The idea of quantum state storage is generalized to describe the coherent transfer of quantum information through a coherent data bus. In this universal framework, we comprehensively review our recent systematical investigations to explore the possibility of implementing the physical processes of quantum information storage and state transfer by using quantum spin systems, which may be an isotropic antiferromagnetic spin ladder system or a ferromagnetic Heisenberg spin chain. Our studies emphasize the physical mechanisms and the fundamental problems behind the various protocols for the storage and transfer of quantum information in solid state systems.

I. INTRODUCTION

The current development of quantum information science and technology demands optimal systems serving as long-lived quantum memories, through which the quantum information carried by a quantum system with short decoherence time can be coherently transferred \cite{1}. In this sense a quantum channel or a quantum data bus is needed for perfect transmission of quantum states. In this article, we will demonstrate that both the quantum information storage and the quantum state transfer can be uniquely described in a universal framework.

There exist some schemes \cite{2,3,4} concerning about quantum storage of photon states, while there are also some efforts devoted to the universal quantum storage for a qubit (a basic two-level system) state, which is necessary in quantum computation. For example, most recently an interesting protocol \cite{5,6,8} was presented to reversely map the electronic spin state onto the collective spin state of the surrounding nuclei. Because of the long decoherence time of the nuclear spins, the information stored in them can be robustly preserved. It was found that \cite{2}, only under two homogeneous conditions with low excitations, such many-nuclei system approximately behaves as a single mode boson to serve as an efficient quantum memory.

The low excitation condition requires a ground state with all spins orientated, which can be prepared by applying a magnetic field polarizing all spins along the same direction. With the concept of spontaneous symmetry breaking (SSB), one can recognize that a ferromagnetic Heisenberg spin chain usually has a spontaneous magnetization, which naturally offers such a kind of ground state. In happen of SSB, the intrinsic interaction between spins will strongly correlate with the nuclei to form the magnon, a collective mode of spin wave, even without any external magnetic field. With these considerations, Wang, Li, Song, and Sun \cite{10} explored the possibility of using a ferromagnetic quantum spin system, instead of the free nuclear ensemble, to serve as a robust quantum memory. A protocol was present to implement a quantum storage element for the electronic spin state in a ring array of interacting nuclei. Under appropriate control of both the electron and the external magnetic field, an arbitrary quantum state of the electronic spin qubit, either pure or mixed state, can be coherently stored in the nuclear spin wave and then read out in reverse process.

On the other hand, designed for a more realistic quantum computing, a scalable architecture of quantum network should be based on the solid state system \cite{11,12}. However, the intrinsic feature of solid state based channels, such as the finiteness of the correlation length \cite{13,14} and the environment induced noise (especially the low frequency noise) may block this scalability. Fortunately, analytical study shows that a spin system possessing a commensurate structure of energy spectrum matched with the corresponding parity can ensure the perfect state transfer \cite{15,16,17}. Based on this fact, an isotropic antiferromagnetic spin ladder system can be pre-engineered as a novel robust kind of quantum data bus \cite{15}. Because the effective coupling strength between the two spins connected to a spin ladder is inversely proportional to the distance of the two spins, the quantum information can be transferred between the two spins separated by a longer distance. Another example of the near-perfect transfer of quantum information was given to illustrate an application of the theorem. The protocol of such near-perfect quantum state transfer is proposed by using a ferromagnetic Heisenberg chain with uniform coupling constant, but an external parabolic magnetic field \cite{17}.

The present paper will give a broad overview of the present situation of the our investigations mentioned above on quantum state storage and quantum information coherent transfer based on quantum spin systems. We will understand the physical mechanisms and the fundamental problems behind these protocols in the view of a unified conception, the generalized quantum information storage.
II. GENERALIZED QUANTUM STORAGE AS A DYNAMIC PROCESS

For the dynamic process recording and reading quantum information carried by quantum states, we first describe the idea of generalized quantum storage, which was also introduced in association with the Berry’s phase factor [13]. Let \( M \) be a quantum memory possessing a subspace spanned by \(|M_n⟩, n = 1, 2, ..., d\), \((M_n |M_m⟩ = δ_{mn})\), which can store the quantum information of a system \( S \) with basis vectors \(|S_n⟩, n = 1, 2, ..., d\). If there exists a controlled time evolution interpolating between the initial state \(|S_n⟩ \otimes |M⟩\) and the final state \(|S⟩ \otimes |M_n⟩\) for each index \( n \) and arbitrarily given states \(|S⟩\) and \(|M⟩\), we define the usual quantum storage by using a factorized evolution of time \( T_m \)

\[
|Φ(T_m)⟩ = U(T_m) |Φ(0)⟩ = |S⟩ \otimes |M_n⟩, \tag{1}
\]

starting from the initial state \(|Φ(0)⟩ = |S_n⟩ \otimes |M⟩\). The corresponding readout process is an inverse evolution of time \( T_f(\gg T_m) \)

\[
|Φ(T_f)⟩ = U(T_f) |Φ(0)⟩ = |S_n⟩ \otimes |M⟩. \tag{2}
\]

In this sense, writing an arbitrary state \(|S(0)⟩ = \sum_n c_n |S_n⟩\) of \( S \) into \( M \) with the initial state \(|M⟩\) of quantum memory can be realized as a controlled evolution from time \( t = 0 \) to \( t = T_m \)

\[
\sum_n c_n |S_n⟩ \otimes |M⟩ \rightarrow |S⟩ \otimes \sum_n c_n |M_n⟩. \tag{3}
\]

The readout process from \( M \) is another controlled evolution from time \( t = T_m \) to \( t = T_f \)

\[
|S⟩ \otimes \sum_n c_n |M_n⟩ \rightarrow \sum_n c_n |S_n⟩ \otimes |M⟩. \tag{4}
\]

Obviously, the combination of these two processes forms a cyclic evolution that a state totally returns to the initial one.

