor wave function, unusual boundary conditions, and a shifted flatband induced by the external scalar potential. Our findings provide a fully electrostatic-based route to generate protected robust spin ordering edge states without requiring any sort of magnetism, extrinsic or intrinsic. The states can be exploited for spintronics and quantum information processing applications, e.g., realization of a gate-controlled spin-1 Dirac electron transistor or quantum switch. With rapid advances in generalized Dirac materials, especially those hosting the spin-1 generalization of ordinary Dirac/Weyl fermions and with the state-of-the-art measurement technologies, experimental confirmation of the states discovered here is possible.

We note a distinct feature of the system studied: the inherent midgap flatband hosting macroscopically degenerate states. Without the applied electrostatic potential ($V_g = 0$),
we obtain the flatband states, i.e., $E(p) = 0$, given by (non-normalized) 

$$\Psi_{k,0}(r) \sim \frac{1}{\sqrt{2}} [v_F |p| e^{-i\zeta}, -\sqrt{2} \Delta, -v_F |p| e^{i\zeta}]^T e^{i k_r \sigma}, \quad (4)$$

with the wave-vector $k = (k_x, k_y) \equiv p/\hbar$ making an angle $\zeta = \arctan(k_y/k_x)$ with the $x$ axis. The states result in a vanishing current and a trivial spin distribution over the space as well as a vanishing Chern number [40,69,70]. Our finding is that a locally applied potential shifts the flatband relative to the surrounding and surprisingly leads to a class of exotic edge excitations that inherit the (quasi)flat dispersionlessness but attain a nontrivial feature associated with the emerging domain-wall-like spin ordering. Due to the vanishing Chern number of the flatband in the configuration in Fig. 1(b), the regions with different applied potentials $V_x$ possess the same Chern number. This indicates that the uncovered in-gap states do not have a topological origin. It has been known that flatbands can lead to exotic physical phenomena, such as zero-refractive index, unconventional Anderson localization [71,72], itinerant ferromagnetism [73], and unconventional superconductivity [74,75]. Moreover, the finite gap opening makes it possible to categorize the unperturbed bulk system into the phase of class D with a particle-hole symmetry and a broken time-reversal symmetry, which also arises in $p + ip$ superconductors [40]. In this regard, the two-dimensional gapped pseudospin-1 system represents a paradigm to investigate high-spin topological phases with exotic edge excitations and flatband physics. With enriched pseudospin degrees of freedom, graphene-based heterostructures, such as the graphene-In$_2$Te$_3$ bilayer [68] and the twisted bilayer graphene superlattice [76], can also be exploited for possible experimental realization of the topological edge states uncovered in this paper.

Taken together, the main contributions of this paper are as follows: (1) In-gap edge modes can arise in a topologically trivial spin-1 Dirac insulators with local electrical gating or nonmagnetic doping, (2) the in-gap edge modes possess pseudospin-polarized textures akin to localized domain walls of either the hedgehog or the vortex type without requiring any external pseudospin-resolved field, (3) the edge modes are robust against boundary deformations and disordered scalar impurities, (4) the edge modes are nearly dispersionless in energy and intrinsically possess the capability of strong charge and spin confinement/localization, and (5) all these features of the in-gap edge modes can be electrically controlled within the same material setting. We note that the existing mechanisms for in-gap bound modes or excitations can be either topological or nontopological. Examples are the extensively studied topological in-gap edge modes [15,16], the nontopological Yu-Shiba-Rusinov bound states associated with magnetic impurities in superconductors [77–79], vacancy defects or particular lattice termination-induced bound states in crystalline lattice systems [80,81], and modes induced by nonmagnetic impurities in topologically nontrivial band insulators [82]. There was also a recent work [83] hinting that the multicomponent character of the Dirac-Bloch wave function and the associated boundary conditions would enable nontopological Dirac materials, through proper engineering of the graphene lattice boundaries, to potentially host robust

**APPENDIX A: BASICS**

In the position representation $r = (x, y)$, the Hamiltonian for a massive spin-1 generalization of Dirac/Weyl fermion reads

$$\hat{H} = v_F \hat{S} \cdot \hat{p} + \Delta \hat{S}_z + U(r), \quad (A1)$$

where $v_F$ is the Fermi velocity, $\hat{p}$ is the momentum operator, $\hat{S} = (S_x, S_y)$ and $\hat{S}_z$ are spin-1 matrices, $\Delta$ denotes a Dirac-type mass, and $U(r)$ is a scalar type of perturbation (e.g., an electrostatic potential). The energy eigenstates $\Psi(r) = [\psi_1(r), \psi_2(r), \psi_3(r)]^T$ can be determined by the generalized Dirac-Weyl equation,

$$\hat{H} \Psi(r) = E \Psi(r). \quad (A2)$$

For a spatially homogeneous/constant potential, e.g., $U(r) = V_0$, the eigenenergies are $E = V_0$ and $V_0 + s \sqrt{\Delta^2 + \hbar v_F |k|^2}$ with $s = \pm$ being the dispersion band index. The corresponding plane-wave solutions can be written as

