Version of Record: A version of this preprint was published at Journal of Orthopaedic Surgery and Research on December 1st, 2021. See the published version at https://doi.org/10.1186/s13018-021-02870-z.
Abstract

Objective: The purpose of this present study was to estimate complication and other outcomes associated with staples and sutures closure after hip arthroplasty through meta-analysis techniques and system review.

Methods: We searched for articles on EMBASE, PubMed, Medline, Web of Science and Cochrane Library. Eligibility of the searched trials. Cochrane Collaboration’s Review Manager software is used to perform meta-analysis.

Results: Four randomized controlled trials and one retrospective cohort trial chosen into our study. Our study indicated that the risk of infection and prolonged discharge higher with staples than with sutures for skin closure after hip arthroplasty. Meanwhile, there was no significant difference in allergic reaction, dehiscence, inflammation, abscess formation, Hollander Wound Evaluation Score and patient's satisfaction with skin closure methods between the two groups after hip arthroplasty. However, the suture group may require additional operating time.

Conclusions: Closure with suture have a lower risk of infection and prolonged discharge when compared with staples skin closure in hip arthroplasty, while it may take more time.

Introduction

Hip arthroplasty is the famous surgical operation for the treatment of degenerative and traumatic hip disease. With the aging of population and the progress of medical technology, the rate of arthroplasty has consistently been rising over the past decades(1, 2). Hip arthroplasty included total hip arthroplasty and hemiarthroplasty(3). It is estimated that by 2030, the major total hip arthroplasty operations in the United States will be 572,000 per year, an increase of 174% over 2005(4).

Wound complications are one of the main morbidity of hip arthroplasty, which can prolong hospitalization time or lead to readmission, increase costs and reduce patient satisfaction(5, 6). Surgical site infections (SSIs) are one of the most common, and most important complication after hip arthroplasty(7). Good skin closure in hip arthroplasty can achieve an appropriate closure and rapid healing, with acceptable cosmesis and minimize complications such as infection, delayed dehiscence and hematoma(5); besides, the stress of early activities and accelerated rehabilitation programs on wounds highlights the importance of skin closure(8).

There are many kinds of skin closure methods in hip arthroplasty, staples and sutures are the two most commonly used skin closure materials in hip arthroplasty(9). However, there seems to be no consensus in the literature as to which method of skin closure is superior in hip arthroplasty. Some studies have shown that skin staples were associated with a similar complication rate to an sutures, at the same time, they report that suture can reduce costs and sutures are less painful to remove(6, 10-12). In addition, Yao Lu et al found that the incidence of complications of suture closure was significantly lower than that of suture staples(13). The main disadvantage of suture is that it takes longer time to suture the wound, besides suture also requires surgeons to have better suture skills(14). Unlike suture, the surface of the staples rarely touches the edge of the wound and does not penetrate the incision at the depth of the incision. Staples do much less damage to wound defense and also reduce the immune response. In the process of suture and removal, staples are also considered faster than sutures(15, 16). However Singh, B et al(6) shows that using staples more than three times costlier than sutures. Therefore, further critical evidence is needed to prove which skin closure methods is more suitable for surgical suture after hip arthroplasty.

Until recently some meta-analyses and systematic reviews comparing staples with sutures for skin closure after orthopedic procedures or total knee arthroplasty have been published(17-20). However, after extensive searching for a large number of literature in the past, there was no related study comparing the wound complication, perioperative details and resource utilization of patients whose skin closure were closed with staples or sutures after hip arthroplasty. Meanwhile, some randomized controlled trials about staples versus sutures for wound closure in hip arthroplasty have been published in recent years. The purpose of this present study was to estimate complication and other outcomes associated with staples and sutures closure after hip arthroplasty through meta-analysis techniques and system review. We hypothesized that skin staples would be associated with better outcomes in the assessment of all relevant variables.

Materials And Methods

Literature search

From the establishment of the database to Mar 2021, two investigators independently conducted an extensive search of electronic databases such as EMBASE, PubMed, Medline, Web of Science and Cochrane Library. When searching, we use the following keywords and their combinations: staples, clips, suture, arthroplasty, hip, wound, closure and skin. Our study included only English-language publications on human trials. In addition, the bibliographies of the included studies and dissertations were searched for additional publications. Hand-search of relevant trials, reviews and related articles were also performed. Authors were contacted when possible to obtain missing information.