However, in the view of the decoding approach, one need not the “totally returning” to revival the information of initial state and a difference is allowed by \( n \) \( - \) independent unitary transformation \( W = W_S \otimes I \), namely,

\[
|S⟩ \otimes W_M \sum_n c_n |M_n⟩ \rightarrow (W_S \sum_n c_n |S_n⟩) \otimes |M⟩. \tag{5}
\]

This is a quantum dynamic process for recording and reading, which defines a quantum storage. Because the factor \( W_S \) is known to be independent of the initially state, it can be easily decoded from \( W_S \sum_n c_n |S_n⟩ \) by the inverse transformation of \( W_S \). We notice that the quantum storage usually relates to two quantum subsystems.

![FIG. 1: Demonstration of quantum state transfer as a process of generalized quantum information storage by grouping the data bus \( D \) and the target subsystem \( S^B \) as a generalized quantum memory.](image)

We will show as follows that the quantum state transfer can be understood as a generalized quantum storage with three subsystems, the input one with the Hilbert space \( S^A \), the data bus with \( D \) and output one with \( S^B \). As illustrated in Fig. 1, the two subsystems \( S^A \) and \( S^B \) located at two distant locations \( A \) and \( B \) respectively. Then the Hilbert space of the total system can be written as

\[
S_T = S^A \otimes D \otimes S^B \equiv S^A \otimes M, \tag{6}
\]

where \( M = D \otimes S^B \) can be regarded as the generalized quantum memory with the memory space spanned by \(|M_n⟩ = |D⟩ \otimes U_B |S_n^B⟩\). Here \(|D⟩\) is a robust state of the data bus and \( U_B \) represents some local unitary transformations with respect to \( B \), which are independent of the initial state. With this notation, the quantum state transfer indeed can be regarded as a generalized QDR.

In fact, if one input a state of \(|S^A⟩ = \sum_n c_n |S^A_n⟩\) localized at \( A \) at \( t = 0 \), the initial state of whole system can be written as

\[
|ψ(0)⟩ = \sum_n c_n |S^A_n⟩ \otimes |M⟩ \tag{7}
\]

where \(|M⟩ = |D⟩ \otimes |S^B⟩\). The quantum state transfer can be usually described as a factorized time evolution at time \( t = T_f \)

\[
|ψ(T_f)⟩ = |S⟩ \otimes |D⟩ \otimes \sum_n c_n U_B |S^B_n⟩ = |S⟩ \otimes \sum_n c_n |M_n⟩ \tag{8}
\]

with \(|M_n⟩ = |D⟩ \otimes U_B |S^B_n⟩\). The above equations just demonstrate that the quantum state transfer is essentially a generalized quantum memory with \( W_M = (1 \otimes U_B) \). In this sense the revisable quantum state transfer can be regarded as a general readout process.

Now we would like to remark on the differences between generalized quantum state storage and other two
types of quantum processes, quantum teleportation and quantum copy. In fact, quantum teleportation is theoretically perfect, yielding an output state which revives the input with a fidelity $F = 1$. Actually one of necessary procedure in teleportation is to measure the Bell state at location $A$, which will induce the collapse of wavepacket. On the other way around, the quantum state storage process is always on time evolution without any measurement. As for quantum copy the initial state remains unchanged during its copy can be generated in a dynamic process.

III. QUANTUM STATE TRANSFER IN SPIN SYSTEMS

A robust quantum information processing based on solid state system is usually implemented in a working spaces panned by the lowest states, which are well separated from other dense spectrum of high excitations. In this sense the energy gap of the solid state system is an important factor we should take into account. The decoherence induced by the environmental noise can also destroy the robustness of quantum information processing, such as the low frequency (e.g, $1/f$ ) noise dominating in the solid state devices. People believe that the gap of the data bus can suppress the stay of transferred state in the middle way in order to enhance the fidelity, but the large gap may result in a shorter correlation length. The relationship between correlation length and the energy gap is usually established in the system with translational symmetry. So we need to consider some modulated-coupling systems or artificially engineered irregular quantum spin systems where the strong correlation between two distant site can be realized.