$$\Psi_{k,0}(r) = \frac{1}{\sqrt{2}} [k e^{-i\zeta}, -\sqrt{2} \delta, -k e^{i\zeta}]^T e^{i k_r \sigma},$$

and

$$\Psi_{k,\pm}(r) = \frac{1}{2} \left( \alpha e^{-i\zeta} \frac{\sqrt{2}}{\beta e^{i\zeta}} \right) e^{i k_r \sigma}, \quad (A3)$$

where the wave-vector $k = (k_x, k_y)$ has length $k = \sqrt{\epsilon^2 - \delta^2}$ with

$$\epsilon = (E - V_0)/\hbar v_F, \quad \delta = \Delta/\hbar v_F,$

which makes an angle $\zeta = \arctan(k_y/k_x)$ with the $x$ axis. Other factors are $\alpha = k/(-\epsilon - \delta)$ and $\beta = k/(-\epsilon + \delta)$. The current operator is defined based on Eq. (A1) as

$$\hat{u} = \nabla \times \hat{H} = v_F \hat{S}. \quad (A4)$$
The local current associated with state $\Psi(r) = [\psi_1, \psi_2, \psi_3]^T$ can be calculated from the local expectation value of $\hat{u}$ as

$$u(r) = v_F (\psi^*_1, \psi^*_2, \psi^*_3) S \left( \begin{array}{c} \psi_1 \\ \psi_2 \\ \psi_3 \end{array} \right)$$

$$= \sqrt{2} v_F \{ \text{Re}[\psi^*_2(\psi_1 + \psi_3)], -\text{Im}[\psi^*_2(\psi_1 - \psi_3)] \}.$$  

(A5)

By definition, the local current is the local probability density of spin-vector $(S_x, S_y)$. Using the plane-wave solution (A3), we obtain

$$u = v_F - \frac{\epsilon}{\sqrt{\epsilon^2 - \delta^2}} k.$$  

The effects of the applied scalar potential are to shift the Dirac point ($k = 0$) in the energy domain, to tune the kinetic-energy $\epsilon = (E - V_0)/h v_F$, and to alter the particle attributes from hole to electron type, and vice versa.

The time-reversal symmetry operator is

$$\mathcal{T} = \begin{pmatrix} 0 & 0 & -1 \\ 0 & 1 & 0 \\ -1 & 0 & 0 \end{pmatrix} K \quad \text{for} \quad k \rightarrow -k,$$

where $K$ is the operator for complex conjugation. Due to the Dirac-like mass term, the time-reversal symmetry is broken.

APPENDIX B: EIGENSOLUTIONS OF TYPE-II QUANTUM DOTS OF MASSIVE SPIN-1 PARTICLES

We obtain the eigensolutions of the spin-1 massive Dirac system when an electrostatic potential is applied to a circular domain: $U(r) = V_0 \Theta(r - R)$. This is effectively type-II quantum (anti-)dot configuration for Dirac-like massive spin-1 particles. Because of the rotational symmetry, it is convenient to use polar coordinates $r = (r, \theta)$ where the eigenfunction is

$$\hat{H} \Psi(r) = 2 \left( \begin{array}{c} \psi_1 \\ \psi_2 \\ \psi_3 \end{array} \right) = E \left( \begin{array}{c} \psi_1 \\ \psi_2 \\ \psi_3 \end{array} \right),$$  

(B1)

where

$$\hat{H} = \frac{\hbar v_F}{\sqrt{2}} \begin{pmatrix} 0 & \hat{\mathcal{L}}_+ & 0 \\ \hat{\mathcal{L}}_- & 0 & 0 \\ 0 & 0 & \Delta S_z + U(r) \end{pmatrix},$$

with

$$\hat{\mathcal{L}}_\pm = -i e^{\pm i\theta} \begin{pmatrix} \partial_r \pm \frac{i}{r} \partial_\theta \end{pmatrix}.$$

Because the total angular momentum operator $\hat{J} = -i \partial_\theta + \hat{S}_z$ commutes with the Hamiltonian $\hat{H}$, the common set of eigenstates has the general form

$$\Psi_l(r) = [R_1(r) e^{i(l-1)\theta}, R_2(r) e^{il\theta}, R_3(r) e^{i(l+1)\theta}]^T,$$

(B2)

with $l \in \mathbb{Z}$. For the dispersive bands, we have

$$\Psi^\mu_l(r) = \frac{C_l}{\sqrt{2}} \begin{pmatrix} \alpha_\mu Z^\mu_{l-1}(k_l r) e^{i\theta} \\ i \sqrt{2} Z^\mu_l(k_l r) e^{il\theta} \\ -\beta_\mu Z^\mu_{l+1}(k_l r) e^{i(l+1)\theta} \end{pmatrix} e^{il\theta},$$  

