A Regularized Boundary Element Formulation for Contactless SAR Evaluations within Homogeneous and Inhomogeneous Head Phantoms

Rajendra Mitharwal and Francesco P. Andriulli
Computational Electromagnetics Research Laboratory, Microwave Department, Télécom Bretagne, Brest, France

Abstract

This work presents a Boundary Element Method (BEM) formulation for contactless electromagnetic field assessments. The new scheme is based on a regularized BEM approach that requires the use of electric measurements only. The regularization is obtained by leveraging on an extension of Calderon techniques to rectangular systems leading to well-conditioned problems independent of the discretization density. This enables the use of highly discretized Huygens surfaces that can be consequently placed very near to the radiating source. In addition, the new regularized scheme is hybridized with both surfacic homogeneous and volumetric inhomogeneous forward BEM solvers accelerated with fast matrix-vector multiplication schemes. This allows for rapid and effective dosimetric assessments and permits the use of inhomogeneous and realistic head phantoms. Numerical results corroborate the theory and confirms the practical effectiveness of all newly proposed formulations.

Keywords: Computational Dosimetry, SAR Assessments, Boundary Element Method, Calderón Preconditioning.

1. Introduction

Cellular phones, laptops, bluetooth/wireless hotspots, broadcasting systems are all devices that emit mid-to-high doses of electromagnetic radiation that penetrates materials and biological tissues in their vicinities. Recommendations from various institutions in Europe and United States, dictate strict limits on the amount of electromagnetic radiation that can be tolerated within tissues and anatomical parts surrounding a radiating source. The guidelines from the International Commission on Non-Ionizing Radiation Protection (ICNIRP), that are the legal standard in Europe [1, 2], are dictating restrictions in terms of electric field induced in tissues (frequency range up to 100kHz [3, 4]), specific absorption rate (SAR, frequency range 100 kHz- 10 GHz [5]), and incident power density (frequency range 10 GHz- 300 GHz [5]). The early validation against these lim-
its is a crucial step in every industrial process involving radiating elements in the design.

Common technologies and standards that industry uses to assess the electromagnetic exposure and field levels are largely based on internal probes [6] and phantoms [6, 7, 8]. Phantoms are suitably designed dielectric structures obtained by filling with a dissipative liquid a container mimicking the shape of different anatomical parts whose electromagnetic exposition needs to be studied [9, 10]. The measuring probes penetrate the phantom and effectuate measures of the electric and/or magnetic field [11, 12]. Unfortunately however, such an invasive measurement procedure presents several drawbacks. It is costly, since it necessitates ad-hoc mechanical set-ups. It does not guarantee a perturbation-free measurement since an internal probing can perturb the value of the measured fields [13, 14]. Finally, it has the need of repeatedly penetrating the dielectric phantom, something that prevents the use of solid dielectric materials and, as a consequence, liquid filled phantoms provide homogeneous and isotropic dielectric profiles only. This is a poor and unrealistic modeling of biological tissues whose dielectric/resistive properties are often both inhomogeneous and anisotropic [15, 16, 17, 18].

A first class of partial solutions to some of the above mentioned issues relies on techniques for determining optimal sets of measurement samples. This for the purpose of reducing the overall number of measurements that are necessary for a full characterization of the radiation exposure [19, 20, 21, 22]. Although these techniques decrease the complexity of a standard, phantom-based, electromagnetic exposure analysis, they are still very complicated to implement, and they leave the modeling limitations of the phantom/probe approach, lamentably, unaltered. A second and more recent class of enhanced dosimetry assessment techniques relies on the use of computational imaging tools to complement the raw measurements of the electromagnetic field. Under this category fall several schemes that adopt finite element based discretizations of models of human tissues and, given an external measurements of the electromagnetic field, solve the electromagnetic problem by using FDTD [23, 24, 25], FEM [26, 27, 28], and related methods [29, 30, 31, 32, 33]. Although effective and easily available from commercial simulation toolboxes, these schemes often rely on a good knowledge of radiation sources, something that is often unavailable in dosimetry assessment.

