Geographic Gossip on Geometric Random Graphs via Affine Combinations

Abstract

In recent times, a considerable amount of work has been devoted to the development and analysis of gossip algorithms in Geometric Random Graphs. In a recently introduced model termed “Geographic Gossip,” each node is aware of its position but possesses no further information. Traditionally, gossip protocols have always used convex linear combinations to achieve averaging. We develop a new protocol for Geographic Gossip, in which counter-intuitively, we use non-convex affine combinations as updates in addition to convex combinations to accelerate the averaging process. The dependence of the number of transmissions used by our algorithm on the number of sensors \(n\) is \(n \exp(O(\log \log n)^2) = n^{1+o(1)}\). For the previous algorithm, this dependence was \(\tilde{O}(n^{1.5})\). The exponent \(1+ o(1)\) of our algorithm is asymptotically optimal. Our algorithm involves a hierarchical structure of \(\log \log n\) depth and is not completely decentralized. However, the extent of control exercised by a sensor on another is restricted to switching the other on or off.

1 Introduction

Geometric Random Graphs have become an accepted model for wireless ad hoc and sensor networks. Due to applications in distributed sensing, a significant amount of effort has been directed towards developing energy efficient algorithms for information exchange on these graphs. The problem of distributed averaging has been studied intensively because it appears in several applications such as estimation on ad hoc networks, and encapsulates many of the difficulties faced in asynchronous distributed computation. Let \(v_1, \ldots, v_n\) be \(n\) points independently chosen uniformly at random from a unit square in \(\mathbb{R}^2\). A Geometric Random Graph \(G(n, r)\) is obtained from these points by connecting any two points within
Euclidean distance $r$. A Gossip Algorithm is an averaging algorithm that, after a certain number of information exchanges and updates, leaves each node with a value close to the average of all the originally held values.

### 1.1 Related Work

There is an extensive body of work surrounding the subject of gossip algorithms in various contexts. Here, we only survey the results relevant in a narrow sense to the question under consideration.

Gupta and Kumar [4] gave conditions under which $G(n, r)$ is connected with high probability (w.h.p.). It is sufficient that $r$ scales as $\Omega(\sqrt{\frac{\log n}{n}})$ in order that $G(n, r)$ be connected with probability greater than $1 - n^{-\Theta(1)}$.

A distributed Gossip Algorithm for arbitrary graphs was presented by Boyd et al [1]. In this algorithm, when the clock of a sensor $s$ ticks, $s$ sends its value $x_s$ to a sensor $v$ chosen uniformly at random from its neighbors, and receives the value $x_v$ of $v$. Thereafter $s$ and $v$ set their values to $\frac{x_s + x_v}{2}$. The dependence of the number of transmissions required by this algorithm on $n$ is $\tilde{O}(n^2)$. The performance was related to the mixing time of the natural random walk on that graph. In fact they showed that if the connectivity graph is $G$, the number of transmissions made in the course of the algorithm is $\Theta(n T_{mix}(G))$, where $T_{mix}(G)$ is the mixing time of $G$.

In the standard framework for modeling sensor networks, $n$ sensors are placed at random on a unit square $\Box$ and have a radius of connectivity $r = \Theta(\sqrt{\frac{\log n}{n}})$. One does not assume that a sensor possesses any information about its own location. In this model, the number of transmissions that the best known algorithm uses is $\tilde{O}(n^2)$ as described above.\(^1\)

A more powerful model was proposed by Dimakis et al [5], wherein each sensor is aware of its own location with reference to $\Box$, but possess no further information. It is mentioned in [5] that this is reasonable in typical scenarios. With this model, by exploiting geographic information, they were able to provide an algorithm that requires $\tilde{O}(n^{1.5})$ transmissions. In their algorithm, each node exchanges its value with the node nearest to a position chosen randomly on $\Box$, and both nodes replace their values by the average as in the algorithm of Boyd et al [1]. Rejection sampling is used to make the distribution roughly uniform on nodes. The routing takes $\tilde{O}(\sqrt{n})$ hops w.h.p, but since the mixing time on the complete graph is $O(1)$, one obtains an algorithm using $\tilde{O}(n^{1.5})$ transmissions, which is an improvement over [1] by a factor of $\tilde{O}(\sqrt{n})$.

A natural approach to obtaining more efficient algorithms would be to engage in long-range

\(^1\)In using $\tilde{O}$, we ignore polylogarithmic factors and depending on context, the dependence on parameters other than $n$. 

information exchanges less frequently than short-range ones. However, it appears that the benefit derived from an improved mixing time with long-range transmissions more than compensates for the additional cost in terms of hops for a long-range routing. Due to this fact, simply altering the probability distribution with which a node picks targets seems to be counterproductive.