(B3)

where the index $\mu = I, O$ labels the inner and outer regions of the circular domain boundary, $\alpha_\mu = \hbar v_F k_\mu/(E_\mu - \Delta)$ and $\beta_\mu = \hbar v_F k_\mu/(E_\mu + \Delta)$ with $\hbar v_F k_\mu = \sqrt{E^2 - \Delta^2}$ and $(E_\mu, E_O) = (E - V_0, E)$, and $Z^\mu_l(x) = J_l(x)$ and $Z^\mu_{l+1}(x)$ are the Bessel and the Hankel functions of the first kind, respectively. Matching the spinor wave-functions $\Psi^I_l$ and $\Psi^O_l$ at the domain boundary (interface) $r = R$ yields the following transcendental equation:

$$J_l(k_l R) [\alpha_\mu H^{(1)}_{l-1}(k_l R) - \beta_\mu H^{(1)}_{l+1}(k_l R)]$$

$$= H^{(1)}_{l+1}(k_l R) [\alpha_\mu J_{l-1}(k_l R) - \beta_\mu J_{l+1}(k_l R)],$$  

(B4)

which can be calculated numerically to yield the eigenenergies and eigenstates with high accuracy. Figure 7 shows some representative results. For reference, we have also included the corresponding results for the standard massive spin-1/2 Dirac fermion system. We see that, for the massive spin-1 system, apart from the conventional quantum dot bound states, an additional group of modes emerge in the gap. Whereas edge states can arise in the band gap as in conventional topological insulators, some kind of magnetic perturbations are required [8–16]. As there is no magnetic perturbation of any sort in our quantum dot system for massive spin-1 Dirac particles; the emergence of the states in the band gap is quite counterintuitive and striking.

We show analytically that the modes in the band gap possess a unique spectral peculiarity and are, in fact, edge states with domain-wall-like topologically nontrivial spin textures. In particular, in the gap $|E_{\mu}| < |\Delta|$, the radial wave numbers are purely imaginary, which can be redefined as

$$k_{O,R} = \frac{\sqrt{E^2 - \Delta^2}}{\hbar v_F / R} = \sqrt{\epsilon^2 - \delta^2} = i p, \quad k_{l,R} = i \epsilon - v_0 \delta = i q.$$  

(B5)

(B6)

With the substitutions,

$$K_l(x) = \frac{\pi}{2} i^l H^{(1)}_{l+1}(ix), \quad I_l(x) = i^{-l} I_{l+1}(ix),$$

we rewrite the eigenvalue equation Eq. (B4) as

$$I_l(p) \left[ \frac{p}{\epsilon - \delta} K_{l-1}(p) + \frac{p}{\epsilon + \delta} K_{l+1}(p) \right]$$

$$= -K_{l-1}(p) \left[ \frac{q}{\epsilon - v_0 - \delta} I_l(q) + \frac{q}{\epsilon - v_0 + \delta} I_{l+1}(q) \right],$$

(B7)

with the associated eigenstates given by

$$\Psi_l(r) = \langle O | \Psi_l \rangle + \langle I | \Psi_l \rangle,$$

$$= \frac{\sqrt{2}i^{-l} C_l}{\pi} \begin{pmatrix} i \epsilon_{l-1} K_{l-1}(pp) e^{-i\theta} \\ \sqrt{2} K_{l}(pp) e^{-i\theta} \\ i \epsilon_{l+1} K_{l+1}(pp) e^{-i\theta} \end{pmatrix} e^{il\theta} \Theta(r - R)$$

$$+ \frac{i C_l}{\sqrt{2}} \begin{pmatrix} q \epsilon_{l-1} I_{l-1}(qq) e^{-i\theta} \\ i \sqrt{2} I_{l}(qq) e^{-i\theta} \\ q \epsilon_{l+1} I_{l+1}(qq) e^{-i\theta} \end{pmatrix} e^{il\theta} \Theta(R - r),$$

where $\epsilon_{l\mu} = \epsilon^{l\mu}(r) - \Delta(r)$, $\epsilon^{l\mu}(r) = \epsilon(r) - \Delta(r)$.
FIG. 7. A type-II Dirac material quantum dot for massive spin-1 generalization of Dirac fermions and the associated eigenstates. (a) Energy band diagram of a type-II quantum dot for Dirac-type massive spin-1 particles. (b) Top: wave probability patterns for the eigenstates indicated by the corresponding colored arrows in the bottom panel for both massive spin-1 and massive spin-1/2 particles. Bottom: eigenenergies versus angular momentum. Parameters are $\Delta = V_0 = 6\hbar v_F / R$ for both cases.

\[
\begin{align*}
\rho &= r/R,
I_l(x) \text{ and } K_l(x) \text{ are modified Bessel functions. Making use of asymptotic expansions of high-order Bessel functions [84], i.e., } l \gg 1, \\
I_l(x) &\sim \frac{1}{\sqrt{2\pi l}} \left( \frac{e x}{2l} \right)^l, \quad K_l(x) \sim \sqrt{\frac{\pi}{2l}} \left( \frac{e x}{2l} \right)^{-l},
\end{align*}
\]

we obtain, from the eigenvalue equation Eq. (B4), the following relation:

\[
\lim_{l \to \infty} \left[ \frac{1}{\epsilon + \delta} \sqrt{l + 1 \left( \frac{l+1}{l} \right)} + \frac{1}{\epsilon - v_0 - \delta} \sqrt{l - 1 \left( \frac{l-1}{l-1} \right)} \right] \to 0. \tag{B9}
\]

