Abstract: Glyphosate (GLY) and glufosinate ammonium (GLUA) are broad spectrum, non-selective, contact herbicides which are commonly used in fruit farms. Achieving the separation and detection of glyphosate and glufosinate from soil samples by chromatograph are a challenging task as they are ionic and highly water soluble compounds. The aim of this study is conducted to determine the dissipation of GLY and GLUA applied at two dose levels in three depth soils of orange orchards. The residues of GLY and GLUA were determined by HPLC-UV detector. The residual detection limit of GLY and GLUA of the method were 0.03 and 0.05 ng/g in soil respectively. The obtained data indicated that GLY persistent in soil is very short, only for 7 days, following applications of 1 to 2 kg/fed in orange crop. GLUA dissipated in soil within 14 days of application, regardless of dose. The half-life (T/2) of GLY and GLUA were 1.68 and 1.42 days in at 0 cm depth, respectively. There was no significant difference between the half-life of the two herbicides in soil at three depths. These results showed that GLY dissipation occurs rapidly in soil. However, GLUA was moderately persistent in soil. The two compounds tested showed reduction of dry weight for four types of weeds after 14 days of recommended and double rate application.

Keywords: Glufosinate-ammonium, Glyphosate, Herbicide dissipation, Soil, Weeds control

1 Introduction

Glyphosate (N-(phosphonomethyl) glycin)is a non-selective herbicide widely used for the elimination of weeds in aquatic environments, for drying in no-till crops and among rows of perennial crops (Chamkasem and Harmon 2016). It is applied after emergence through aposymplastic translocation. Target of glyphosate enzyme 5-enolpyruvylshikimate-3-phosphate synthase (EPSPS) interfering with the biosynthesis of amino acids (Roberts et al 1998, Carretta et al 2021). Glufosinate (2-amino-4-[hydroxyl (methyl)phosphoryl]butanoic acid), also called phosphinothricin is used throughout the world to control a broad range of broadleaf weeds in fruit orchards, other crops and pre-emergence in vegetables (Royer et al 2000, Chamkasem and Harmon 2016). In soil, glufosinate ammonium is primarily broken down to methyl phosphinico-propionic acid (MPP), which can be further degraded into 2-methylphosphinico-acetic acid. In general, GLY is not metabolized by plants and is therefore not selective, only genetically modified varieties will be resistant consequently, virtually the entire concentration of the active ingredient used hits the soil in its original state (Halim and Kuntom 2013, Nagatomi et al 2013 Janaki et al 2019). Soil degradation in field indicate that GLUA is not very persistent (DTsalab. Corr. 20°C = 6-11 days). The degradation half-life for GLUA in soil ranged from 2.30 to 2.93
days in a field (Zhang et al 2014). Bandana et al 2015, reported that the GLY is slow degraded by microorganisms, it is highly adsorbed by soil and the half-life of GLY was between 5 to 19 days in tea field soil. The degree of degradation of GLY depends on the kind of microbial community found in soil because it degrades easily due to enzymes freed from microbes (Tu et al 2001). Phosphorous content in GLY is responsible for its microbial degradation. because micro-organisms require phosphorus to perform their metabolic functions (Lane et al 2012). Different methods were used in the analysis of glyphosate and glufosinate-ammonium. However, the unique physico-chemical characteristics of glyphosate make it difficult to determine residue concentrations, especially in soils with high levels of organic matter so two extraction methods have been used for detection of glyphosate in soil using tandem mass spectrometry HPLC (De Gerónimo et al 2018. According to Ding et al 2015, glyphosate and its major metabolites were analysed using gas or liquid chromatography combined with mass spectrometry. Zhang et al 2014, detected glufosinate residues in soil by GC-FPD (Flame Photometric Detector) after bypassing TMOA using a molten silica column. The dissipation of GLY and GLUA at different depths and their effect on associated weeds are not investigated under Egyptian conditions on citrus field. The objective of this study is to assess the degradation of GLY and GLUA after treatment at two rates at three depths of soil in orange orchards using HPLC.

2 Material and Method

A field experiment was carried out at the Farm of the Higher Institute for Agricultural Cooperation of Ain Shams University in 2019-2020. The experiment was structured into rows with three replicates per each sample. Commercial formulations of glyphosate (95% SG) and glufosinate ammonium (20% SC) were purchased from SHOURA chemicals (Egypt) Herbicides were sprayed, using a mini sprayer hand Atomizer, control weeds surrounding trees with two rates of application per herbicide 1 and 2 L/Fed for glyphosate while for glufosinate ammonium 2 and 4 L/Fed.