An effective remedy to these issues is proposed by methods relying on the use of the Huygens principle [34, 35], where the (potentially unknown) source is replaced by a surfacic distribution of equivalent sources that are determined together with the field values necessary for the dosimetric assessment. These strategies however, often require the use of densely discretized Huygens surfaces and, when differential equation based methods are the leading modeling formulation, CFL conditions and low-frequency issues (see [36] and references therein) may render the approach computationally expensive. A good alternative could be the use of Huygens principle formulations based on Boundary Element Methods (BEMs). These approaches discretize only material boundaries and are not subject to CFL constraints so that an increase of discretization density in some
parts of the Huygens screen would not result in increase in other parts of the simulation volume. Very promising formulations following these strategies have been presented in [37, 38, 39]. These schemes encompass the model of a dosimetric phantom with an equivalent surface and establish a suitable integral relationship linking equivalent sources with magnetic and electric field measurements. Such a strategy falls in the more general category of inverse source approaches that have been studied extensively in the electromagnetic characterization of radiating sources [40, 41, 42, 43, 44, 45]. The problem of characterizing the sources, especially in the presence of severe ill-posedness has also been impacted by more general techniques in inverse scattering and imaging where the regularization techniques of inverse problems related to imaging have been adapted to microwave imaging for human body tissues and their anomalies [46, 47, 48, 49, 50, 51, 52, 53].

Integral equation techniques however, are not panaceas; BEM methods in fact suffer from a major drawback viz. they give rise to dense interaction matrices, resulting in high computational costs when realistic modeling are called for. Moreover, classical formulations rely often on Diraclet-to-Neumann mappings (linking magnetic to electric field quantities and vice-versa) that are well-known to be ill-posed and unbounded operators [54]. For this reason although the use of dense equivalent surfaces does not impact a volume discretization (as in CFL prone methods) it still gives rise to ill-conditioned system as a function of the discretization density that can result in high computational costs for the solution and in numerical instabilities in real case scenarios.

This work focuses in addressing these drawbacks and its contribution is threefold: (i) It will propose a BEM based formulation that requires the use of electric measurements only. This is done at the cost of solving an additional integral problem with respect to the works in [37], but it has the practical advantage of avoiding magnetic field measurements and the theoretical advantage of providing more freedom in the choice of the mapping operators and in the integral formulation modeling the dosimetric phantom. (ii) This additional freedom will be exploited to use a Huygens formulation that can be regularized. For this purpose this work will propose a Calderon-based strategy for rectangular matrices that will provide well-conditioned systems independent on the discretization density of the Huygens screen. (iii) Finally, we will hybridize our formulation with both surfacic homogeneous and volumetric inhomogeneous forward BEM solvers accelerated with fast matrix-vector multiplication schemes. This allows for rapid and effective dosimetric assessments and it permits the use of inhomogeneous and realistic head phantoms.

This paper is organized as follows: Section 2 presents background material and sets the notation. Section 3 presents the Huygens formulation we are adopting here. Section 4 presents a Calderon regularization for rectangular matrices. Section 5 presents numerical results that confirms the practical effectiveness of the new approaches. Section 6 presents our conclusions and avenues for future work.
2. Background and Notation

Consider a volume $\Omega_h$ (please refer to Fig. 1) characterized by a (potentially lossy and inhomogeneous) dielectric permittivity $\varepsilon_h(r)$ and residing in a free-space of dielectric permittivity and magnetic permeability $\varepsilon$ and $\mu$, respectively. The surface of $\Omega_h$ is denoted as $\Gamma_h = \partial \Omega_h$. Consider a (potentially unknown) source radiating the electromagnetic field $(E'(r), H'(r))$; the source resides in the interior of the closed surface $\Gamma$ (an equivalent, Huygens, surface). The total electric field $E(r)$ is assumed to be known on a surface $\Gamma_m$ as a result of a measurement procedure. In our application scenario, $\Omega_h$ will model a (potentially lossy and inhomogeneous) head phantom while the source, entirely included in the closed surface $\Gamma$, will model a mobile phone radiator (the model of which is potentially unknown).