Using the identity \( \lim_{n \to \infty} (1 + 1/n)^n = e \), we arrive at an equation that can be solved to yield the asymptotic eigenenergies,

\[
\frac{2\epsilon - v_0}{(\epsilon + \delta)(\epsilon - v_0 - \delta)} \to 0 \quad \Rightarrow \quad \epsilon \to \frac{v_0}{2}. \tag{B10}
\]

The eigenenergies are independent of the angular momentum and are, thus, in-gap (energy) dispersionless excitations.
associated eigenstates are approximately given by
\[
\Psi_l(r) \approx C_l \left\{ \begin{array}{c}
\rho^{-l} \left( \frac{\rho^{l+\delta}}{\rho^{l+\delta}} e^{-i\theta} \right) \\
\rho^{l} \left( \frac{\rho^{l+\delta}}{\rho^{l+\delta}} e^{-i\theta} \right) \end{array} \right\} \Theta(\rho - 1) + \rho^{l} \left( \frac{\rho^{l+\delta}}{\rho^{l+\delta}} e^{-i\theta} \right) \Theta(1 - \rho) e^{i\theta},
\]
(B11)
where
\[
C_l = \sqrt{\frac{2^{2l-1} C_0}{\pi}} \frac{1}{\sqrt{2 \pi} (\sqrt{\delta^2 - \frac{I_0^2}{4/2l})^{-1}}.
\]
(B12)

So, inside the domain \( \rho < 1 \), we have
\[
\langle I | \Psi_l \rangle \approx C_l \rho^{-l} \left( \frac{\rho^{l+\delta}}{\rho^{l+\delta}} e^{-i\theta} \right) e^{i\theta}
\]
and
\[
\langle O | \Psi_l \rangle \approx C_l \rho^{-l} \left( \frac{\rho^{l+\delta}}{\rho^{l+\delta}} e^{-i\theta} \right) e^{i\theta}
\]
(B13)

Outside of the domain \( \rho > 1 \), we have
\[
\langle I | \Psi_l \rangle \approx C_l \rho^{l} \left( \frac{\rho^{l+\delta}}{\rho^{l+\delta}} e^{-i\theta} \right) e^{i\theta}
\]
and
\[
\langle O | \Psi_l \rangle \approx C_l \rho^{l} \left( \frac{\rho^{l+\delta}}{\rho^{l+\delta}} e^{-i\theta} \right) e^{i\theta}.
\]
(B14)

We, thus, have that the in-gap excitations are localized edge modes and exhibit domain-wall-like spin textures for high angular momentum values.

Note that, for a given value of \( l \), in the semiclassical limit \( p, q \gg 1 \), we have, approximately,
\[
I_l(x) \sim \frac{e^{x}}{\sqrt{2\pi x^3}}, \quad K_l(x) \sim \sqrt{\frac{\pi}{2x}} e^{-x}.
\]

From the eigenvalue equation, we have
\[
\frac{\epsilon - v_0}{\rho} + \frac{\epsilon}{\rho} \approx 0 \implies v_0(\rho - 2\epsilon) \approx 0 \implies \epsilon \approx \frac{v_0}{2},
\]
(B15)

which leads to the same in-gap spectral properties as those from the large \( l \) regime. The associated semiclassical eigenstates are
\[
\Psi_l(r) \approx i^{-l} C_l \frac{e^{-x}}{\sqrt{\pi}} \frac{e^{-x(|l-1|)}}{\sqrt{\kappa}} \left( \begin{array}{c}
\frac{ik}{\rho^{l+\delta}} e^{-i\theta} \\
\frac{i k}{\rho^{l+\delta}} e^{i\theta} \end{array} \right) \Theta(\rho - 1) + \frac{ik}{\rho^{l+\delta}} e^{-i\theta} \Theta(1 - \rho) e^{i\theta},
\]
(B16)

where \( \kappa = \rho \approx 2000 \sqrt{\delta^2 - \frac{I_0^2}{4/2l}} \). We obtain the resulting spin textures as
\[
\left( \begin{array}{c}
\langle S_1 \rangle \\
\langle S_2 \rangle \end{array} \right) \approx \left( \begin{array}{c}
|C_0|^2 e^{-2\epsilon} \frac{\sin \theta}{\pi \kappa} e^{2\epsilon \rho^{-1}} \frac{4\delta}{\kappa} \left( \begin{array}{c}
\cos \theta \\
\sin \theta \end{array} \right) [2\Theta(\rho - 1) - 1],
\end{array} \right)
\]
(B17)

which exhibit a Bloch type of domain-wall spin ordering about the domain boundary as a result of the applied electrostatic potential. Semiclassically, the in-gap states are, thus, exponentially localized edge modes with spontaneously topological spin textures, which are reminiscent of the interfacial Jackiw-Rebbi modes, but, here, the modes have a distinct spectral features and an unconventional physical origin.