1.2 Our Contribution

An affine combination of two vectors \( \mathbf{a} \) and \( \mathbf{b} \) has the form \( \alpha \mathbf{a} + (1 - \alpha) \mathbf{b} \). Unlike the case of convex combinations, \( \alpha \) need not belong to \([0, 1]\). We introduce counter-intuitive update rules which are affine combinations rather than convex combinations (with coefficients possibly as large as \( \Omega(\sqrt{n}) \)) to achieve faster averaging. The total number of transmissions used by the proposed algorithm in order that the \( \ell_2 \)-distance of the output from the average diminish by a multiplicative factor of \( \epsilon \) w.h.p. is \( n \exp(\O((\log \log n) \log \log \frac{1}{\epsilon})) \). When \( \epsilon = \exp(\frac{n \log \log n}{\sqrt{n}}) \) the number of transmissions is \( n^{1+o(1)} \). The exponent \( 1+o(1) \) is asymptotically optimal, since every node must make at least one transmission for an averaging algorithm to work. Like previous algorithms, ours makes packet exchanges with random nodes. Due to the instability introduced into the system by the use of non-convex combinations, for the present analysis to hold, a certain amount of control needs to be exercised and our algorithm is not truly decentralized. However, the extent of control exerted by any sensor on another is restricted to switching the other on or off.

2 Preliminaries

The standard model for a sensor network is as follows. We assume that each node or sensor has a clock that is a Poisson process with rate 1, and that these processes are independent. This model is equivalent to having a single clock that is Poisson of rate \( n \), and assigning clock ticks to nodes uniformly at random. We assume that the time units are adjusted so communication time between any two adjacent nodes is insignificant in comparison with the length of an average time slot \( n^{-1} \). Our algorithm involves packet forwarding when two non-adjacent nodes communicate. We shall assume that the time taken to forward a packet is also insignificant in comparison with \( n^{-1} \), and that a single packet exists in the network in each time slot w.h.p.. We assume some limited computational power, which amounts to memory of logarithmic size, and the ability to do floating point computations.

For our purposes, a Geometric Random Graph is defined in the following way. Let \( v_1, \ldots, v_n \) be \( n \) points independently chosen uniformly at random from a unit square in \( \mathbb{R}^2 \). A Geometric Random Graph \( G(n, r) \) is obtained from these points by connecting any two points within Euclidean distance \( r \).
2.1 Problem Statement

Let node $v_i$ for $i = 1, \ldots, n$ hold a value $x_i(t)$ at the $t^{th}$ global clock tick, the initial values being $x_i(0)$. Without loss of generality, we assume $x(0) = 0$. Given $\epsilon, \delta > 0$, the task is to design an algorithm such that $\|x(t)\| < \epsilon\|x(0)\|$ for all possible choices of $x(0)$ with probability $> 1 - \delta$. The cost of the algorithm is the expected number of transmissions made until $t$.

In the rest of the paper, we shall make the standard assumption that the radius of connectivity $r(n) = \Theta\left(\sqrt{\frac{\log n}{n}}\right)$ (eg [5]). Under this assumption, the probability of the graph $G(n, r)$ being disconnected is $\Omega(n^{-O(1)})$, for an appropriate constant $a$. As a consequence, it is not possible to drive $\delta$ below $n^{-O(1)}$. For this reason, in the analysis, we shall assume that $\delta = n^{-O(1)}$. On the other hand $\epsilon$ can be made arbitrarily small by running the averaging algorithm for a sufficiently long interval of time. In this paper, we shall assume that $\log \frac{1}{\epsilon} = n^{o(1)} \log \log n$. This does not allow $\epsilon$ to be exponentially small but permits it to be the reciprocal of a quasipolynomial. A sufficiently large constant $a$ will appear in the parameters of our algorithm described later. When we use the term high probability, we shall mean with probability $1 - n^{-\Theta(1)}$.