On the equivalent surface $\Gamma$ we can define the following surface operators

$$S_k \Gamma(f(r)) = ik \int_{\Gamma} \frac{e^{ik|r-r'|}}{4\pi|r-r'|} f(r') d\Gamma - \frac{1}{ik} \int_{\Gamma} \frac{e^{ik|r-r'|}}{4\pi|r-r'|} \nabla' \cdot f(r') d\Gamma \quad (1)$$

$$D_k \Gamma(f(r)) = - \int_{\Gamma} \frac{e^{ik|r-r'|}}{4\pi|r-r'|} \times f(r') d\Gamma \quad (2)$$

where $k$ is the free space wave number.

When the dielectric profile of $\Omega_h$ is homogeneous, i.e. $\epsilon_h(r) = \epsilon_h$, we denote with $k_h$ the associated wave number in $\Omega_h$. In this case, with identical definitions with respect to the ones in (1) and (2), we define the operators $S_{\Gamma_h}^k, D_{\Gamma_h}^k$ and $S_{\Gamma_h}^{k_h}, D_{\Gamma_h}^{k_h}$ for which the integrals are defined on the surface $\Gamma_h$ and for which the wave numbers are set equal to $k$ and $k_h$, respectively. In the following we will also need the definition of the surface operators $T_{\Gamma_h}^k = \hat{n} \times S_{\Gamma_h}^k, T_{\Gamma_h}^{k_h} = \hat{n} \times S_{\Gamma_h}^{k_h}, K_{\Gamma_h}^k = \hat{n} \times D_{\Gamma_h}^k$ and $K_{\Gamma_h}^{k_h} = \hat{n} \times D_{\Gamma_h}^{k_h}$ for an outward directed normal $\hat{n}$ on
the surface $\Gamma_h$ and the definition of the free space and relative wave impedance $\eta = \sqrt{\mu/\epsilon}$ and $\eta_r = k/k_h$, respectively.

When the dielectric profile of $\Omega_h$ is inhomogeneous, i.e. for general, potentially position-dependent, $\epsilon_h(r)$, we define the dielectric contrast ratio as $\chi(r) = 1 - \frac{\epsilon_h(r)}{\epsilon}$. In this case, we define the volume operator

$$S_{kh}^k(\chi^h(r')) = \frac{1}{ik} \int_{\Omega_h} \frac{\chi(r')f(r')}{4\pi|\mathbf{r} - \mathbf{r}'|} d\Omega$$

$$- \frac{1}{ik} \int_{\Omega_h} \frac{\nabla \cdot \nabla' \cdot (\chi(r')f(r'))}{4\pi|\mathbf{r} - \mathbf{r}'|} d\Omega.$$  (3)

3. The Inverse Source Scheme

It is very well-known from potential theory [55] that we can represent the field radiated outside $\Gamma$ from sources located inside $\Gamma$ as

$$E_{ext}(r) = \alpha S_{1h}^k(\mathbf{J}(r', \alpha, \beta)) + \beta D_{1h}^k(\mathbf{M}(r', \alpha, \beta))$$  (4)

and

$$\eta H_{ext} = \frac{1}{ik} \mathbf{n} \times E_{ext}(r)$$  (5)

where $\alpha$ and $\beta$ can be arbitrarily chosen. The values of $\mathbf{J}(r')$ and $\mathbf{M}(r')$ will be a function of this arbitrary choice while the resulting value of $E_{ext}(r)$ will be independent of it. A common choice is $\alpha = \beta = 1$ for which $\mathbf{J}(r')$ and $\mathbf{M}(r')$ have the particularly physical meaning of being the Love’s currents [56] equal to $\hat{n}_r \times \mathbf{H}_{ext}(r)$ and $-\hat{n}_r \times \mathbf{E}_{ext}(r)$ respectively ($\hat{n}_r$ represents the outward directed normal on $\Gamma$). Given that we want to avoid the measurement of the magnetic field, however, this choice does not suit our treatment. We select instead $\alpha = 1$ and $\beta = 0$, in this case we deal only with the current distribution $\mathbf{J}(r')$ that in the general case however, does not have a straightforward physical interpretation. We thus define $\mathbf{J}(r')$ the (unknown) current distribution on $\Gamma$ such that

$$E_{ext}(r) = S_{1h}^k(\mathbf{J}(r'))$$  (6)

and

$$\eta H_{ext}(r) = \frac{1}{ik} \nabla \times S_{1h}^k(\mathbf{J}(r'))$$  (7)