**APPENDIX C: EFFECTS OF SMOOTHLY VARYING ELECTROSTATIC POTENTIAL PROFILES AND IMPURITIES ON IN-GAP MODES IN MASSIVE SPIN-1 DIRAC SYSTEMS**

Realistically, the applied electrostatic potential will not be infinitely sharp at the domain boundary, but, rather, the potential file varies smoothly across the boundary. From an experimental standpoint, it is necessary to investigate if the in-gap states can persist when the domain boundary is “smeared.” The test would provide further support for the robustness and topological origin of those states. To be concrete, we use the following smoothly varying potential profile:
\[
U(r) = \frac{V_0}{2} \tanh \left( \frac{r - R}{d} \right) + \frac{V_0}{2},
\]
(C1)

where \( d \) is a characteristic length. We, thus, exploit the finite difference method recently developed for massless spin-1/2 Dirac fermions \cite{85–88} and generalize it to massive spin-1 particles. In particular, taking advantage of the rotational symmetry of \( U(r) \) and using the polar decomposition ansatz,
\[
\psi_l(r, \theta) = \frac{e^{i\theta}}{\sqrt{\rho}} \left( \begin{array}{c}
R_1(\rho) e^{-i\theta} \\
R_2(\rho) e^{-i\theta} \\
R_3(\rho) e^{-i\theta} \end{array} \right),
\]
(C2)

we obtain the corresponding radial eigenvalue equation of the three-component spinor \( \mathbf{R} = [R_1, R_2, R_3]^T \) as
\[
\hat{H}_r \mathbf{R} = \mathbf{E} \mathbf{R},
\]
(C3)

where
\[
\hat{H}_r = \left[ \begin{array}{ccc}
0 & -i/\sqrt{2} & 0 \\
i/\sqrt{2} & 0 & i/\sqrt{2} \\
0 & -i/\sqrt{2} & 0
\end{array} \right] - \frac{1}{2} \frac{L}{r} + \frac{i}{r} \frac{1}{r} \mathbf{S} \mathbf{A} + U(r).
\]
(C3)

When discretizing this equation on a finite lattice/grid, we need to judiciously specify the difference scheme and the
Fig. 8. Eigenenergy spectra numerically calculated from the finite differential solver for massive spin-1 Dirac systems with a smooth potential domain boundary. (a) For massive spin-1 Dirac particles, eigenenergy versus angular momentum (left panel) and the resulting local DOS versus energy (right panel). (b) Results for the corresponding massive spin-1/2 Dirac fermion system for comparison.

Boundary conditions at the ends of the lattice so as to preserve the Hermiticity of the Hamiltonian. A feasible procedure is to use the backward-forward-backward difference scheme to approximate the derivatives of the three components in Eq. (C3),

\[
\partial_r R_1 \approx \frac{R(r) - R(r - h)}{h},
\]

\[
\partial_r R_2 \approx \frac{R(r + h) - R(r)}{h},
\]

\[
\partial_r R_3 \approx \frac{R(r) - R(r - h)}{h},
\]

where \( h = L/(N + 1) \) is the discretization step size for the system in the range of \( 0 < r < L \) with \( N + 2 \) lattice points. The boundary conditions can be deduced from the Hermitian constraint of \( \hat{H}_r \),

\[
\int_0^L \left[ R_\alpha^{\dagger} \hat{H}_r R_\beta - (\hat{H}_r R_\alpha)^\dagger R_\beta \right] dr = 0,
\]

which can be explicitly written as

\[
-\frac{i}{\sqrt{2}} \left[ (R_{3\alpha} + R_{3\beta})^\dagger R_{2\beta} + R_{2\alpha}^\dagger (R_{3\beta} + R_{3\alpha}) \right]_0^L = 0. \tag{C5}
\]

The specific boundary conditions on \( R(0) \) and \( R(L) \) then become \( R_1(0) + R_3(0) = 0 \) and \( R_2(L) = 0 \). Implementing this procedure results in an eigenvalue problem for a \( 3N \times 3N \) Hermitian matrix \( H_{3N \times 3N} = [H_{\mu\nu}] \) with entries given by

\[
H_{(3n-2)(3n-1)} = U_n + \Delta, \quad H_{(3n-1)(3n-1)} = U_n,
\]

\[
H_{3n,3n} = U_n - \Delta,
\]

\[
H_{(3n-2)(3n-1)} = \frac{i}{\sqrt{2}h} - \frac{l - 1/2}{\sqrt{2}r_n},
\]

\[
H_{(3n-1)(3n-1)} = (H_{(3n-2)(3n-1)})^*,
\]

\[
H_{3n,3n} = -\frac{i}{\sqrt{2}h} - \frac{l + 1/2}{\sqrt{2}r_n},
\]

\[
H_{3n,3n} = (H_{3n,3n})^*,
\]

for \( n = 1, \ldots, N \). For \( n < N \), the matrix elements are

\[
H_{(3n-2)(3n+1-1)} = -\frac{i}{\sqrt{2}h},
\]

\[
H_{3n,3n+1-1} = \frac{i}{\sqrt{2}h},
\]

\[
H_{3n(3n+1-1)3n} = -\frac{i}{\sqrt{2}h},
\]

\[
H_{3n(3n+1-1)3n} = \frac{i}{\sqrt{2}h},
\]