3 Overview of Algorithm

Let $\Box$ be the unit square in which the $n$ sensors are randomly placed. Let the initial values carried by sensors be $x_i(0)$, for $i = 1$ to $n$. We consider a partition of $\Box$ into $\sim n^{1/2}$ smaller squares $\Box_i$. Let $\Box_i$ contain $\#(\Box_i)$ sensors. Let $time(n)$ represent the expected number of transmissions until $\|x(t)\| \leq \epsilon\|x(0)\|$ w.h.p., where $\epsilon$ is some function of $n$ that we shall not investigate at the moment. Suppose that we had a "nearly perfect" averaging protocol $A$ on the smaller squares $\Box_i$, i.e. when $A$ is run on each square, after $t = time_A(\sqrt{n})$ transmissions, within $\Box_i$ the values are for practical purposes equal to the average of the original values. That is,

$$(\forall i)(\forall s \in \Box_i)x_s(t) \simeq \frac{\sum_{s \in \Box_i} x_s(0)}{\#(\Box_i)}.$$  

Definition 1 For each square $\Box_i$, let $s(\Box_i)$ be the sensor closest to the center of $\Box_i$.

This can be determined by each square, using a constant number of transmissions w.h.p.

The $s(\Box_i)$ exchange values among themselves by Greedy Geographic Routing (see [5]).

Consider the following protocol. Suppose that $A$ has been run on each subsquare of the form $\Box_i$ independently, and the values carried by the nodes within $\Box_i$ are all equal. When $s(\Box_i)$
becomes active, the following round takes place.

1. $s_i := s(\Box_i)$ picks a square $\Box_j$ uniformly at random. $s_i$ geographically routes a packet with its value to $s_j := s(\Box_j)$.

2. $s_j$ routes its own value to $s_i$ by greedy geographic routing.

3. $x_{s_i} \leftarrow x_{s_i} + \frac{2\sqrt{n}}{5} (x_{s_j} - x_{s_i})$.

4. $x_{s_j} \leftarrow x_{s_j} + \frac{2\sqrt{n}}{5} (x_{s_i} - x_{s_j})$.

5. $\mathcal{A}$ is independently run on $\Box_i$ (the process being activated by $s_i$ by switching certain nodes on) and on $\Box_j$ (initiated by $s_j$ similarly).

6. $\mathcal{A}$ is ended on square $\Box_i$ by $s_i$ (by turning certain nodes off), and $\mathcal{A}$ is ended on $\Box_j$ by $s_j$ (by switching certain nodes off.)

Now, let $z_i(t) := \sum_{s \in \Box_i} x_s(t)$. Without loss of generality, we assume that $\sum_i x_i = 0$, since this only adds a constant offset and does not affect the rate of convergence. An application of the Chernoff Bound tells us that $(\forall i) \left| \frac{\#(\Box_i)}{\sqrt{n}} - 1 \right| < \frac{1}{10}$ w.h.p. If we examine the evolution of $z$, we see that after a round of the kind described above

- $z_i(t) = (1 - \alpha_i)z_i(t-1) + \alpha_j z_j(t-1)$
- $z_j(t) = (1 - \alpha_j)z_j(t-1) + \alpha_i z_i(t-1)$

where $\forall i, \alpha_i \in (\frac{1}{2}, \frac{3}{5})$. From Lemma 1, it follows that

$$\mathbb{E}[\|z(t)\|^2] < (1 - \frac{1}{2\sqrt{n}})^t \|z(0)\|^2$$. Roughly speaking after $O(\sqrt{n} \log(\frac{n}{\epsilon}))$ of these steps, we have a distribution $x(t')$ such that $\|x(t')\| < \epsilon \|x(0)\|$.

Each geographical routing mentioned above takes $O(\sqrt{n})$ transmissions w.h.p (see [5]). Also, each process of initiating or ending $\mathcal{A}$ on a square $\Box_i$ takes $O(\sqrt{n})$ transmissions.

So, the total number of transmissions with $n$ nodes $\text{time}(n)$ satisfies a recurrence of the form:

$$\text{time}(n) \leq O \left( \sqrt{n} \log(\frac{n}{\epsilon}) (\text{time}_{\mathcal{A}}(\sqrt{n}) + O(\sqrt{n})) \right)$$.

Ignoring the dependence on $\epsilon$, it would allows us to recursively define the algorithm $\mathcal{A}$ on $\Box$, for which $\text{time}_{\mathcal{A}}(n) = n \exp(O(\log \log n))$. 