2.1 Sampling of soil

Soil samples were randomly collected at approximately 0, 10 and 25 cm depth at successive intervals, i.e. 0, 3, 7, 14, 35 and 55 days after application. Samples were transferred directly to the laboratory into polyethylene bags and was stored at -20°C until the extraction.

2.2 Sample extraction, clean up and HPLC determination of tested herbicides

Glyphosate: The extraction was performed according to De Gerónimo et al 2018, with slight modifications. Briefly, 1 g soil sample was added to 5 ml of phosphoric acid: Water: methanol (1:1:8). The samples were kept overnight into the extraction solvent then, filtered using filter paper. The humidity was removed from the extract using anhydrous sodium sulfate which was placed on filter paper.

Glufosinate ammonium: The test was performed according to Zhang et al 2014, with slight modifications. Briefly, 1 g soil sample was added to 5 ml of distilled water. The samples were afterwards shaken using a mechanical shaker device for at least an hour, then filtered through filter paper (Whatman No1 H), then 5ml of acetone was added. The separating funnel was agitated vigorously for 3 min. The layer of solvent containing the residue of the herbicide was transferred to a separation funnel, then 10 ml methylene chloride was added and repeated at least 3 times. The extraction solvent was taken to dryness using a rotary evaporator set at 50-55°C. The extraction solvent layer was transferred to the solvent (petroleum ether) for the purification phase.

Clean up: The extracts of both herbicides were cleaned up following the same procedure. A solid phase extraction (SPE) clean up by using cartridge C18 was utilized as reported by Chamkasem and Harmon 2016. C18 cartridge was prepared with methanol follow-up water: methanol (50:50) containing 0.5 ml of sample extract and formic acid both separately, was loaded into the packed cartridge C18. The eluting solution of this conditioning step has been removed. A second step, the sample extract (0.5 ml) was charged into cartridge C18 using eluted water: methanol containing formic acid, the same previous flows. The procedure was repeated 3 times. The elutes were collected into around bottomed flask and then concentrated to dryness. The residues of both glyphosate and glufosinate were dissolved in 1 ml methanol and transferred in vials for HPLC.
2.3 Chromatographic conditions

The extracted samples (1 µL) were injected into the HPLC Agilent Technologies 1100 system under the following conditions: quaternary pump, UV detector. The mobile phase used for glyphosate was 25% methanol: 75% acetonitrile and for glufosinate-ammonium was 10% methyl acetate: 80% acetonitrile and 10% methanol. The mobile flow rate was 3 ml/min. C18: (25 cm length x 4.0 µg particles, x 4.6 mm internal diameters (i.d).

2.4 Recovery study

The reliability of the analytical methods was tested with untreated samples containing known quantities of pesticides studied at concentrations of 0.1, 0.5 and 1 µg. gm⁻¹. The specimens were prepared according to the same extraction and cleaning procedures. The average recovery rates for glyphosate and glufosinate ammonium were 93.38% and 91.71% in soil, respectively (Table 1). The observed concentrations of the obtained residues were corrected by the recovery rates.

Table 1. Percentage of recovery of glyphosate and glufosinate ammonium in soil

| Concentrations | Glyphosate (µg/g) | Glufosinate ammonium (µg/g) |
|----------------|-------------------|-----------------------------|
| 1              | 94.66             | 92.261                      |
| 0.5            | 92.972            | 91.62                      |
| 0.1            | 92.515            | 90.26                      |
| Average        | 93.38             | 91.38                      |

*Average of four replicates

2.5 Standard curve of glyphosate and glufosinate ammonium

Series of graduated concentrations 0.4, 0.8, 1.2, 1.6, 2, 2.4, 2.8, 3.2, 3.6 and 4 µg (a.i.) gm⁻¹ in acetonitrile was prepared and each concentration was injected under the previously mentioned conditions. The resulted peak area was plotted against µg gm⁻¹ of each concentration and calibration curve was established. The obtained results are illustrated in Fig (1 and 2). The calibration curves demonstrated a correct linear relationship (r² =0.96 and 0.98).

2.6 Efficiency of glyphosate and glufosinate against present weeds in citrus orchards

Herbicides phytotoxic effects of their recommended and double rate on citrus associated weeds were tested through the following dry weight. Dry weight (mg) was recorded on 7 and 14 days using an electric balance after drying in an oven 70°C for 48 h (Ashraf and Akhlaq 2007).