Inclusion and exclusion criteria

To be included in this study, the trials must meet the following inclusion criteria(1) All full-text randomized controlled trials (RCTs) and high quality retrospective cohort studies(2) staples versus sutures(3) patients treated with primary hip arthroplasty, included total hip arthroplasty and hemiarthroplasty; (4) the study provided at least one of the key outcome. Here are the exclusion criteria for our article: (1) skin adhesives as a primary or adjunct means of skin closure(2) barbed suture(3) Case reports, discourses, basic research, conference papers, non-English articles and other studies that do not contain the results.
of our interest; (4) data that could not be extracted. How deeper tissues were closed, the type of suture or stitch technique are not our exclusion criteria. The two authors independently assessed whether the article met the criteria for inclusion, and then discussed their differences until they reached a consensus.

Selection of the Literature

After eliminating duplicates, two independent researchers (Zirui Liu, Binfeng Liu) scanned titles and abstracts according to predetermined selection criteria and selected randomized controlled trials that might be relevant. Retrieve hard copies of all relevant articles and read the full text for further identification. Relevant data are extracted through a pre-determined standardized procedure involving the first author, the year of publication, the demographic characteristics of countries, participants and treatment options for each group.

Quality Assessment

Cochrane collaboration tool for assessing risk of bias was used to evaluate the methodological quality of the included randomized controlled trials(21). This tool focuses on the internal validity of the trial and assessment of risk of possible bias in different phases of the trial. The details are as follows: random sequence generation, allocation concealment, blinding of outcome assessment, blinding of participants and personnel, incomplete outcome data, selective reporting, and other bias. Each item was classified according to a high, low, or unclear risk of bias that is represented as high (H), low (L), and unclear (U), respectively. The Newcastle-Ottawa Scale (NOS) was used to assess the quality of cohorts and case-control studies. NOS ranges from 0 to 9 stars; research scores above 5 are considered high quality. All of the assessments were conducted by 2 independent reviewers (Zirui Liu, Binfeng Liu).

Data Extraction

The relevant data from the eligible papers were double extracted by author (Zirui Liu, Hao Yang) according to a predefined standardized protocol. We extracted the baseline of each included study from trials included the following information: design, closure material, age (mean), sex, cohort size, follow-up, information on study objective. When inadequate information existed in the studies, contacting the 1st authors to obtain and clarify the relevant data were essential as specified by the standardized protocol.

Outcome Assessment

We extracted infection, Prolonged discharge, abscess, wound dehiscence, allergic reaction, inflammation as our primary evaluated outcome. Secondary outcomes evaluated included Wound Closure time, length of stay in hospital, Hollander Wound Evaluation score, visual analogue scale.

Statistical Analysis

The Review Manager Software Package (RevMan Version5.3, The Cochrane Collaboration, Copenhagen, 2014) was used to generate forest plots. The overall effect of staples or sutures for wound closure was calculated as the weighted average of the inverse variance adjusted individual effects and 95% confidence intervals (95% CIs). The statistical heterogeneity among the individual studies was evaluated based on Cochrane Q test and the I² index(23) and the statistical heterogeneity was confirmed if I² was >50% and P < 0.10(24). A variance-based fixed effect model was applied to calculate the pooled effect; otherwise, a random effect model was used in the presence of statistically significant heterogeneity(25). If appropriate, the heterogeneity was identified and explained using a subgroup analysis (23). Evidence grading was evaluated according to the Grading of Recommendations, Assessment, Development, and Evaluation system(26).

Ethical Statement

As all analyses were grounded on previously published studies, ethical approval was not necessary.

Result

Literature search

There were 2102 articles in the initial literature search. According to inclusion and exclusion criteria, A total of 155 articles were screened through duplicates checking and title and abstract screening. Finally, after careful reading of the full text, four randomized controlled trials (6, 11, 12, 27) and one retrospective cohort trial (13) were included in our study. The flowchart process of screened and selected trials was presented in Figure 1.