5
4 Description of the Algorithm

4.1 Notation

The square $□$ is partitioned into $n_1$ subsquares $□_{i_1}$, where $n_1$ is the nearest integer to $\sqrt{n}$ that is the square of an even number. For a square $□_{i_1...i_r}$, let $E_{#□_{i_1...i_r}}$ denote the expected number of sensors within $□_{i_1...i_r}$. Then, while $E_{#□_{i_1...i_r}} > (\log n)^8$, the square $□_{i_1...i_r}$ is partitioned into $n_{r+1}$ subsquares $□_{i_1...i_{r+1}}$, where $n_{r+1}$ is the nearest integer to $\sqrt{E_{#□_{i_1...i_r}}}$ that is the square of an even number. Let

\[ \ell := 1 + \sup_{□_{i_1...i_r}} r, \]

i.e. the number of levels in this recursion. Given a square $□_{<i>}$, let $s(□_{<i>})$ denote the sensor nearest to its center. By our construction, these centers are well separated, and any sensor has this property with respect to at most one square w.h.p.. We shall denote this by $□(s)$. We assign a Level to each node by the following rule: If $s = s(□_{i_1...i_r})$, $s$ has level $\ell - r$. These nodes are have Levels 1, ..., $\ell$. There is a single root node at Level $\ell$, namely $s(□)$. The nodes at Level 0 are the nodes not of the form $s(□_{i_1...i_r})$. In the informal discussion earlier, we did not concern ourselves with the error in the averaging carried out on subsquares $□_{i_r}$. However, these errors propagate up the hierarchy rapidly, and hence it is necessary to obtain results with greater accuracy in smaller squares. Thus we define the desired accuracy recursively. Let $\epsilon_r$ be the accuracy for the averaging process in a square $□_{i_1...i_{r-1}}$. Lemma 2 tells us that it is sufficient to take $\epsilon_r$, to be $\frac{\epsilon_{r-1}}{\text{poly}(n)}$ for a polynomial of sufficiently large degree.

Let $\epsilon_0 = \epsilon$, $\delta_0 = \delta$. We recursively define $\epsilon_{r+1} := \frac{\epsilon_r}{25n^{2+a}}$ and $\delta_{r+1} = \frac{\delta_r}{n^{2+a}}$.

We define $\text{time}(n, \ell - 1, \epsilon_r, \delta_r)$ to be $\left( (\log \frac{n}{\epsilon_{r-1}}) \log(\delta_{r-1}^{-1}) \right)^{16}$. Thereafter, we define $\text{time}(n, r - 1, \epsilon_{r-1}, \delta_{r-1}) := \text{time}(n, r, \epsilon_r, \delta_r)n^a \left( (\log \frac{n}{\epsilon_r}) \log(\delta_r^{-1}) \right)^{16}$.

Let $s \in □_{i_1...i_{r-1}}$.

4.2 The Protocol

Every node $s$ has two states, a $\text{local.state}$ and a $\text{global.state}$, both of which are initially $= \text{off}$, but can also take the value $\text{on}$. Each node $s$ possesses a private counter $\text{counter}(s)$. During initialization, the $\text{global.state}$ of $s(□)$ is set to $\text{on}$ but every other $\text{global.state}$ is 0. The $\text{local.state}$ of all nodes is set to $\text{off}$ at this juncture.

Let us suppose that the clock of $s$ ticks. We describe the protocol followed by it below. We consider two cases. If $s$ is at Level 0, it obeys the following protocol: {
1. If $\text{local.state}(s) = \text{on}$
   $\text{Near}(s)$;
}

$\text{Near}(s)$

1. $s$ picks an adjacent node $v$ contained in $\square_{i_1 \ldots i_{\ell-1}}$ uniformly at random.

2. $s$ sets $x_s(t + 1) = \frac{x_s(t) + x_v(t)}{2}$;
   $v$ sets $x_v(t + 1) = \frac{x_s(t) + x_v(t)}{2}$;
}

We next describe the protocol if $s$ is at a Level greater than 0. The subroutine $\text{Near}$ is the same as above. Let $\square(s) =: \square_{i_1 \ldots i_r}$.

1. If $\text{global.state}(s) = \text{on}$

   (a) If $\text{counter}(s) = 0$ $\text{Activate.square}(s)$;
   (b) With probability $n^{-a} \text{time}(n, r, \epsilon, \delta)^{-1}$
       
       - $\text{Far}(s)$;
       - $\text{counter}(s) \leftarrow 0$;

2. If $\text{local.state}(s) = \text{on}$
   $\text{Near}(s)$;

3. If $\text{counter}(s) \geq \text{time}(r, n, \epsilon, \delta)$ $\text{Deactivate.square}(s)$;
   Else $\text{counter}(s) \leftarrow \text{counter}(s) + 1$;
}

$\text{Far}(s)$

1. $s$ picks a square $\square_{i'_1 \ldots i'_r} \nsubseteq s$ uniformly at random. Let $s' := s(\square_{i'_1 \ldots i'_r})$. Node $s$ routes its value to $s'$ geographically.