$\forall r \in \mathbb{R}^3/\Omega$. The reader should again notice that the current $\mathbf{J}(r')$ will not be a simple function of the tangential component of the total magnetic field, like the standard electric current is, but it will be a more complicated function of tangential components of both total electric and magnetic fields. Given however that the radiated fields are to be recovered only in the external region of the equivalent surface, the complicated relationship between the current and the total fields will never be used nor required to be made explicit.
3.1. Homogeneous Head Model

We assume in this section that the dielectric profile of the head is homogeneous in $\Omega_h$. The purpose of the dosimetric assessment is to find the value of $E(r) = \mathbf{E}(r)$, $r \in \Omega_h$, i.e. the total electric field within the head. This field is computed using the surface currents on the surface $\Gamma_h$. These unknown surface currents on the head due to the external field radiated by the equivalent current $J(r)$, given the homogeneity of the dielectric profile on $\Gamma_h$ can be obtained by solving the PMCHWT integral equation given by

$$
\begin{bmatrix}
\left[T_{T_h}^k + T_{T_h}^{k_h}/\eta_r \right] & -\left(K_{T_h}^k + K_{T_h}^{k_h}/\eta_r \right) \\
\left(K_{T_h}^k + K_{T_h}^{k_h} \right) & \left(T_{T_h}^k + \eta_r T_{T_h}^{k_h} \right)
\end{bmatrix}
\begin{bmatrix}
M_h(r') \\
J_h(r')
\end{bmatrix}
= 
\begin{bmatrix}
-\hat{n} \times \eta H_{ext}(r) \\
-\hat{n} \times E_{ext}(r)
\end{bmatrix},
$$

(8)

where the unknown electric and magnetic surface currents denoted by $J_h(r')$ and $M_h(r')$ for $r' \in \Gamma_h$ respectively can be found using

$$
\begin{bmatrix}
M_h(r') \\
J_h(r')
\end{bmatrix}
= 
\begin{bmatrix}
\left(T_{T_h}^k + T_{T_h}^{k_h}/\eta_r \right) & -\left(K_{T_h}^k + K_{T_h}^{k_h} \right) \\
\left(K_{T_h}^k + K_{T_h}^{k_h} \right) & \left(T_{T_h}^k + \eta_r T_{T_h}^{k_h} \right)
\end{bmatrix}^{-1}
\begin{bmatrix}
-\hat{n} \times \eta H_{ext}(r) \\
-\hat{n} \times E_{ext}(r)
\end{bmatrix},
$$

(9)

and from which the field $E_h(r)$ scattered by the head can be obtained as

$$
E_h(r) = S_h^k(J_h(r')) + D_h^k(M_h(r')) \quad r \in \mathbb{R}^3/\Omega_h.
$$

(10)

or

$$
E_h(r) = \left[S_h^k - D_h^k\right] \begin{bmatrix}
\left(T_{T_h}^k + T_{T_h}^{k_h}/\eta_r \right) & -\left(K_{T_h}^k + K_{T_h}^{k_h} \right) \\
\left(K_{T_h}^k + K_{T_h}^{k_h} \right) & \left(T_{T_h}^k + \eta_r T_{T_h}^{k_h} \right)
\end{bmatrix}^{-1}
\begin{bmatrix}
-\hat{n} \times \eta H_{ext}(r) \\
-\hat{n} \times E_{ext}(r)
\end{bmatrix}.
$$

(11)