1. Theorem for the perfect quantum state transfer

Quantum mechanics shows that perfect state transfer is possible. To sketch our central idea, let us first consider a single particle system with the usual spatial reflection symmetry (SRS) in the Hamiltonian $H$. Let $P$ be the spatial reflection operator. The SRS is implied by $[H, P] = 0$. Now we prove that at time $\pi/E$ any state $\psi(r)$ can evolve into the reflected state $\pm \psi(-r)$ if the eigenvalues $\varepsilon_n$ match the parities $p_n$ in the following way

$$\varepsilon_n = N_n E_0, \quad p_n = \pm (-1)^{N_n}$$

for arbitrary positive integer $N_n$ and

$$H \phi_n(r) = \varepsilon_n \phi_n(r), \quad P \phi_n(r) = p_n \phi_n(r).$$

Here, $\phi_n(r)$ is the common eigen wave function of $H$ and $P$, $r$ is the position of the particle. We call Eq. (9) the spectrum-parity matching condition (SPMC). The proof of the above rigorous conclusion is a simple, but heuristic exercise in basic quantum mechanics. In fact, for the spatial reflection operator, $P \psi(r) = \pm \psi(-r)$. For an arbitrarily given state at $t = 0$, $\psi(r, t)|_{t=0} = \psi(r)$, it evolves to

$$\psi(r, t) = e^{-iN_n E_0 t} \phi_n(r)$$

at time $t$, where $C_n = \langle \phi_n | \psi \rangle$. Then at time $t = \pi/E_0$, we have

$$\psi(r, \pi/E_0) = \sum_n C_n (-1)^{N_n} \phi_n(r) = \pm P \psi(r)$$

that is, $\psi(r, \pi/E_0) = \pm \psi(-r)$. This is just the central result discovered for quantum spin system that the evolution operator becomes a parity operators $\pm P$ at some instant $t = (2n + 1) \pi/E_0$, that is $\exp[-iH \pi/E_0] = \pm P$. From the above arguments we have a consequence that if the eigenvalues $\varepsilon_n = N_n E_0$ of a 1-D Hamiltonian $H$ with spatial reflection symmetry are odd-number spaced, i.e. $N_n - N_{n-1}$ are always odd, any initial state $\psi(x)$ can evolve into $\pm \psi(-x)$ at time $t = \pi/E_0$. In fact, for such 1-D systems, the discrete states alternate between even and odd parities. Consider the eigenvalues $\varepsilon_n = N_n E_0$ with odd-number spaced. The next nearest level must be even-number spaced, then the SPMC is satisfied. Obviously, the 1-D SPMC is more realizable for the construction of the model Hamiltonian to perform perfect state transfer.

Now, we can directly generalize the above analysis to many particle systems. For the quantum spin chain, one can identify the above SRS as the MIS with respect to the center of the quantum spin chain. As the discussion in Ref. [20], we write MIS operation

$$P \Psi(s_1, s_2, \ldots, s_{N-1}, s_N) = \Psi(s_N, s_{N-1}, \ldots, s_2, s_1)$$

for the wave function $\Psi(s_1, s_2, \ldots, s_{N-1}, s_N)$ of spin chain. Here, $s_n = 0, 1$ denotes the spin values of the $n$-th qubit.

2. Perfect state transfer in modulated coupling system

Based on the above analysis, in principle, perfect quantum state transfer is possible in the framework of quantum mechanics. According to SPMC, many spin systems can be pre-engineered for perfect quantum states transfer. For instance, two-site spin-$\frac{1}{2}$ Heisenberg system is the simplest example which meets the SPMC. Recently, M. Christandl et al [15, 16] proposed a $N$-site XY chain with an elaborately designed modulated coupling constants between two nearest neighbor sites, which ensures a perfect state transfer. It is easy to find that this model corresponds the SPMC for the simplest case $N_n = n$. 

A natural extension of the application of the theorem leads to discover other models with $N_n \neq n$. Following this idea, a new class of different models whose spectrum structures obey the SPMC exactly were proposed for perfect state transfer. Consider an $N$-site spin-$1/2$ $XY$ chain with the Hamiltonian

$$H = 2 \sum_{i=1}^{N-1} J_i [S^x_i S^x_{i+1} + S^y_i S^y_{i+1}]$$

(14)

where $S^x_i, S^y_i$ and $S^z_i$ are Pauli matrices for the $i$–th site, $J_i$ is the coupling strength for nearest neighbor interaction. For the open boundary condition, this model is equivalent to the spin-less fermion model. The equivalent action. For the open boundary condition, this model is

$$J_k$$

-dependent eigenstates are

$$2(\epsilon_{n+1} - \epsilon_n)$$

The special case of our general model in $k$

where the coefficients $c_n$ can be explicitly determined by

$$|\phi_n\rangle = \sum_{i=1}^N c_{ni} |i\rangle = \sum_{i=1}^N c_{ni} a_i^\dagger |0\rangle$$

(16)

where the coefficients $c_{ni}$ can be explicitly determined by the recurrence relation presented in Ref. [18].

It is obvious that the model proposed in Ref. [15] is just the special case of our general model in $k = 0$. For arbitrary $k$, one can easily check that it meets the our SPMC by a straightforward calculation. Thus we can conclude that these spin systems with a set of pre-engineered couplings $J_i^{[k]}$ can serve as the perfect quantum channels that allow the qubit information transfer.

3. Near-perfect state transfer

In real many-body systems, the dimension of Hilbert space increase with the size $N$ exponentially. For example, $N$-site spin-$1/2$ system, the dimension is $D = 2^N$, and the symmetry of the Hamiltonian can not help so much. So it is almost impossible to obtain a model to be exactly engineered. In the above arguments we just show the possibility to implement the perfect state transfer of any quantum state over arbitrary long distances in a quantum spin chain. It sheds light into the investigation of near-perfect quantum state transfer. There is a naive way that one select some special states to be transported, which is a coherent superposition of commensurate part of the whole set of eigenstates. For example, we consider a truncated Gaussian wavepacket for an harmonic oscillator with lower eigenstates to be harmonic.