2. $x_s(t + 1) = x_s(t) + \frac{2}{\delta}(\mathbb{E}_{\# \square_{i_1 \ldots i_r}} x_{s'}(t) - \mathbb{E}_{\# \square_{i_1 \ldots i_r}} x_s(t))$.

3. $s'$ sends back to a packet with its value $x_{s'}(t)$ to $s$ by greedy geographic routing.

4. Node $s$ computes $x_s(t + 1) = x_s(t) + \frac{2}{\delta}(\mathbb{E}_{\# \square_{i_1 \ldots i_r}} x_{s'}(t) - \mathbb{E}_{\# \square_{i_1 \ldots i_r}} x_s(t))$. 

7
5. \( counter(v) \leftarrow 0. \)

}\n
\text{Activate.square}(s)\{

1. If \( s \in \text{Level } 1 \), send packets to each node \( s' \) in \( \square(s) \) setting \( \text{local.state}(s') \leftarrow \text{on} \) by flooding.

2. If \( s \in \text{Level } i > 1 \), send packets to each Level \( i-1 \) node \( s' \) in \( \square(s) \) by greedy geographic routing, setting \( \text{global.state}(s') \leftarrow \text{on} \).

\}

\text{Deactivate.square}(s)\{

1. If \( s \in \text{Level } 1 \), send packets to each node \( s' \) in \( \square(s) \) setting \( \text{local.state}(s') \leftarrow \text{off} \) by flooding.

2. If \( s \in \text{Level } i > 1 \), send packets to each Level \( i-1 \) node \( s' \) in \( \square(s) \) by greedy geographic routing, setting \( \text{global.state}(s') \leftarrow \text{off} \).

\}

5 Analyzing the number of Transmissions

Let \( H(n, r, \epsilon_r, \delta_r) \) denote the number of transmissions used in our protocol in one round of \( \square_{i_1 \ldots i_r} \), in order to diminish the variance (of the values carried by sensors in \( \square_{i_1 \ldots i_r} \)) by a factor \( \epsilon_r \), with probability \( 1 - \delta_r \).

\textbf{Observation 1} In one round, i.e. the duration between \( s \) activating \( \square(s) := \square_{i_1 \ldots i_r} \) and deactivating \( \square(s) \), the number of long-range packet exchanges between sensors of the kind \( s(\square_{i_1 \ldots i_r, i_{r+1}}) \) is \( \Theta \left( \tilde{n} \log \left( \frac{n}{\epsilon_r} \right) \right) \) w.h.p, where

\[ \tilde{n} = \frac{\mathbb{E}[\#(\square_{i_1 \ldots i_r})]}{\mathbb{E}[\#(\square_{i_1 \ldots i_r, i_{r+1}})]}. \]

Each of these involves \( O(\sqrt{\mathbb{E}[\#(\square(s))]})\tilde{n} \) hops w.h.p (see [5]). Therefore the total number of transmissions here is \( O \left( \tilde{n}^2 \log \left( \frac{n}{\epsilon_r} \right) \right) \) w.h.p.
Each of these long-range packet exchanges is followed by a period of averaging within the involved subsquares, and this takes $H(n, r + 1, \epsilon_{r+1}, \delta_r) = \Omega(\tilde{n})$ transmissions. Thus we have the recurrence

$$H(n, r, \epsilon_r, \delta_r) = O\left( (H(n, r + 1, \epsilon_{r+1}, \delta_{r+1}) + \tilde{n}) \log(\frac{\tilde{n}}{\epsilon_r}) \right)$$

$$= O\left( H(n, r + 1, \epsilon_{r+1}, \delta_{r+1}) \tilde{n} \log(\frac{\tilde{n}}{\epsilon_r}) \right).$$

As mentioned in subsection 4.1, we let $\epsilon_0 = \epsilon$, $\delta_0 = \delta$ and recursively define $\epsilon_{r+1} := \frac{\epsilon_r}{2^{\delta_0 n^{\frac{1}{2}}}}$ and $\delta_{r+1} = \frac{\delta_0}{n^2}$. For these parameters, $\delta_r = \Omega(\frac{1}{\text{poly}(n)})$, since $\delta_0 = \Omega(\frac{1}{\text{poly}(n)})$ and the $\tilde{n}$ telescope. $\epsilon_r = \epsilon_0 \Omega(n^{-O(\log \log n)})$ since $\ell \sim \log \log n$. Now, the smallest squares that we create have $O(\text{polylog} n)$ sensors each w.h.p. Since the ordinary averaging that we do there (described by the procedure 'Near(s)') has an averaging time that is quadratic \cite{1,2}, $H(n, \ell, \epsilon_\ell, \delta_\ell) = \Omega(\text{polylog}(\frac{n}{\epsilon_\ell})).$ And so using the recurrence for $H$ and telescoping, we see that the total number of transmissions is