This can be further written as a function of $J(r')$ on $\Gamma$ by leveraging on (6) and (7) as

$$
E_h(r) = \left[S_h^k - D_h^k\right] \begin{bmatrix}
\left(T_{T_h}^k + T_{T_h}^{k_h}/\eta_r \right) & -\left(K_{T_h}^k + K_{T_h}^{k_h} \right) \\
\left(K_{T_h}^k + K_{T_h}^{k_h} \right) & \left(T_{T_h}^k + \eta_r T_{T_h}^{k_h} \right)
\end{bmatrix}^{-1}
\begin{bmatrix}
-\hat{n} \times \eta \overline{H}_n \cdot \nabla \times S_h^k(J(r')) \\
-\hat{n} \times S_h^k(J(r'))
\end{bmatrix}.
$$

(12)

By enforcing the condition $E(r) = E_{ext}(r) + E_h(r)$ on $\Gamma_m$ we obtain

$$
S_h^k(J(r')) + \left[S_h^k - D_h^k\right] \begin{bmatrix}
\left(T_{T_h}^k + T_{T_h}^{k_h}/\eta_r \right) & -\left(K_{T_h}^k + K_{T_h}^{k_h} \right) \\
\left(K_{T_h}^k + K_{T_h}^{k_h} \right) & \left(T_{T_h}^k + \eta_r T_{T_h}^{k_h} \right)
\end{bmatrix}^{-1}
\begin{bmatrix}
-\hat{n} \times \eta \overline{H}_n \cdot \nabla \times S_h^k(J(r')) \\
-\hat{n} \times S_h^k(J(r'))
\end{bmatrix} = E(r), \quad r \in \Gamma_m.
$$

(13)

As pointed out in the previous section, the field $E(r)$ is assumed to be known as a result of a measurement procedure, so that the unknown current distribution $J(r')$ can be obtained by inverting (13). This inversion will be obtained by subsequent use of boundary element discretizations as explained in the following section.
3.1.1. Discretization

In order to solve numerically the integral equations defined in the previous section, it is necessary to discretize the involved surface operators. As in any standard boundary element method, we need to approximate the various geometries present with a triangular tessellation giving rise to surface meshes for $\Gamma_h$, $\Gamma$ and $\Gamma_m$. On the internal edges of these surface meshes, we can define the sets of Rao-Wilton-Glisson (RWG) basis functions \[ \{ f^h_n \}_{n=1}^{N_h} \] and \[ \{ f^m_n \}_{n=1}^{N_m} \] respectively ($N_h$, $N$ and $N_m$ being the number of edges on $\Gamma_h$, $\Gamma$ and $\Gamma_m$ respectively). The surface currents can be approximated as

\[
J_h(r) = \sum_{n=1}^{N_h} \alpha_n f^h_n(r) \\
M_h(r) = \sum_{n=1}^{N_h} \beta_n f^h_n(r) \\
J(r) = \sum_{n=1}^{N} \gamma_n f_n(r).
\]

The different blocks in equation (13) can be discretized as explained in what follows. The PMCHWT operators $T_{\Gamma h}^k$, $T_{\Gamma h}^{k h}$, $K_{\Gamma h}^k$ and $K_{\Gamma h}^{k h}$ are discretized using the sets of RWG basis functions both as source and testing functions resulting in the matrices

\[
(T)_{mn} = \left\langle \hat{n} \times f_m^h(r), T_{\Gamma h}^k (f_n^h(r)) \right\rangle_{\Gamma h}, \\
(T')_{mn} = \left\langle \hat{n} \times f_m^h(r), T_{\Gamma h}^{k h} (f_n^h(r)) \right\rangle_{\Gamma h}, \\
(K)_{mn} = \left\langle \hat{n} \times f_m^h(r), K_{\Gamma h}^k (f_n^h(r)) \right\rangle_{\Gamma h}, \\
(K')_{mn} = \left\langle \hat{n} \times f_m^h(r), K_{\Gamma h}^{k h} (f_n^h(r)) \right\rangle_{\Gamma h},
\]

where the notation $\left\langle a \cdot b \right\rangle_\chi = \int_\chi a \cdot b \, d\chi$ and $(A)_{mn}$ represents the element in the row $m$ and the column $n$ of a matrix $A$. The discretized version of the continuous operators applied to the equivalent source currents radiating the fields on the head surface are given by

\[
(K_{\Gamma})_{mn} = \left\langle \hat{n} \times f_m^h(r), -\hat{n} \times \frac{1}{i k} \nabla \times S_{k}^h (f_n^h(r)) \right\rangle_{\Gamma h}, \\
(T_{\Gamma})_{mn} = \left\langle \hat{n} \times f_m^h(r), -\hat{n} \times S_{k}^h (f_n^h(r)) \right\rangle_{\Gamma h}.
\]