It is obvious that such system allows some special states to transfer with high fidelity. We can implement such approximate harmonic system in a natural spin chain without the pre-engineering of couplings, but the present of a modulated external field. Another way to realize near perfect state transfer is to achieve the entangled states and fast quantum states transfer of two spin qubits by connecting two spins to a medium which possesses a spin gap. A perturbation method, the Fröhlich transformation, shows that the interaction between the two spins can be mapped to the Heisenberg type coupling.

3.1 Spin ladder

We sketch our idea with the model illustrated in Fig. 2. The whole quantum system we consider here consists of two qubits (A and B) and a $2 \times N$-site two-leg spin ladder. In practice, this system can be realized by the engineered array of quantum dots [21]. The total Hamiltonian $H = H_M + H_q$ contains two parts, the medium Hamiltonian

$$H_M = J \sum_{\langle ij \rangle \perp} S_i \cdot S_j + J \sum_{\langle ij \rangle \parallel} S_i \cdot S_j$$

(17)

describing the spin-1/2 Heisenberg spin ladder consisting of two coupled chains and the coupling Hamiltonian

$$H_q = J_0 S_A \cdot S_L + J_0 S_B \cdot S_R$$

(18)

FIG. 2: Two qubits A and B connect to a $2 \times N$-site spin ladder. The ground state of $H$ with a-type connection (a) is singlet (triplet) when $N$ is even (odd), while for b-type connection (b), one should have opposite result.
As the famous Bell states, with the effective coupling constant the above effective Hamiltonian we use analytical and numerical methods as follows. To deduce the corresponding eigen-values. The zero order eigenstates \( |m\rangle \) can then be written as in a joint way

\[
|j, m\rangle = |j, m\rangle_{AB} \otimes |\psi_g\rangle_M, \quad |\psi_{\alpha}^m(s^z)\rangle = |j, m\rangle_{AB} \otimes |\psi_{\alpha}\rangle_M
\]

Here, we have considered that \( z\)-component \( S^z = S^z_A + S^z_B \) of total spin is conserved with respect to the connection Hamiltonian \( H_q \). Since \( S^z_A \) and \( S^z_B \) commute with \( H_M \), we can label \( |\psi_{\alpha}\rangle_M \) as \( |\psi_{\alpha}(s_M, s'_M)\rangle_M \) and then \( s^z = m + s^z_A \) can characterize the non-coupling spin state \( |\psi_{\alpha}^m(s^z)\rangle \).

When the connections between the two qubits and the medium are switched off, i.e., \( J_0 = 0 \), the degenerate ground states of \( H \) are just \( |j, m\rangle \) with the degenerate energy \( E_g \) and spin 0,1 respectively, which is illustrated in Fig. 3(a). When the connections between the two qubits and the medium are switched on, the degenerate states with spin 0,1 \( S^z_A \) should split as illustrated in Fig. 3(b) and (c). In the case with \( J_0 \ll J \) at lower temperature \( kT < J/2 \), the medium can be frozen to its ground state and then we have the effective Hamiltonian

\[
H_{\text{eff}} \approx \sum_{j', m', j, m, s^z} \frac{|\langle j, m| H_q |\psi_{j'}^m(s^z)\rangle|^2}{E_g - E_\alpha} \langle j, m \rangle_{gg} \langle j, m \rangle
\]

\[
= J_{\text{eff}}. \text{Diag.} \left( \frac{1}{4}, \frac{1}{4}, \frac{1}{4}, \frac{1}{4}, -\frac{3}{4}, \varepsilon \right)
\]

(20)

where

\[
J_{\text{eff}} = \sum_{\alpha} \frac{J_{\alpha}^2 |L(\alpha)R^*(\alpha) + R(\alpha)L^*(\alpha)|}{E_g - E_\alpha},
\]

(21)

This just proves the above effective Heisenberg Hamiltonian \( H_{\text{eff}} \). Here, the matrix elements of interaction \( K(\alpha) = M |\psi_g\rangle_S^\alpha |\psi_{\alpha}(1, 0)\rangle_M \) can be calculated only for the variables of data bus medium. We also remark that, because \( S^z \) and \( S^z \) are conserved for \( H_q \), off-diagonal elements in the above effective Hamiltonian vanish.

In temporal summary, we have shown that at lower temperature \( kT < J/2 \), \( H \) can be mapped to the effective Hamiltonian \( H_{\text{eff}} \), which seemingly depicts the direct exchange coupling between two separated qubits. Notice that the coupling strength has the form \( J_{\text{eff}} \sim g(L)J_0^2/J \), where \( g(L) \) is a function of \( L = N + 1 \), the distance between the two qubits we considered. Here we take the \( N = 2 \) case as an example. According to Eq. 21 one can get \( J_{\text{eff}} = -(1/4)J_0^2/J \) and \((1/3)J_0^2/J\) when \( A \) and \( B \) connect the plaque-diagonally and adjacently, respectively. This result is in agreement with the theorem 22 about the ground state and the numerical result when \( J_0 \ll J \). In general cases, the behavior

![Diagram](image_url)
$g(L)$ vs $L$ is very crucial for quantum information since $L/|J_{eff}|$ determines the characteristic time of quantum state transfer between the two qubits $A$ and $B$. In order to investigate the profile of $g(L)$, a numerical calculation is performed for the systems $L = 4, 5, 6, 7, 8,$ and 10, with $J = 10, 20, 40,$ and $J_0 = 1$. The spin gap between the ground state(s) and first excite state(s) are calculated, which corresponds to the magnitude of $J_{eff}$. The numerical result is plotted in Fig. 4, which indicates that $J_{eff} \sim 1/(LJ)$. It implies that the characteristic time of quantum state transfer linearly depends on the distance and then guarantees the possibility to realize the entanglement of two separated qubits in practice.