3 Results and Discussion

3.1 The dissipation of GLY residues in soil

The obtained data in Table 2, early deposits of GLY residues in the soil at 0 and 10 cm immediately after the application were found to be 1.563 and 0.99 µg/g; 3.17 and 1.36 µg/g at 1 and two kg/fed application rates respectively. However, there is no detected residue at 25 cm depth. After 3 days GLY residues has been discovered 0.454, 0.67 and 0.32 µg/g in 0, 10 and 25 cm depth at 1 kg/fed rate of application.

Furthermore, glyphosate residues were found to be 0.094 and 0.49 µg/g, respectively in 0 and 10 cm depth at 2 kg/fed. doses of glyphosate application, but, not detected residue at 25 cm. Seven days after application, GLY dissipation was observed with low levels with a 1 and 2.0 kg/fed application rates and the residues detected were 0.032 and 0.072; 0.043 and 0.081 µg/g at 10 and 25 cm depth, respectively, with no detected residue at 0 cm. After the seventh day from application, GLY level gradually dissipated until it could not be detected, except at 25 cm depth after 14 days it was recorded 0.09 and 0.010 µg/g which was degraded and no longer detected in the successive intervals.

These results are in harmony with (La Cecilia and Maggi 2018) who mentioned that glyphosate breaks down rapidly in soil, and it is completely degraded by soil micro-organisms. Glyphosate appeared to be directly and quickly degraded by microbes, even at high rates of application, without negatively affecting microbial activity, (Haney et al 2000). The amount of glyphosate was comparable with Tseng et al 2004, where GLY levels in clay, red soil and brown loam, medium loam 0.91, 0.13; <0.14,0.10 µg/g at 42 days' post-application.

3.2 The dissipation of GLUA residues in soil

The glufosinate residue has been detected as 2.56, 0.39 and 0.002 µg/g at depth 0 cm on 0th, 3th and 7th day respectively when it was used with 2 kg/fed; while it was 3.17, 0.57 and 0.004 µg/g at depth 0 cm on 0th, 3th and 7th day respectively when it was used with 2L/ fed 1.72, 0.80 and 0.097, 1.92, 1.05 and 0.09 µg/g at depth 10 cm, 0, 0.10 and 0.037, 0, 0.20 and 0.06 µg/g at depth 25 cm in soil on 0th, 3th and 7th day respectively, irrespective of the application rate (Table 3). The residues of glufosinate in soil declined progressively with time and on 14th day it was below

ND: Not detected below limit of detection (0.05 ng/g)

0.024 µg/g except for 25cm on double dose. The residues of the tested herbicides were not detected in all successive intervals of soil samples after 14 days of spraying in recommended and double dose in soil. Glufosinate ammonium was relatively moderately persistent in soil, this result agreement with results by Janaki et al (2019) who reported that the initial residue in soil on 0, 15 cm depths was extended from 0.098 - 0.165 and 0.012 - 0.023 mg kg-1, respectively, it was less than the residue after 30 days (0.011-0.017 mg kg-1), irrespective of the application rate. A low concentration in soil at day 0 could be occurred due to of faster degradation mainly due to microbial activity (Behrendt et al 1990).

3.3 Dissipation kinetic of glyphosate (GLY) and glufosinate ammonium (GLUA) in soil

Degradation curves of herbicide residues over time were provided in Table 4. The charts show that the GLY and GLUA dissipate at 3 depths at two doses application. Pseudo-first order kinetic decay curve was observed at two doses. The coefficients, rate constants and regression equations are summarized in Table 4. Following application, the GLY concentration in treated soil was gradually reduced. The half-life (T/2) of Glyphosate was 0.56 days at 0 cm depth with a correlation coefficient of 1. There was no major difference in the half-life (T/2) of glyphosate in soil at 3 depths. Half-life (T/2) values for the glufosinate ammonium at all three depths for two doses of applications (1 and 2 lit/ha) were found to be 0.25 and 0.27 days; 0.37 and 0.37 days; and 0.81 and 0.63 days, respectively. half-life (T/2) of GLUA was comparable to glyphosate at 3 depths. No significant half-life difference was observed for GLU at 3 depths. The highest tenth life period (T/10) for glufosinate ammonium was found to be 15.38 days at 25 cm for recommended rate.

Glyphosate is highly adsorbed by soil, so degradation by microorganisms rather rapid. It has a middle half-life in soil of two months (Tu et al 2001). In addition to, the half-life for GLY averaged ranged from 5 to 19 days in tea field soil (Bandana et al 2015). The Glyphosate Herbicide Handbook (1989), reports that glyphosate is moderately persistent in the field with a typical half-life in the field of 40 -60 days. The lower half-life values for this study can be attributable to the combined effect of the soil type.