Similarly, the discretized version of the continuous operators applied to the surface currents on the head radiating the fields on the measurement surface
are given by
\((S_{\Gamma_h})_{mn} = \langle f^m_m(r), S^k_{\Gamma_h}(f^n_n(r)) \rangle_{\Gamma_h}\),
\((D_{\Gamma_h})_{mn} = \langle f^m_m(r), D^k_{\Gamma_h}(f^n_n(r)) \rangle_{\Gamma_h}\).  
(17)

The incident electric field due to the equivalent source currents on the measurement surface represented as a matrix is given by
\((S_{\Gamma})_{mn} = \langle f^m_m(r), S^k_{\Gamma}(f^n_n(r)) \rangle_{\Gamma_m}\).  
(18)

The overall right hand side vector reads
\(v_m = \langle f^m_m(r), E(r) \rangle_{\Gamma_m}\).  
(19)

Finally, define the unknown current coefficients vector
\((\gamma)_m = \gamma_m\).  
(20)

Leveraging on all the definitions above, the discretization of equation (13) reads
\[ S_{\Gamma} \gamma + \left[ S_{\Gamma_h} \ D_{\Gamma_h} \right] \begin{bmatrix} (T + T'/\eta_r) & -(K + K') \\ (K + K') & (T + \eta_r T) \end{bmatrix}^{-1} \begin{bmatrix} K_{\Gamma} \\ T_{\Gamma} \end{bmatrix} \gamma = v. \]  
(21)

3.2. Inhomogeneous Head Model

In realistic scenarios, the modeling of the human head phantom may result in inhomogeneous dielectric profiles modeling different tissues (typically scalp, skull and brain). The objective of dosimetric assessments remains unchanged from the case analyzed in the previous section, i.e. the total electric field inside the head region must be recovered starting from measurements in the vicinities of the radiating source. The total electric field now is the sum of the external field radiated by the equivalent current \(J(r')\) and the equivalent volume current \(J^v_{\Gamma_h}(r')\) inside the human head model. The mapping between the volume currents and the external field can be expressed using a Volume Integral Equation (VIE) [58, 59]
\[ \left[ (1 - \chi(r)) \frac{I}{ik} + S^k_{\Omega_h} \right] J^v_{\Gamma_h}(r') = E_{ext}(r) \quad r \in \Omega_h. \]  
(22)

where \(I\) is the identity operator and the unknown volume current is given by
\[ J^v_{\Gamma_h}(r) = -\left[ (1 - \chi(r)) \frac{I}{ik} + S^k_{\Omega_h} \right]^{-1} E_{ext}(r') \quad r \in \Omega_h. \]  
(23)

The electric field in the external region due to the volume current inside the head is given by
\[ E_h(r) = -S^k_{\Omega_h} J^v_{\Gamma_h}(r') \quad r \in \mathbb{R}^3/\Omega_h. \]  
(24)
or
\[
E_h(r) = -S^k_{\Omega_h} \left[ (1 - \chi(r)) \frac{I}{i k} + S^k_{\Omega_h} \right]^{-1} E_{ext}(r').
\] (25)

which can be written in terms of surface currents on the equivalent surface as
\[
E_h(r) = -S^k_{\Omega_h} \left[ (1 - \chi(r)) \frac{I}{i k} + S^k_{\Omega_h} \right]^{-1} S^k_{\Gamma}(J(r')).
\] (26)

The total electric field on the measurement surface \(\Gamma_m\) is thus obtained as
\[
S^k_{\Gamma}(J(r')) - S^k_{\Omega_h} \left[ (1 - \chi(r)) \frac{I}{i k} + S^k_{\Omega_h} \right]^{-1} S^k_{\Gamma}(J(r')) = E(r) \quad r \in \Gamma_m.
\] (27)

The above equation gives the relationship between the unknown equivalent surface current and the measured electric field in the presence of an inhomogeneous head model. The unknown surface current \(J(r')\) can be obtained by solving the discretized version of the above equation as explained in the next subsection.