In order to verify the validity of the effective Hamiltonian $H_{eff}$, we need to compare the eigenstates of $H_{eff}$ with those reduced states from the eigenstates of the whole system. In general the eigenstates of $H$ can be written formally as

$$|\psi\rangle = \sum_{jm} c_{jm} |j, m\rangle_{AB} \otimes |\beta_{jm}\rangle_M$$

where $\{|\beta_{jm}\rangle_M\}$ is a set of vectors of the data bus, which is not necessarily orthogonal. Then we have the condition $\sum_{jm} |c_{jm}|^2_M = 1$ for normalization of $|\psi\rangle$. In this sense the practical description of the A-B subsystem of two qubits can only be given by the reduced density matrix matrix

$$\rho_{AB} = Tr_M(|\psi\rangle \langle \psi|) = \sum_{jm} |c_{jm}|^2 |j, m\rangle_{AB} \langle j, m|$$

where $Tr_M$ means the trace-over of the variables of the medium. By a straightforward calculation we have

$$|c_{11}\rangle^2 = |c_{1-1}\rangle^2 = \langle \psi| \left( \frac{1}{4} + S_A^z \cdot S_B^z \right) |\psi\rangle,$$

$$|c_{00}\rangle^2 = \langle \psi| \left( \frac{1}{4} - S_A^z \cdot S_B^z \right) |\psi\rangle,$$

$$|c_{10}\rangle^2 = 1 - 2 |c_{11}\rangle^2 - |c_{00}\rangle^2.$$

Now we need a criteria to judge how close the practical reduced eigenstate is to the pure state for the effective two sites coupling $H_{eff}$. As we noticed, it has the singlet and triplet eigenstates $|j, m\rangle_{AB}$ in the subspace spanned by $|0, 0\rangle_{AB}$ with $S^z = S_A^z + S_B^z = 0$, we have $|c_{11}\rangle^2 = |c_{10}\rangle^2 = |c_{1-1}\rangle^2 = 0, |c_{00}\rangle^2 = 1, \text{ for triplet eigenstate } |0, 0\rangle_{AB}$, we have $|c_{11}\rangle^2 = |c_{1-1}\rangle^2 = |c_{00}\rangle^2 = 0, |c_{10}\rangle^2 = 1$. With the practical Hamiltonian $H$, the values of $|c_{jm}|^2, i = 1, 2, 3, 4,$ are numerically calculated for the ground state $|\psi_g\rangle$ and first excited state $|\psi_1\rangle$ of finite system systems $L = 4, 5, 6, 7, 8, 10$ with $J = 10, 20, 40, (J_0 = 1)$ in $S^z = 0$ subspace, which are listed in the Table 1(a,b,c) of Ref. [17]. It shows that, at lower temperature, the realistic interaction leads to the results about $|c_{jm}|^2$, which are very close to that described by $H_{eff}$, even if $J$ is not so large in comparison with $J_0$.

We address that the above tables reflect all the facts distinguishing the difference between the results about the entanglement of two end qubit generated by $H_{eff}$ and $H$. Though we have ignored the off-diagonal terms in the reduced density matrix, the calculation of the fidelity $F(|j, m\rangle) \equiv \langle j, m| \rho_{AB} j, m \rangle_M = |c_{jm}|^2$ further confirms our observation, that the effective Heisenberg type interaction of two end qubits can approximates the realistic Hamiltonian very well. Then the quantum information can be transferred between the two ends of the $2 \times N$-site two-leg spin ladder, that can be regarded as the channel to share entanglement with separated Alice and Bob. Physically, this is just due to a large spin gap existing in such a perfect medium, whose ground state can induce a maximal entanglement of the two end qubits. We also pointed out that our analysis is applicable for other types of medium systems as data buses, which possess a finite spin gap. Since $L/|J_{eff}|$ determines the characteristic time of quantum state transfer between the two qubits, the dependence of $J_{eff}$ upon $L$ becomes important and relies on the appropriate choice of the medium.

In conclusion, we have presented and studied in detail a protocol to quantum state transfer. Numerical results show that the isotropic antiferromagnetic spin ladder system is a perfect medium through which the interaction between two separated spins is very close to the Heisenberg type coupling with a coupling constant inversely proportional to the distance even if the spin gap is not so large comparing to the couplings between the input and output spins with the medium.
3.2 Spin chain in modulated external magnetic field

Let us consider the Hamiltonian of \((2N+1)\)-site spin-\(\frac{1}{2}\) ferromagnetic Heisenberg chain

\[
H = -J \sum_{i=1}^{2N} \mathbf{S}_i \cdot \mathbf{S}_{i+1} + \sum_{i=1}^{2N+1} B(i) S_i^z
\]

(25)

with the uniform coupling strength \(-J < 0\), but in the parabolic magnetic field

\[
B(i) = 2B_0(i - N - 1)^2
\]