Characteristics of the trials

A total of 751 patients: 359 in the staples group and 392 in the sutures group were recruited in our study. Every patient we selected from this eligible study underwent total hip replacement or hemiarthroplasty. A RCT (27) is divided into three groups: skin clips group, OCA (2-octylcyanoacrylate) group and suture group. The OCA group was excluded from this meta-analysis. The retrospective cohort trials (13) also divided into three groups: subcuticular suture group, staple group and interrupted suture group. Due to staples were used in subcuticular suture group as a supplementary means of skin closure, so we also remove subcuticular suture group from this meta-analysis. There was no difference in demographic and clinical data among each study. The mean age of the participants range from 55.7 years to 71 years in the staples groups and 57.8 years to 69 years in the suture groups. The sample size of our included study was range from 17 to 141. More detailed baseline characteristics of eligible studies are shown in Table 1.

Risk of bias assessment
Based on the Cochrane Collaboration recommendation, three RCTs (11, 12, 27) reported the detailed methods of random sequence generation. Two RCTs (12, 27) reported allocation concealments. The participants and personnel were blinded in 3 RCTs (6, 12, 27). In addition, full details of withdrawals and dropouts were described in all studies. In some studies, the follow-up rate was 100%. Details of deviation risk are shown in Figure 2. The bias risk of retrospective cohort trials assessed with NOS is shown in Table 2.

**Infection**

All the trials included in our study compare the infection rates between staples group and suture, regardless of superficial or deep infection. 11 out of 359 patients in the staples group were infected, while 2 out of 392 patients in the suture group. The fixed-effects meta-analysis of 5 trials showed that the risk of infection higher with staples than with sutures for skin closure after hip arthroplasty. The Odds Ratio of infection was 3.57 (95% CI, 1.15 to 11.05; P = 0.03) and there was no heterogeneity ($\chi^2=2.45; I^2=0%; p=0.65$). The Forest plot are illustrated in Supplemental in Figure 3. In addition, we further compared the infection rate between with staples and with suture for skin closure after total hip arthroplasty. Data regarding infection after total hip arthroplasty were reported in three studies (11, 12, 27). After total hip arthroplasty, 5 out of 231 patients in the staples group were infected, while 1 out of 234 patients in the suture group. However, The fixed-effects meta-analysis showed no significant difference in infection rate between two groups after total hip arthroplasty, with OR (Odds Ratio) of 2.61 (95% CI 0.60 to 11.41; p=0.20) and no heterogeneity ($\chi^2=2.10; I^2=5%; P=0.35$). The Forest plot are illustrated in Figure 4. All Pooled outcomes comparing staples to suture for skin closure after arthroplasty are listed in Table 3.

**Discharge**

Overall 4 studies (6, 11, 13, 27) reported the discharge after hip arthroplasty. All of them show there were no significant difference in discharge rate after hip arthroplasty between staples group and suture group. However, the fixed-effects meta-analysis of all 4 trials revealed that the risk of discharge lower with suture than with staples for skin closure after hip arthroplasty. The Odds Ratio of discharge was 2.73 (95% CI, 1.07 to 6.95; P = 0.03), and there was no heterogeneity ($\chi^2=1.43; I^2=0%; p=0.70$). The Forest plot is listed in Figure 5.

**Abscess**

Two study (13, 27) compared number of participant whose wound formed an abscess after hip arthroplasty. A total of 321 patients, only one patient in suture group formed an abscess. The OR-based models revealed that skin staples were associated with a similar abscess rate to an sutures (OR=0.30; 95% CI 0.01–7.54; P=0.46) with no heterogeneity. The Forest plot are illustrated in Figure 6.

**Wound dehiscence**

Data regarding wound dehiscence were reported in two studies (12, 13). Only one patient had a wound dehiscence. The fixed-effects meta-analysis of 2 trials revealed that there was no significant difference in the risk of wound dehiscence between the two group after hip arthroplasty (OR=0.42; 95% CI 0.02–10.41; P=0.60) with no heterogeneity. The Forest plot are illustrated in Figure 6.

**Allergic reaction**

There were two trials (11, 27) reported the allergic reaction. Two out of 300 patients appear allergic reaction and our finding shows that there was no significant difference in the risk of allergic reaction between staples group and suture group after hip arthroplasty (OR=0.39; 95% CI 0.09–1.69; P=0.21; heterogeneity: $\chi^2=0.03; P>0.86; I^2=0$). The Forest plot are illustrated in Figure 6.