$$H(n, 0, \epsilon_0, \delta_0) = (H(n, \ell, \epsilon_{r+1}, \delta_{r+1})) \prod_r \left( \frac{\mathbb{E}_{\# \square_{i_1...i_r}}}{\mathbb{E}_{\# \square_{i_1...i_r, i_{r+1}}} \log n} \frac{\epsilon}{\epsilon_r} \right)$$

$$= n \left( \log \frac{n}{\epsilon} \right)^{O(\log \log n)}.$$

This is $n^{1+o(1)}$ if $\epsilon = \exp(-n^{\frac{o(1)}{\log \log n}})$, and $\delta = n^{-O(1)}$.

### 6 Notes on Correctness

In the algorithm proposed in this paper, each square $\square(s)$ has a certain latency, which is the averaging time restricted to that square. In order for our algorithm to be correct, we require that $\square(s)$ be undisturbed by the long-range exchanges that $s$ is involved in, during this period. This is not a condition that can be imposed without the long-range exchanges of $s$ losing their i.i.d property, which is crucial in our analysis of convergence. In order to retain this, and have an algorithm that is successful w.h.p we have set the rates at which long-range exchanges of $s$ occur to be lower than the inverse of the latency by a factor $n^a$. As a consequence, w.h.p, in the course of the entire algorithm, there are no long-range transmissions made by any node $s$ while $\square(s)$ is active. The only issue that we have not dealt with in detail is of showing that our choice of errors $\epsilon_r$ achieves the desired end. This follows from Lemma \cite{2} interpreted as follows: The nodes $i$ represent subsquares $\square_{i_1...i_r, i_{r+1}}$ of $\square_{i_1...i_r}$ and the $y_j(t)$ for different $j$ represent the sum of the values held by the nodes in a subsquare $\square_{i_1...i_r, j}$ after $t$ long distance transmissions between subsquares since the activation of $\square_{i_1...i_r}$. We set $\epsilon := \epsilon_{r+1} ||x(0)||$. The perturbations $n(t)$ represent the errors generated from imperfect averaging within these subsquares.
7 Concluding Remarks

We introduced non-convex affine combinations, in our averaging protocol in order to accelerate Geographic Gossip in Geometric random graphs. The number of transmissions used in the course of our protocol is \( n^{1+\alpha(1)} \). This exponent is asymptotically optimal. Our algorithm, unlike the previous one in [5], is not completely decentralized. However as far as we can see, this is not a necessary feature associated with the use of affine combinations.

8 Future Directions

It would be interesting to study whether affine combinations can be used to develop a completely decentralized algorithm for Geographic Gossip that is also energy efficient.

A Appendix

Let $K_n$ be the complete graph on $n$ vertices $\{1, \ldots, n\}$. $\forall i$, let $\alpha_i \in (\frac{1}{3}, \frac{1}{2})$. At time $t \geq 0$, for $i = 1, \ldots, n$, let node $i$ hold the value $x_i(t)$. Consider the following update rule. If the $i^{th}$ clock tick belongs to node $i$, then, $i$ chooses a node $j$ uniformly at random, and the following update occurs:

- $x_i(t) = (1 - \alpha_i)x_i(t - 1) + \alpha_jx_j(t - 1)$.
- $x_j(t) = (1 - \alpha_j)x_j(t - 1) + \alpha_ix_i(t - 1)$.

Lemma 1 $\mathbb{E}[\mathbf{x}(t)^T \mathbf{x}(t)] < (1 - \frac{1}{2n})^t \mathbf{x}(0)^T \mathbf{x}(0)$.