(26)

where \(B_0\) is a constant. In single-excitation invariant subspace with the fixed \(z\)-component of total spin \(S^z = N - 1/2\), this model is equivalent to the spin-less fermion hopping model with the Hamiltonian

\[
H = -J \sum_{i=1}^{2N} (a_i^\dagger a_{i+1} + h.c.) + \frac{1}{2} \sum_{i=1}^{2N+1} B(i) a_i^\dagger a_i
\]

(27)

where we have neglected a constant in the Hamiltonian for simplicity. For the single-particle case with the set basis\(\{|n\rangle = |0,0,...,1,0...\rangle |n = 1,2,...\}\) which is just the same as that of the Hamiltonian of Josephson junction in the Cooper-pair number basis Ref. [24] for \(E_f = J, E_c = 2B_0\). Analytical analysis and numerical results have shown that the lower energy spectrum is indeed quasi-harmonic in the case \(E_f \gg E_c\) [27]. Although the eigenstates of the Hamiltonian (36) does not satisfy the SPMC precisely, especially for high energy range, there must exist some Gaussian wavepacket states expanded by the lower eigenstates. Such kind of state can be transferred with high fidelity.

We consider a Gaussian wavepacket at \(t = 0, x = N_A\) as the initial state

\[
|\psi(N_A,0)\rangle = C \sum_{i=1}^{2N+1} e^{-\frac{1}{2}\alpha^2(i-N_A-1)^2} |i\rangle
\]

(28)

where \(|i\rangle\) denotes the state with \(2N\) spins in down state and only the \(i\)th spin in up state, \(C\) is the normalization factor. The coefficient \(\alpha^2 = 4\ln 2/\Delta^2\) is determined by the width of the Gaussian wavepacket \(\Delta\). The state \(|\psi(0)\rangle\) evolves to \(|\psi(t)\rangle = e^{-iHt} |\psi(N_A,0)\rangle\) at time \(t\) and the fidelity for the state \(|\psi(0)\rangle\) transferring to the position \(N_B\) is defined as

\[
F(t) = |\langle \psi(N_B,0)| e^{-iHt} |\psi(N_A,0)\rangle|.
\]

(29)

In Fig. 5 the evolution of the state \(|\psi(0)\rangle\) is illustrated schematically. From the investigation of Ref. [25], we know that for small \(N_A = -N_B = x_0\), where \(N_B\) is the mirror counterpart of \(N_A\), in large \(\Delta\) limit, if we take \(B_0 = 8 \ln 2/\Delta^2\), \(F(t)\) has the form

\[
F(t) = \exp[-\frac{1}{2}\alpha^2 N_A^2 (1 + \cos \frac{2t}{\alpha^2})]
\]

(30)

which is a periodic function of \(t\) with the period \(T = \alpha^2 \pi\) and has maximum of 1. This is in agreement with our above analysis. However, in quantum communication, what we concern is the behavior of \(F(t)\) in the case of the transfer distance \(L \gg \Delta\), where \(L = 2 |N_A| = 2 |N_B|\). For this purpose the numerical method is performed for the case \(L = 500, \Delta = 2, 4, 6\) and \(B_0 = 8 \ln 2/\Delta^2\) \(\lambda\). The factor \(\lambda\) determines the maximum fidelity and then the optimal field distribution can be obtained numerically. In the Ref. [18], Fig. 2(a), (b) and (c) the functions \(F(t)\) are plotted for different values of \(\lambda\). It shows that for the given wavepackets with \(\Delta = 2, 4\) and 6, there exists a range of \(\lambda\), during which the fidelities \(F(t)\) are up to 0.748, 0.958 and 0.992 respectively. For finite distance, the maximum fidelity decreases as the width of Gaussian wavepacket increases. On the other hand, the strength of the external field also determines the value of the optimal fidelity for a given wavepacket. There exists an optimal external field to obtain maximal fidelity, meanwhile the period of \(F(t)\) close to \(T = \alpha^2 \pi\). This shows a difference from the ideal system, i.e. continuous harmonic systems, in which the fidelity is independent of the strength of the external field. Numerical results indicate that it is possible to realize near-perfect quantum state transfer over a longer distance in a practical ferromagnetic spin chain system.

In summary, we have shown that a perfect quantum transmission can be realized through a universal quantum channel provided by a quantum spin system with spectrum structure, in which each eigenenergy is commensurate and matches with the corresponding parity.

V. QUANTUM STORAGE BASED ON THE SPIN CHAIN

Recently a universal quantum storage protocol was presented to reversibly map the electronic spin state onto the collective spin state of the surrounding nuclei ensemble in a quantum well (see the Fig. 6). Because of the long decoherence time of the nuclear spins, the information stored in them can be robustly preserved. When all nuclei (with spin operators $I_z^{(i)}$, $I_y^{(i)}$, $I_x^{(i)}$) of spin $I_0$ are coupled with a single electron spin with strength $g_i$, a pair of collective operators $B$

$$B = \frac{\sum_{i=1}^{N} g_i I^{(i)}}{\sqrt{2I_0} \sum_i g_i^2}$$  \hspace{1cm} (31)$$

and its conjugate $B^\dagger$ are introduced to depict the collective excitations in ensemble of nuclei with spin $I_0$ from its polarized initial state $(G) = \cdots |\cdots N I_0 \rangle = \prod_{i=1}^{N} |\cdots i \rangle$, which denotes the saturated ferromagnetic state of nuclei ensemble. There is an intuitive argument that if the $g_i$s have different values, while the distribution is “quasi-homogeneous”, $B$ and $B^\dagger$ can also be considered as boson operators satisfying $[B, B^\dagger] \to 1$ approximately.