**Inflammation**

A total of two trials (6, 13) reported inflammation. In staples group, there were sign of inflammation in 12 patients from 128 participant, while only were seven patients from 158 participant have the sign of inflammation. However, our pooled result revealed that the differences noted between group A and group B were not statistically significant (OR=3.78; 95% CI 0.05–317.93; $P=0.56$; heterogeneity: $\chi^2=7.43, P=0.006, I^2=87$). Because the heterogeneity is more than 50%, so we choose the fixed-effects model. In addition, there is no more data to support our further sensitivity or subgroup analysis. The Forest plot are illustrated in Figure 7.

**Systematic Review**

In addition to the six outcomes assessed in our study, four other secondary outcomes (length of stay, Holland Wound Assessment Score, closure time and visual analogue score) were compared in the systematic review section of our study. Because these included trials do not provide appropriate data types to conduct a meta-analysis.

**Wound closure time**

Two studies reported the time required to close different layers of tissue. Khan, R. J. et al (27) and Rui, M. et al (12) both indicated that wound closure with skin staples was significantly faster than with suture. The data about wound closure time with skin staples or suture are listed in Table 4.

**Length of stay**

Three studies indicated the length of stay in hospital for wound closure with skin staples or suture after hip arthroplasty. Khan, R. J. et al (27) and Lu, Y. et al (13) both showed that there were no significant difference in the median length of stay in hospital. However, Rui, M. et al (12) reported length of stay in hospital in staples group compared with suture group. The median and Interquartile range of length of stay in hospital are listed in Table 4.

**HWES (Hollander Wound Evaluation Score)**

There were two studies used Hollander Wound Evaluation Score to evaluate wound after hip arthroplasty. In the two articles (12, 27), The HWES of staples group was lower than that of suture group, but there was no significant difference in Holland's wound evaluation score. The Hollander Wound Evaluation Score are listed in Table 4.
VAS (visual analogue scale): Two studies (12, 27) use visual analogue scale (VAS) to evaluate satisfaction of patients with skin wound closure methods. The study Khan et al judged that patient satisfaction with skin closure technology was assessed with the Visual Analogue Scale (VAS) between 0 and 100, of which 100 expressed the greatest satisfaction, while Rui, M et al was assessed with the Visual Analogue Scale (VAS) between 0 and 10 expressed the greatest satisfaction, of which 10 indicated the greatest satisfaction. Both of them reported that there was no significant difference in the satisfaction of patients for staples group and suture group after hip arthroplasty. The Visual Analogue Scale (VAS) are listed in Table 4.

Discussion

Hip arthroplasty is the ultimate treatment for debilitating hip joint disease. In recent years, the number of hip replacement has been increasing. (2). The main goal of the skin closure in hip arthroplasty is to obtain an adequate closure and fast healing, with an acceptable appearance and to reduce complications; delayed healing, dehiscence, hematoma and infection (10, 28). There are many kinds of skin closure methods in hip arthroplasty, staples and sutures have served as a primary method of superficial skin closure in hip arthroplasty (29). At present, there is no clear clinical guideline for the method skin closure after hip arthroplasty. Overall, our aim of this system review and meta-analysis was to provide valuable information about Sutures versus staples for wound closure in hip arthroplasty. In the present study, we evaluated infection, prolonged discharge, abscess, wound dehiscence, allergic reaction, inflammation, wound closure time, length of stay in hospital, Hollander Wound Evaluation Score, patient's satisfaction with skin closure methods from four eligible RCTs and one retrospective cohort trial that compared outcomes with staples or suture for skin wound closure after hip arthroplasty.