Zhang et al 2014, reported that glufosinate ammonium gradually degrades to MPP and dissipates rapidly into the soil to MPA in a few hours. In addition, micro-organisms are the most significant factor affecting the degradation of GLUA in soil and leaving no residual activity. It was further degraded by microorganisms and half-lives ranging from 1 to 25 days (Gallina and Stephenson 1992, Accinelli et al 2004). European Food Safety Authority (EFSA 2005) stated that the persistence of GLUA in soil is attributed to the clay content rather than organic matter. According to the EPA 2005 the half-life of GLUA ranges from 8.5 to 23.0 days in soil based on the rate of application in aerobic soil. The calculated half-lives were 9.51 and 10.04 days, respectively, at the recommended dose (0.5 kg/ha) and twice the recommended dose (1.0 kg/ha) (Behrendt et al 1990).
Examining the obtained results, it revealed that the rapid dissipation of glyphosate and glufosinate at surface layer of soil could attributed to photo-degradation or volatilization process from soil, the Vapor Pressure of glyphosate and glufosinate are 9.8X10-8 mm Hg /1.31X10-2 mPal at 25°C and 1.0 X 10-04 at 25°C, respectively (Tomlin 1997). Considering that the field experiments were carried out under high Sunlight Intensity. Furthermore, glyphosate and glufosinate ammonium are ionic and highly water soluble compounds, whereas, partition coefficient (LogP) for glyphosate and glufosinate ammonium are -3.4 (Sangster 1997) and < 0.1 (Lyman et al 1990, Tomlin 1997), which indicates high polarity of these compounds. Such high-solubility in water generates a rapid leaching in soil column. Also, the effect of soil texture which contains high coarse of particles that increases the rate of move-down mobility. As for the 10 and 25 cm depths, there was extreme rain after 20 days from the spraying period.

3.4 Efficiency of glyphosate and glufosinate ammonium against present weeds

All tested herbicides significantly reduced the dry weight of all weed (Cynodondactylon L, Convolvulus arvensis L, Sonchusoleraceus L and Sisymbriumirio L) [Table 5 and 6]. The heights reductions (100%) were observed of the double rate of glufosinate ammonium, except for, reduction in Bermuda grass was showed of 99.89 % of dry weight. However, the highest % reduction dry weight was recorded against weeds after 7 days by the two tested herbicides especially, recommended double rate.

Barbora et al, 2002, Singh et al, 2011, they indicated that glyphosate exhibited perfect weed control (annual and perennial grass and broadleaved) in different orchard crops such as citrus. GLY and GLUA were found to reduce weed biomass 28 days after treatment (Mohamed 2017). Following treatment and disruption of biochemical processes by glyphosate, plants begin to die. Annual plants begin to exhibit symptoms within two to four days, whereas perennials take seven to ten days (Franz et al 1997). Wibawa et al 2009, reported that variable in response of weed species to glyphosate or glufosinate-ammonium may have attributed to the growth and dominance characteristics of weed groups such as density, frequency and productivity of weed community or it might contribute to the difference in the target site actions. glyphosate is inhibitor of the EPSPS, a key enzyme in shikimate pathway which blocks the synthesis of the essential amino aromatic acids such as phenyl aniline and tryptophan causing accumulations of shikimate in the plant tissues then plant death. In addition to, glyphosate can deactivate the chlorophyll synthesis in plant causing yellowish leave through increase in chlorophyll content in plants (Cole 1985, Gravena et al 2012). Plants sensitive to ammonium glufosinate showed deficiency in glutamine poisoning by accumulation of ammonia, glutamate, glyoxalate, fracture of the chloroplast structure and suppression of photosynthesis (Coetzer and Al-Khatib 2001, Carbonari et al 2016, Dayan et al 2015).

Table 4. Degradation kinetics of glyphosate and glufosinate ammonium residue in soil

| Dose       | Depths | Kinetic equation | Correlation coefficient (R²) | Half-lives (T/2, days) | Half-lives (T/10, days) |
|------------|--------|-----------------|-----------------------------|-----------------------|------------------------|

4 Conclusion

Examining the obtained results, it is concluded that, the rapid dissipation of glyphosate and glufosinate at surface layer of soil compare of 5, 20 cm depth were revealed. Glyphosate and glufosinate were dissipated in soil within 7 and 14 days of application, respectively, regardless of dose. Additionally, both tested pesticides showed significant herbicidal activity against the four examined weeds, particularly, after 14 days of application.