Proof: Let the update rule for $\mathbf{x}(t)$ be given by $A(t - 1)$, i.e. $\mathbf{x}(t) = A(t - 1)\mathbf{x}(t - 1)$. Note that $A(t - 1) = I - (\alpha_i \mathbf{e}_i - \alpha_j \mathbf{e}_j)(\mathbf{e}_i^T - \mathbf{e}_j^T)$, if the $i^{th}$ vector of the standard basis is denoted by $\mathbf{e}_i$.

\[
\mathbb{E}[\mathbf{x}(t)^T \mathbf{x}(t)|\mathbf{x}(t-1)] = \mathbb{E}[\mathbf{x}(t-1)^T A(t-1)^T A(t-1)\mathbf{x}(t-1)|\mathbf{x}(t-1)] = \mathbf{x}(t-1)^T \mathbb{E}[A(t-1)^T A(t-1)] \mathbf{x}(t-1).
\]

Let $\alpha_i \mathbf{e}_i - \alpha_j \mathbf{e}_j = \alpha_{ij}$ and $\mathbf{e}_i - \mathbf{e}_j = \mathbf{e}_{ij}$. Then, $\mathbb{E}[A(t-1)^T A(t-1)] = \mathbb{E}[(I - \mathbf{e}_{ij} \alpha_{ij}^T) (I - \mathbf{e}_{ij} \alpha_{ij}^T)]$.

Let $E_{ij}$ denote the $n \times n$ matrix whose $ij^{th}$ entry is 1 and every other entry is 0.

Then, by expanding, one finds that

\[
\mathbb{E}[A(t-1)^T A(t-1)] = I + \sum_i \frac{(1 - 2\alpha_i)^2 - 1}{n} E_{ii} + \sum_{i \neq j} \frac{(1 - (1 - 2\alpha_i)(1 - 2\alpha_j))E_{ij}}{n(n-1)} = I(1 - \frac{1}{n-1}) + \frac{11^T}{n(n-1)} - \frac{(1 - 2\alpha)(1 - 2\alpha)^T}{n(n-1)} + \sum_i \frac{(1 - 2\alpha_i)^2E_{ii}}{n-1}.
\]
An application of the formula for $E[x(t)^T x(t)|x(t-1)]$, now gives us the following:

$$
E[x(t)^T x(t)|x(t-1)] = E[x(t-1)^T A(t-1)^T A(t-1)x(t-1)|x(t-1)] = x(t-1)^T E[A(t-1)^T A(t-1)] x(t-1)
$$

We know that $\forall i, 1 - 2\alpha_i \in (0, \frac{1}{3})$.

Let us upper bound $x(t-1)^T E[A(t-1)^T A(t-1)] x(t-1)$ using the expression for $E[A(t-1)^T A(t-1)]$ derived earlier.

$$
x(t-1)^T I(1 - \frac{1}{n-1}) x(t-1) = (1 - \frac{1}{n-1}) \|x(t-1)\|^2,
$$

$$
x(t-1)^T \frac{11^T x(t-1)}{n-1} = 0,
$$

and

$$
-\frac{x(t-1)^T (1 - 2\alpha)(1^T - 2\alpha^T) x(t-1)}{n(n-1)} \leq 0
$$

Adding up the above inequalities,

$$
E[x(t)^T x(t)|x(t-1)] \leq \left( 1 - \frac{8}{9(n-1)} \right) x(t-1)^T x(t-1).
$$

As a consequence,

$$
E[\|x(t)\|^2 | x(t-1)] < \left( 1 - \frac{1}{2n} \right) \|x(t-1)\|^2.
$$

Successively conditioning on $x(t-2), \ldots, x(0)$, we see that

$$
E[\|x(t)\|^2] < \left( 1 - \frac{1}{2n} \right)^t \|x(0)\|^2.
$$

This proves the lemma. \qed

An application of Markov’s inequality gives us the following corollary.

**Corollary 1**

$$
\mathbb{P}(\|x(t)\| > \epsilon \|x(0)\|) \leq \epsilon^{-2} \left( 1 - \frac{1}{2n} \right)^t.
$$
Proof:

\[
\mathbb{P} (\|x(t)\| > \epsilon \|x(0)\|) = \mathbb{P} \left( \frac{\|x(t)\|^2}{\|x(0)\|^2} > \epsilon^2 \right) \\
\leq \epsilon^{-2} \mathbb{E} \left( \frac{\|x(t)\|^2}{\|x(0)\|^2} \right) \quad \text{(Markov's inequality)} \\
\leq \epsilon^{-2} \left( 1 - \frac{1}{2n} \right)^t
\]

□

An application of Markov’s inequality gives us the following corollary.

**Corollary 2**

\[
\mathbb{P} (\|x(t)\| > \epsilon \|x(0)\|) \leq \epsilon^{-2} \left( 1 - \frac{1}{2n} \right)^t.
\]

We now consider a modified update rule, and prove a lemma similar to Lemma 1.