We use the typical experimental values of the DOS [85,87,88] to measure the spectral features and study the effects of the smooth potential profile and impurity on the in-gap states.
FIG. 9. Effect of smooth domain boundaries on the bounded edge states. (a) Color-coded DOS versus energy $E$ and boundary smoothness $d$. (b) Left panel: partial DOS of the $l = -4$ state versus $E$ for a smooth potential domain of $d/h = 10$ as depicted in the inset. Right panel: wave density profile associated with the resonance in the partial DOS. (c) The corresponding results for the case of infinitely sharp potential domain for comparison.

where the DOS is defined as

$$D(E, r_0) = \sum_l \sum_{\nu} \frac{\Gamma}{\pi} \frac{|\langle R_{\nu}(r = r_0) \rangle|^2}{(E - E_{l\nu})^2 + \Gamma^2},$$

with $\nu$ labeling the obtained radial eigenstates for fixed $l$ and $\langle R_{\nu}(r = r_0) \rangle = \int_0^L dr |R_{\nu}(r)|^2 e^{-(r - r_0)^2/2\lambda}$ represents a spatial average of the wave function centered at $r = r_0$ with a Gaussian weight $\lambda$. We approximate the $\delta$ function by a Lorentzian with the broadening parameter $\Gamma$. In our simulations, we use a system of size $L/R = 10$ and discretize it with a uniform lattice of $N = 600$ sites. Other parameters are chosen as $\Gamma/E_*$ = 0.2 and $\lambda = 0.01R$. Representative results are shown in Figs. 8–10, which provide strong support for the persistence of the in-gap modes in massive spin-1 Dirac systems in realistic systems with a smooth potential profile and impurities.

APPENDIX D: MULTIPLE MULTipoles METHOD: CALCULATION OF EIGENenergies AND EIGENSTATes OF MASSIVE SPIN-1 DIRAC PARTICLES IN ARBITRARY DOMAINS

To test the robustness and to establish the topological origin of the in-gap states for massive spin-1 Dirac particles analytically predicted from the setting of a circular potential domain, we seek to search for such states in systems with a deformed domain. A difficulty that must be overcome is to calculate the eigenenergies and eigenstates of massive spin-1 Dirac particle in deformed domains of an arbitrarily geometric shape. We have succeeded in generalizing the multiple multipole expansion method originally developed in optics [89–93] to massive spin-1 Dirac particles. The end result of this nontrivial generalization is a systematic, reliable, accurate, and efficient computational paradigm incorporating the evanescent waves to detect and ascertain the existence of in-gap excitations/modes for arbitrarily shaped electrostatic potential domains.

1. Method implementation

A concrete setting of a single potential domain of arbitrary shape is illustrated in Fig. 11 where the exact shape of the geometric boundary is specified according to the superformula in botany [58], a simple but powerful prescription that can generate a vast variety of complex geometric shapes. In polar coordinates, the superformula is

$$r(\theta) = \left[\frac{1}{a} \cos \left(\frac{m_1}{4} \theta\right)\right]^{n_1} + \left[\frac{1}{b} \cos \left(\frac{m_2}{4} \theta\right)\right]^{n_2} - 1/n_1,$$

where the parameters $(m_1, m_2, n_1, n_2; a, b)$ control the shape. The boundary defines two subregions, one exterior another interior, denoted by $I$ and $II$, respectively, as shown in Fig. 11. The three-component spinor wave equation for a massive spin-1 Dirac particle in each subregion $\tau \in \{I, II\}$ reads

$$[\hat{S} \cdot \hat{k} + \delta S_z] \Psi^{(\tau)}(r) = \epsilon \Psi^{(\tau)}(r),$$

where $\hat{S}$ is the angular momentum operator, $\hat{k}$ is the momentum operator, and $\delta S_z$ is the Dirac spin operator. The energy eigenvalue $\epsilon$ is determined by solving the eigenvalue problem for the wave function $\Psi^{(\tau)}(r)$ within each subregion.
FIG. 10. Effect of scalar impurities on the in-gap edge modes. (a) DOS as a function of energy for different values of the disorder strength, each obtained from 100 realizations as indicated by multiple colored curves. The insets show the corresponding ensemble-averaged DOS versus energy with thick solid curves where the dashed curves are for the case of absence of disorder. (b) Typical wave density profiles corresponding to the three cases of disorder strength in (a).