Song, Zhang and Sun analyzed the universal applicability of this protocol in practice. It was found that only under two homogeneous conditions with low excitations, the many-nuclei system approximately behaves as a single mode boson and its excitation that can serve as an efficient quantum memory. The low excitation condition requires a ground state with all spins orientated, which can be prepared by applying a magnetic field polarizing all spins along a single direction. With the consideration of spontaneous symmetry breaking for all spins orientated, a protocol of quantum storage element was proposed to use a ferromagnetic quantum spin system, instead of the free nuclear ensemble, to serve as a robust quantum memory.

The configuration of the quantum storage element is illustrated in Fig. 7. The nuclei are arranged in a circle within a quantum dot to form a ring array. To turn on the interaction one can push a single electron towards the center of the circle along the axis that perpendicular to the plane.

The configuration geometry of the nuclei-electron system. The nuclei are arranged in a circle within a quantum dot to form a ring array. A single electron is just localized in the center of the ring array surrounded by the nuclei. The interaction of the nuclear spins is assumed to exist only between the nearest neighbors while the external magnetic field $B_0$ threads through the spin array. Then the electron-nuclei system can be modelled by a Hamiltonian $H = H_n + H_e + H_{en}$. It contains the internal spin Hamiltonian $H_e = g_e \mu_B B_0 \sigma^z$, the nuclear spin Hamiltonian

$$H_n = g_n \mu_n B_0 \sum_{i=1}^{N} S_i^z - J \sum_{i=1}^{N} S_i \cdot S_{i+1}$$  \hspace{1cm} (32)$$

with the Zeeman split and the ferromagnetic interaction $J > 0$, and the interaction between the nuclear spins and
the electronic spin

$$H_{en} = \frac{\lambda}{2N} \sigma^+ \sum_{i=1}^{N} S_i^- + h.c. \quad (33)$$

Here, $g_e$ ($g_n$) is the Lande $g$ factor of electron (nuclei), and $\mu_B$ ($\mu_N$) the Bohr magneton (nuclear magneton). The Pauli matrices $S_i^-$ and $\sigma^+$ represent the nuclear spin of the $i$-th site and the electronic spin respectively. The denominator $N$ in Eq. (33) originates from the envelope normalization of the localized electron wave-function. The hyperfine interactions between nuclei and electron are proportional to the envelope function of localized electron. The electronic wave function is supposed to be cylindrical symmetric, e.g., the $s$-wave component. Thus the coupling coefficient $\lambda \propto |\psi(r)|^2$ is homogenous for all the $N$ nuclei in the ring array.

To consider the low spin wave excitations, the discrete Fourier transformation defines the bosonic operators $b_k$ in the large $N$ limit. Then one can approximately diagonalize the Hamiltonian as

$$H_T = H_N + \sum_{k=1}^{N-1} \omega_k b_k^+ b_k \quad (34)$$

where $H_N$ is a Jaynes-Cummings (JC) type Hamiltonian

$$H_N = \omega_N b_N^+ b_N + \frac{\Omega}{2} \sigma^z + \lambda \sqrt{\frac{s}{2N}} (\sigma^z b_N + \sigma^- b_N^+) \quad (35)$$

Then we obtain the dispersion relation for magnon or the spin wave excitation

$$\omega_k = g_n \mu_n B_0 + 2J_s - 2J_s \cos \frac{2\pi k}{N}. \quad (36)$$

The above results show that $H_T$ only contains the interaction of the $N$-th magnon with the electronic spin and the other $N-1$ magnons decouples with it. Here, the frequency of the boson $\omega_N = g_n \mu_n B_0$ and the two level spacing $\Omega = 2g^* \mu_B B_0$ can be modulated by the external field $B_0$ simultaneously.

The process of quantum information storage can be implemented in the invariant subspace of the electronic spin and the $N$-th magnon. Now we can describe the quantum storage protocol based on the above spin-boson model. Suppose the initial state of the total system is prepared so that there is no excitation in the $N$ nuclei at all while the electron is in an arbitrary state $\rho_e(0) = \sum_{n,m= \pm} \rho_{nm} |n\rangle \langle m|$ where $|+\rangle$ ($|-\rangle$) denotes the electronic spin up (down) state. The initial state of the total system can then be written as

$$\rho(0) = \rho_b(0) \otimes |0_N\rangle \langle 0_N| \otimes \rho_e(0) \quad (37)$$

in terms of $\rho_b(0) = |\{0\}\rangle_{N-1} \langle \{0\}|$ where $|n_1,n_2,\ldots,n_{N-1}\rangle \equiv |\{n_k\}_{N-1} \ (\ k = 1, 2, \ldots, N-1)$ denotes the Fock state of the other $N-1$ magnons. If we set $B_0 = 0$, at $t = T \equiv (\pi/\lambda)\sqrt{N/2s}$, the time evolution from $\rho(0)$ is just described as a factorized state

$$\rho(T) = \rho_b(0) \otimes w_F \otimes |-\rangle \langle -|, \quad (38)$$

where $w_F = \sum_{n,m=0,1} w_{nm} |n_N\rangle \langle m_N|$ is the storing state of the $N$-th magnon with

$$w_{nm} = \rho_{nm} \exp \left[ i \frac{(m-n)\pi}{2} \right]. \quad (39)$$

Here, to simplify our expression, we have denoted $\rho_{++} \equiv \rho_{00}$, $\rho_{+-} \equiv \rho_{01}$, $\rho_{-+} \equiv \rho_{10}$, $\rho_{--} \equiv \rho_{11}$. The difference between $w_F$ and $\rho_e(0)$ is only an unitary transformation independent of the stored initial state $\rho_e(0)$.