Let \( K_n \) be the complete graph on \( n \) vertices \( \{1, \ldots, n\} \). \( \forall i \), let \( \alpha_i \in \left( \frac{1}{3}, \frac{1}{2} \right) \). At time \( t \geq 0 \), for \( i = 1, \ldots, n \), let node \( i \) hold the value \( x_i(t) \). Let \( n(0), n(1), \ldots \) be a sequence of real numbers. Consider the following update rule. If the \( t^{th} \) clock tick belongs to node \( i \), then, \( i \) chooses a node \( j \) uniformly at random, and the following update occurs:

- \( y_i(t) = (1 - \alpha_i)y_i(t-1) + \alpha_j y_j(t-1) + n(t-1) \)
- \( y_j(t) = (1 - \alpha_j)y_j(t-1) + \alpha_i y_i(t-1) - n(t-1) \)

**Lemma 2** Suppose that for each \( t \), \( |n(t)| < \epsilon \), and that \( a > 0 \). Then,

\[
\mathbb{P} \left[ \|y(t)\| > n^{\frac{a}{2}} \left( 1 - \frac{1}{2n} \right)^{t/2} \|y(0)\| + 8\sqrt{2n^{3/2}} \epsilon \right] \leq \frac{5}{n^a}.
\]

**Proof:**

\( y(t) = A(t-1)y(t-1) + n(t-1) \), where \( A(t) = I - (\alpha_i e_i - \alpha_j e_j)(e_i^T - e_j^T) \), and \( n(t-1) = n(t-1)(e_i - e_j) \). Let \( x(0) = y(0) \), and let the \( x(t) \) satisfy \( x(t+1) = A(t)x(t) \) as in Lemma 1. We observe that \( y(1) = x(1) + n(0) \) and more generally,

\[
y(t+1) = x(t+1) + n(t) + \sum_{i=0}^{t-1} A(t)A(t-1) \ldots A(i+1)n(i).
\]

13
An application of the triangle inequality now gives us
\[ \|y(t + 1)\| \leq \|x(t + 1)\| + \|n(t)\| + \sum_{i=0}^{t-1} \|A(t)A(t-1)\ldots A(i+1)n(i)\|. \]

Our approach to proving this Lemma is to upper bound each term in the right hand side.

**Observation 2**
\[
\mathbb{P} \left[ \|x(t)\| > (1 - \frac{1}{2n})^{t/2} n^{a/2} \|x(0)\| \right] \leq \left( (1 - \frac{1}{2n})^{t/2} n^{a/2} \right)^{-2} \mathbb{E} \left( \|x(t)\|^2 \right) \leq \left( (1 - \frac{1}{2n})^{t/2} n^{a/2} \right)^{-2} \left( 1 - \frac{1}{2n} \right)^t = \frac{1}{n^a}.
\]

The above inequalities follow from Lemma 1 and Corollary 2. We shall now upper bound the other terms as well with high probability. Using Corollary 2
\[
\mathbb{P} \left[ \frac{\|A(t-1)\ldots A(i)n(i-1)\|}{\|n(i-1)\|} > (1 - \frac{1}{2n})^{i/2} n^{a/2} \right] \leq \left( (1 - \frac{1}{2n})^{i/2} n^{a/2} \right)^{-2} \left( 1 - \frac{1}{2n} \right)^{t-i} = n^{-(a+1)}(1 - \frac{1}{2n})^{t-i}. \]

However,
\[
\sum_{i=1}^{t-1} (1 - \frac{1}{2n})^{i/2} n^{-(a+1)} < \frac{4}{n^a}
\]
and so,
\[
\mathbb{P} \left[ \exists_i \left\{ \frac{\|A(t-1)\ldots A(i)n(i-1)\|}{\|n(i-1)\|} > (1 - \frac{1}{2n})^{i/2} n^{a/2} \right\} \right] \leq \frac{4}{n^a}.
\]

We next observe that
\[
\sum_{i=t}^{t-1} (1 - \frac{1}{2n})^{i/2} n^{a/2} < 8n^{a/2}.
\]

As a consequence we have

**Observation 3**
\[
\mathbb{P} \left[ \sum_i \frac{\|A(t-1)\ldots A(i)n(i-1)\|}{\|n(i-1)\|} > 8n^{a/2} \right] \leq \frac{4}{n^a}.
\]
Once we put the above two observations together and note that $(\forall i)\sqrt{2} \epsilon \geq \|n(i)\|$, an application of the union bound gives

$$\mathbb{P}\left[\|y(t)\| > n^{\frac{3}{2}} \left(1 - \frac{1}{2n}\right)^{t/2} \|y(0)\| + 8\sqrt{2}n^{3/2}\epsilon\right] \leq \frac{5}{n^a}.$$

□