where $\delta = \Delta / \hbar v_F$ and $\epsilon_r = (E - V_1) / \hbar v_F$. In polar coordinates $r = (r, \theta)$, the spinor cylindrical wave basis of the solutions with angular momentum $l$ is

$$
\Psi_l^{(2)}(r) = \frac{1}{\sqrt{2}} \begin{pmatrix} \alpha_l B_l \phi - \beta_l B_{l+1} \phi e^{i\theta} \\
- \beta_l B_l \phi + \alpha_l B_{l+1} \phi e^{i\theta} \end{pmatrix},
$$

(D3)

where $\alpha_l = k_l / (\epsilon_r - \delta)$, $\beta_l = k_l / (\epsilon_r + \delta)$, and $k_l = \sqrt{\epsilon_r^2 - \delta^2}$. Choosing $B_l(k_l r) = H_l^{(1)}(k_l r)$ (with $H_l^{(1)}$ being the Hankel function of the first kind), we have that the Dirac-type expansion basis wave functions originated at $r_{m_0}$ for the specific region $\tau$ are given by

$$
\Psi_l^{(2)}(d_{m_0}) = \frac{1}{\sqrt{2}} \begin{pmatrix} \alpha_l H_l^{(1)}(k_l d_{m_0}) e^{-i\theta_{m_0}} \\
\beta_l H_l^{(1)}(k_l d_{m_0}) e^{i\theta_{m_0}} \end{pmatrix} e^{i\theta_{m_0}},
$$

(D4)

where $\tau$ denotes the complement of $\tau$, $d_{m_0} \equiv |d_{m_0}| = |r - r_{m_0}|$, and $\theta_{m_0} = \text{Angle}(r - r_{m_0})$.

with $r \in \tau$. Carrying out the expansion in region $\text{II}$, we obtain the wave function as

$$
\Psi_l^{(2)}(r) = \sum_{m_1} \sum_l C_{l_m}^{m_1} \frac{1}{\sqrt{2}} \begin{pmatrix} \alpha_{l_1} H_{l_1}^{(1)}(k_{l_1} d_{m_1}) e^{-i\theta_{m_1}} \\
\beta_{l_1} H_{l_1}^{(1)}(k_{l_1} d_{m_1}) e^{i\theta_{m_1}} \end{pmatrix} e^{i\theta_{m_1}},
$$

(D5)

The wave function in region $I$ has the form

$$
\Psi_l^{(1)}(r) = \sum_{m_1} \sum_l C_{l_m}^{m_1} \frac{1}{\sqrt{2}} \begin{pmatrix} \alpha_{l_1} H_{l_1}^{(1)}(k_{l_1} d_{m_1}) e^{-i\theta_{m_1}} \\
\beta_{l_1} H_{l_1}^{(1)}(k_{l_1} d_{m_1}) e^{i\theta_{m_1}} \end{pmatrix} e^{i\theta_{m_1}} \times e^{i\theta_{m_1}} + \psi_m(r),
$$

(D6)
where

\[ \Psi^\text{in}(r) = \left( \frac{\alpha_I}{\beta_I} \right)^{\frac{3}{4}} e^{i(k_I r - \phi)} \begin{pmatrix} \psi_1^\text{in} \\ \psi_2^\text{in} \\ \psi_3^\text{in} \end{pmatrix} \]  

(D7)

denotes the input source triggered by an applied external excitation outside of the domain [cf., top panel in Fig. 11].

Imposing the relevant boundary conditions parametrized by angle \( \phi \) between the outward normal at any boundary point \( r_j \) and the \( x \) axis,

\[ \left. \begin{array}{c} \psi_2^{(I)} \\ \psi_3^{(I)} \end{array} \right|_{r_j \in \Gamma} = \left. \begin{array}{c} \psi_2^{(II)} \\ \psi_3^{(II)} \end{array} \right|_{r_j \in \Gamma}, \]  

(D8a)

\[ \left. \left( \psi_1^{(I)} e^{i\phi} + \psi_3^{(I)} e^{-i\phi} \right) \right|_{r_j \in \Gamma} = \left. \left( \psi_1^{(II)} e^{i\phi} + \psi_3^{(II)} e^{-i\phi} \right) \right|_{r_j \in \Gamma}, \]  

(D8b)

we obtain

\[ \sum_{m_1} \sum_{l} jA_{lm_1}^{(I)j} C_{m_1}^{lm_1} - \sum_{m_2} \sum_{l} jA_{lm_2}^{(II)j} C_{m_2}^{lm_2} = -j\psi_2^{\text{in}}, \]  

(D9a)

\[ \sum_{m_1} \sum_{l} jB_{lm_1}^{(I)j} C_{m_1}^{lm_1} - \sum_{m_2} \sum_{l} jB_{lm_2}^{(II)j} C_{m_2}^{lm_2} = -j\chi^\text{in}, \]  

(D9b)

where the substitutions are given by

\[ jA_{lm_1}^{(I)} = iH_l^{(I)}(k_I |r_j - r_{m_1}|) e^{i\theta_{m_1}}, \]  