So far we have discussed the ideal case with homogeneous coupling between the electron and the nuclei, that is, the coupling coefficients are the same constant $\lambda$ for all the nuclear spins. However, the inhomogeneous effect of coupling coefficients has to be taken into account if what we concern is beyond the $s$-wave component, in which the wave function is not strictly cylindrical symmetric. In this case, the quantum decoherence induced by the so-called quantum leakage has been extensively investigated for the atomic ensemble based quantum memory. We now discuss the similar problems for the magnon based quantum memory.

For general case, $\lambda_l \propto |\psi(r_l)|^2$ vary with the positions of the nuclear spins where $\psi(r_l)$ is the envelope function of the electron at site $r_l$. In this case, the Hamiltonian contains terms other than the interaction between the spin and $N$-th mode boson, that is, the inhomogeneity induced interaction

$$V = \lambda \sqrt{\frac{s}{2N}} (\sigma^+ \sum_{k=1}^{N-1} \chi_k b_k + h.c.) \quad (40)$$

should be added in our model Hamiltonian $H_T$ where $\chi_k = \sum_{l=1}^{N} \frac{\lambda_l}{N} \chi_k \exp[i2\pi kl/N]$. For a Gaussian distribution of $\lambda_l$, e.g., $\lambda_l = (\lambda/\sqrt{2\pi} \sigma) \exp(-l^{-1}/(2\sigma^2))$ with width $\sigma$ and $\lambda_1 = \lambda$, the corresponding inhomogeneous coupling is depicted by

$$\chi_k = \frac{1}{N} \sum_{l=1}^{N-1} \frac{1}{\sqrt{2\pi} \sigma} \exp \left[-\frac{(l-k)^2}{2\sigma^2} + 2\pi ik \right]. \quad (41)$$

Fig. 8 shows the magnitude of $\chi_k$ for different Gaussian distributions of $\lambda_l$ with different widths $\sigma$. It indicates that the modes near 1 and $N-1$ have a stronger coupling with the electron. When the interaction gets more homogeneous (with larger $\sigma$) the coupling coefficients $\chi_k$ for all the modes from 1 to $N-1$ become smaller. When
the distribution is completely homogeneous, all the couplings with the $N-1$ magnon modes vanish and then we obtain the Hamiltonian $H_T$.

In the following we will adopt a rather direct method to analyze the decoherence problem of our protocol resulting from dissipation. If $N$ is so large that the spectrum of the quantum memory is quasi-continuous, this model is similar to the "standard model" of quantum dissipation for the vacuum induced spontaneous emission [27]. The $N-1$ magnons will induce the quantum dissipation of the electronic spin with a decay rate

$$\gamma = 2\pi \sum_{k=1}^{N} \frac{\lambda^2 s |\chi_k|^2}{2N} \delta \left( \omega_k - 2\lambda \sqrt{\frac{s}{2N}} \right). \quad (42)$$

Let $|\Psi\rangle$ be the ideal evolution governed by the expected Hamiltonian $H_T$ without dissipation while the realistic evolution $|\Psi\prime\rangle$ governed by the Hamiltonian with dissipation. Suppose the initial state of the electron is $(|+\rangle + |-\rangle)/\sqrt{2}$, we can analytically calculate the fidelity

$$F(t) = |\langle \Psi | \Psi\prime \rangle| = \frac{1}{2} \left( 1 + e^{-\gamma t} \right) \times$$

$$\sec \varphi (\cos t \cos (\Delta_t^1 + \varphi) + \sin t \sin \Delta_t^1), \quad (43)$$

where $\varphi = \arcsin \sqrt{2N \gamma^2 / \lambda^2 s}$, $g = \lambda \sqrt{s / 2N}$ and $\Delta_t^1 = \sqrt{g^2 - \gamma^2}$.

Fig. 8 shows the curve of the fidelity $F(t)$ changing with time $t$. We can see that the fidelity exhibits an exponential decay behavior with a sinusoidal oscillation. At the instance when we have just implemented the quantum storage process, the fidelity is about $1 - \pi \gamma / 8$. Therefore, the deviation from the ideal case with homogeneous couplings is very small for $\gamma / g << 1$. Since the ring-shape spin array with inhomogeneous coupling is just equivalent to an arbitrary Heisenberg spin chain in the large $N$ limit, the above arguments means that an arbitrary Heisenberg chain can be used for quantum storage following the same strategy addressed above if $\gamma / g$ is small, i.e., the inhomogeneous effect is not very strong. On the other hand, if $N$ is small, the spectrum of the quantum memory is discrete enough to guarantee the adiabatic elimination of the $N-1$ magnon modes, i.e., $\lambda \sqrt{s / 2N} \sqrt{\kappa / |\omega_k|} << 1$ for the $N-1$ magnon modes. As a consequence of this adiabatic elimination, the quantum decoherence or de-phasing can result from the mixing of different magnon modes.