In the present study, we find that the risk of infection with sutures was less than three times that with staples for skin closure after hip arthroplasty. However, all the studies we have included show that there was no significant difference in the risk of infection after hip arthroplasty comparing sutures to staples was found. We find our pooled result were similar to a previous meta-analysis by Smith, T. O. et al (19), they reported that after orthopedics surgery, the risk of wound infection is significantly higher when the skin wound is closed with staples rather than suture, especially in patients who undergo hip surgery. Meanwhile, the study Shetty et al (30) also showed that the incidence of superficial wound infection was significantly higher when metal staples were used to suture skin wounds after hip fractures. In addition, our meta-analysis show that there were no significant difference in the infection rate between two groups after total hip arthroplasty, which were consistent with three RCTs. Surgical site infection increases the burden of the health care system, increases the length of stay, re-hospitalization rate and the cost of health care, and adversely affects the quality of life and function of patients (31). So our meta-analysis results may be helpful for the choice of skin wound closure methods between staples and suture for hip arthroplasty. However, there are still some potential prognostic factors that remain uncertain. For example, surgical techniques, expertise, aseptic techniques, antibiotic time and patient-specific prognostic factors (such as body mass index) may also influence surgical site infection risk (32). So we need more high quality randomization, blinding, adequate length of follow-up RCTs to be published and then included in our analysis to help us choose skin wound closure methods between staples and suture after hip arthroplasty. In the meantime, our finding suggests that the prolonged wound discharge rate was significant lower in suture group. But all of the included studies in this study were report that there was no significant difference when compared discharge rate between staples group and suture group. Our result and other previous study show that the skin wound closed with staples was more resistant to infection and then affect wound healing and wound discharge (33). Beside, many potential factors, such as the accuracy of skin of the dermal margins and doctor's skill, may affect the exudation of wound discharge (34).

In addition, we compare the incidence of abscess, wound dehiscence, allergic reaction and inflammation between the two group and our analysis found that there were no significant difference in this outcome between the staples group and suture group. Our result lends support to the conclusions by Krishnan, R. et al (18) in which they reported that there no significant difference in allergic reaction, inflammation, dehiscence, and abscess formation between the two groups after orthopedic surgery. However, it is important to note that only two RCTs analyzed LOS (Length of stay), allergic reaction, inflammation, dehiscence, and abscess formation between the two groups. Finally, our systematic review results show that there was no significant difference in HWES and patient's satisfaction with skin wound closure methods after hip arthroplasty. So this is not the factor that affects our choice of skin closure methods after hip arthroplasty. Khan, R. J. et al (27) and Lu, Y. et al (13) both showed that there were no significant difference in the median length of stay in hospital. However, Rui, M. et al (12) reported the median (interquartile range) of length of stay in hospital (day) in staples group was 12 (11-13) and 6.0 (5-8) in sutures group. The results do suggest that the length of hospitalization of the suture needle may be slightly longer than that of skin suture. Khan et al (27) reported an estimated two-minute savings in skin suture with staples for skin closure. Rui, M (12) also reported that the use of staples for skin closure can save about five minutes compared with sutures. The results do suggest that the use of suture needles may be slightly faster than that of skin sutures after hip arthroplasty.

Although this analysis selected 5 studies, the different studies comparison outcome with different method, we try our best to analyze the data that can be included. The limitations of this meta-analysis and systematic review involve restrictions on the small number of included high-quality RCTs, Unified surgical management program and rehabilitation program as well as publishing language. Some literatures or guides have well documented the distorting effects of location bias and publication bias on system evaluation and meta-analysis (35-37). The poor quality of evidence methods reduces the quality of evidence in meta-analysis. Because of some characteristics of surgical techniques, orthopedic surgeons can not cause blindness. Therefore, attention should be paid to interpreting the estimates of this meta-analysis. Future research should focus on high-quality randomized controlled trials. Detailed baseline characteristics and detailed patient recruitment flow charts should be provided.

Conclusion

In summary, the meta-analyses and systematic reviews suggested that the risk of infection and prolonged discharge higher with staples than with sutures for skin closure after hip arthroplasty. Meanwhile, there was no significant difference in allergic reaction, inflammation, dehiscence, abscess formation, Hollander Wound Evaluation Score and satisfaction of patients with skin wound closure methods between the two groups after hip arthroplasty. However, the suture group may require operating surgical time.
Abbreviations List

SSIs - Surgical site infections
RCTs - randomized controlled trials
H - high
L - low
U - unclear
NOS - Newcastle-Ottawa scale
95% CIs - 95% confidence intervals
OCA- 2-octylcyanoacrylate
OR-Odds Ratio
HWES - Hollander Wound Evaluation Score
VAS- visual analogue scale
AR- Androgen Receptor
LOS - Length of stay