### 3.2.1. Discretization

Equation (27) can be discretized after meshing the equivalent surface \(\Gamma\) with triangular cells and the head volume \(\Omega_h\) with tetrahedral cells. On a pair of triangular cells of the equivalent source and measurement surface, we define the sets of RWG basis functions \(\left\{ f^v_n \right\}_{n=1}^{N_v}\) and \(\left\{ f^v_m \right\}_{m=1}^{N_v}\) respectively. Similarly, on a pair of each adjacent tetrahedron of the volume mesh, we define an Schaubert-Wilton-Glisson (SWG) basis function [58] giving rise to the set \(\left\{ f^v_n \right\}_{n=1}^{N_v}\) (\(N_v\) represents the number of triangular cells based on which the SWG basis functions are defined). Using these basis functions, we can discretize the volume and surface currents as
\[
J_v(r) = \sum_{n=1}^{N_v} \alpha_n f^v_n(r)
\] (28)

\[
J(r) = \sum_{n=1}^{N} \gamma_n f_n(r).
\]

The VIE operator can be discretized as
\[
(S_{\Omega_h})_{mn} = \langle f^v_m(r), S^k_{\Omega_h}(f^v_n(r)) \rangle_{\Omega_h}
\] (29)

and the Gram matrix is given by
\[
(G_{\Omega_h})_{mn} = \left\langle f^v_m(r), \frac{1 - \chi(r)}{i k} f^v_n(r) \right\rangle_{\Omega_h}.
\] (30)

The discretized surface operator applied to the equivalent source current radiating on the head surface is given by
\[
(S^k_{\Gamma})_{mn} = \langle f^v_m(r), S^k_{\Gamma}(f_n(r)) \rangle_{\Omega_h}.
\] (31)
Similarly, the discretized volume operator applied to the volume currents of the inhomogeneous head model radiating on the measurement surface is given by

\[(S_{\Gamma}^\Omega h)_{mn} = \langle f_m(r), S_{\Gamma k h} (f_n(r)) \rangle_{\Gamma m} . \tag{32} \]

The discretization of the operator defined for the incident electric field due to the equivalent source currents on the measurement surface

\[(S_{\Gamma})_{mn} = \langle f_m(r), S_{\Gamma k} (f_n(r)) \rangle_{\Gamma m} . \tag{33} \]

and the right hand side and solution vectors

\[v_m = \langle f_m(r), E(r) \rangle_{\Gamma m} . \tag{34} \]

\[(\gamma)_m = \gamma_m . \tag{35} \]

remain similar to those of the homogeneous case (treated in the previous section). By combining the discretizations above we obtain the following discretized version of equation (27)

\[S_{\Gamma}^\gamma - S_{\Omega h}^\Gamma \left[ G_{\Omega h} + S_{\Omega h} \right]^{-1} S_{\Gamma h}^{0b} \gamma = v . \tag{36} \]

4. Calderón preconditioning

As delineated in the previous sections, the linear system of equations (21) and (36) requires near field measurements for building up the right hand side vector. A practical case of interest arises when the equivalent surface and the measurement surface coincide i.e. \(\Gamma_m = \Gamma\). Even in this case, however, the surface meshes on \(\Gamma_m\) and \(\Gamma\) are often different. In fact, the discretization of the measurement surface is dependent on the overall number of degrees of freedom of the measured near field values [19, 20] and also on the limitations of the measurement system setups [21, 60]. On the other hand, the discretization of the equivalent surface depends on how well it can model the near field behaviour of the radiating source and it plays a role in the pseudo-inversion procedure. This results in a different discretization density on the equivalent surface compared to the measurement surface. Therefore, the system matrices in equation (21) and (36) are rectangular and they deal with unequal number of unknowns compared to the number of equations. These equations can be solved in the least squares sense using an iterative solver by applying the transpose to the matrix \(S_\Gamma\) as