(D10a)

\[ jA_{lm_1}^{(II)} = iH_l^{(II)}(k_I |r_j - r_{m_1}|) e^{i\theta_{m_1}}, \]  

(D10b)

\[ jB_{lm_1}^{(I)} = \frac{1}{\sqrt{2}} \left[ \alpha_I H_l^{(I)}(k_I |r_j - r_{m_1}|) e^{i(l-1)\theta_{m_1} + i\phi} - \beta_I H_l^{(II)}(k_I |r_j - r_{m_1}|) e^{i(l+1)\theta_{m_1} + i\phi} \right], \]  

(D10c)

\[ jB_{lm_2}^{(I)} = \frac{1}{\sqrt{2}} \left[ \alpha_I H_l^{(I)}(k_I |r_j - r_{m_2}|) e^{i(l-1)\theta_{m_2} + i\phi} - \beta_I H_l^{(II)}(k_I |r_j - r_{m_2}|) e^{i(l+1)\theta_{m_2} + i\phi} \right], \]  

(D10d)

\[ j\psi_2^{\text{in}} = \frac{1}{\sqrt{2}} e^{i\theta_j(r_j \cos \theta_j - \phi)} \]  

(D10e)

\[ j\chi^\text{in} = \frac{1}{2} \left[ \alpha_I e^{i\phi} + \beta_I e^{-i\phi} e^{i\theta_j(r_j \cos \theta_j - \phi)} \right], \]  

(D10f)

For the boundary shape defined by Eq. (D1), the associated unit normal direction can be written down explicitly,

\[ e^{i\phi} = -ie^{i\phi} \frac{dr(\theta)/d\theta + i\theta}{|dr(\theta)/d\theta + i\theta|}. \]  

(D11)

In principle, the set consists of an infinite number of equations with an infinite number of undetermined expansion coefficients \( C_{m_1}^{lm_1} \) and \( C_{m_2}^{lm_2} \). To solve the system numerically, a finite truncation is necessary, which turns out to be feasible, in practice, by discretizing the boundary to a finite number of points \( J \) and setting the number of basis functions \( M_{\tau} \) in the specific region \( \tau \) and \( l \in [-L, L] \) for all the functions. Carrying out the discretization procedure, we arrive at the following finite-dimensional matrix equation:

\[ \mathbb{M}_{2JN} \cdot \mathbf{C}_{N1} = -\mathbf{Y}_{2J1}, \]  

(D12)
where \( N = (2L + 1)M_I + M_{II} = N_I + N_{II} \) and the compact substitutions are

\[
C_{N \times 1} = [C_{LM_1}^{(1)} \cdots C_{LM_I}^{(1)} C_{LM_2}^{(1)} \cdots C_{LM_I}^{(1)}]^T
\]

\[
Y_{2J \times 1} = [\chi^L \cdots \chi^L \chi^\prime L \cdots \chi^\prime L]^T,
\]

(D13a)

and

\[
\mathbb{M}_{2J \times N} = \begin{bmatrix}
\mathbb{A}(I) & -\mathbb{A}(I) \\
\mathbb{B}(I) & -\mathbb{B}(I)
\end{bmatrix}_{2J \times N},
\]

(D13b)

with

\[
\mathbb{A}^{(r)} = \left[A^{(r)}_{-L_1} \cdots A^{(r)}_{LM_r} \cdots A^{(r)}_{LM_I}\right]_{J \times N_r},
\]

(D13c)

\[
\mathbb{B}^{(r)} = \left[B^{(r)}_{-L_1} \cdots B^{(r)}_{LM_r} \cdots B^{(r)}_{LM_I}\right]_{J \times N_r},
\]

(D13d)

where

\[
B_{LM_r}^{(r)} = \left[1 B_{LM_r}^{(r)} 2 B_{LM_r}^{(r)} \cdots j B_{LM_r}^{(r)} \cdots j B_{LM_r}^{(r)}\right]^T,
\]

\[
A_{LM_r}^{(r)} = \left[1 A_{LM_r}^{(r)} 2 A_{LM_r}^{(r)} \cdots j A_{LM_r}^{(r)} \cdots j A_{LM_r}^{(r)}\right]^T.
\]

As the expansions are generally nonorthogonal, more equations are required than the number of unknowns to enable the deduction of an overdetermined matrix system with \( 2J > N \), which can be solved by the standard pseudoinverse algorithm: \( C = \text{pinv}(\mathbb{M}) \ast Y \). In particular, we use the residual error evaluated at the boundary,

\[
\text{Error} = \frac{\| \mathbb{M} \ast C + Y \|}{\| Y \|},
\]

as the criterion to test convergence. We adjust the number, the order, and/or the positions of the multipole to ensure \( \text{Error} < \) tolerance. After the unknown coefficients \( C \) have been obtained, the associated wave functions and, hence, the local density of states in the specific region can be calculated accordingly.

2. Method validation

To validate the method, we exploit the analytically solvable case of circular geometry. Figure 12 shows a comparison of the eigenenergy spectra obtained analytically and calculated from the multiple multipole method. The agreement is remarkable.