\[S^T_\Gamma [S_\Gamma + \tilde{S}_\Gamma] \gamma = S^T_\Gamma v . \tag{37} \]

where in case of the homogeneous head model

\[\tilde{S}_\Gamma = [S_{\Gamma n} \ D_{\Gamma n}] \left[ \begin{array}{cc} (T + T' / \eta) & -(K + K') \\ (K + K') & (T + \eta T') \end{array} \right]^{-1} [S_\Gamma \ K_\Gamma] , \tag{38} \]
and for the inhomogeneous head model
\[ \tilde{S}_\Gamma = -S_{\Omega h}^T \mathbf{G}_{\Omega h} + S_{\Omega h}^{-1} S_{\Omega h}^T. \] (39)

In equation (37), the matrix \( \tilde{S}_\Gamma \) represents a compact perturbation of the EFIE operator matrix with a negligible contribution to the spectrum of \( S_\Gamma \). The overall system matrix inherits the ill-conditioning of the EFIE operator due to the dense discretization and low frequency breakdown [61]. The condition number of \( S_\Gamma \) shows a behavior of order \( O\left(\frac{1}{(kh)^2}\right) \) [62, 63]. This results in a conditioning behavior of order \( O\left(\frac{1}{(kh)^4}\right) \) for the system matrix \( S_\Gamma^T S_\Gamma \). Therefore, solving equation (37) becomes a challenging task as the discretization on the equivalent surface increases and/or the frequency decreases. In this work we propose to leverage on Calderón preconditioning to solve this problem. Calderón preconditioning is based on the Calderón identity [64, 65]
\[ (\mathcal{T}_k^\Gamma)^2(J(r)) = -\frac{J(r)}{4} + (\tilde{K}_k^\Gamma)^2(J(r)). \] (40)

The discretization of equation (40) results in well conditioned system matrices [64]. The operator \( \mathcal{T}_k^\Gamma \) when discretized with the sets of RWG basis functions \( \{f^n_m\}_{m=1}^N \) and \( \{\hat{n} \times f^n_m\}_{m=1}^N \) results in the matrix \( S_\Gamma \). To realize the discretization of the Calderón identity (equation (40)), however, we also need the sets of Buffa-Christiansen (BC) basis functions \( \{b^n_m\}_{m=1}^N \) and \( \{\hat{n} \times b^n_m\}_{m=1}^N \) (the definition of these functions is omitted here for the sake of brevity, the reader should refer to [66] or [64] for the implementational details of these boundary elements). This discretization gives rise to the matrix \( S_{\Gamma}^{BC} = (b^n_m(r), S_\Gamma(b^n_m(r)))_{\Gamma_m} \). In order to link correctly the basis functions between the two operator matrices \( S_{\Gamma}^{BC} \) and \( S_\Gamma \), we need a suitable Gram matrix \( \mathbf{G}_{\Gamma_m} = (\hat{n} \times f^n_m(r), b^n_m(r))_{\Gamma_m} \). The proposed regularized linear system of equations for dosimetry assessment then reads
\[ [S_{\Gamma}^{BC}]^T [\mathbf{G}_{\Gamma_m}]^{-1} [S_\Gamma + \tilde{S}_\Gamma] \gamma = [S_{\Gamma}^{BC}]^T [\mathbf{G}_{\Gamma_m}]^{-1} \mathbf{v}. \] (41)

5. Numerical Results

The first test focused on the validation of the BEM formulation, developed in section 3.1 for homogeneous phantom profiles. The electric field radiated by a mobile phone antenna in the presence of an homogeneous head phantom is shown in Figure 2a. The mobile antenna has been enclosed in a parallelepiped’s equivalent surface that is also used as measurement surface. After applying the numerical procedure detailed in section 3.1, the electric field is reconstructed in Figure 2b. Figure 2c shows the reconstruction relative error computed as
\[ \varepsilon(r) = \frac{|E(r) - E_s(r)|}{|E(r)|} \] (42)
where the electric field \( E(r) \) and \( E_s(r) \) are due to the radiating source and the Huygens surface in presence of the head respectively. The maximum field relative error stays below 1% confirming the validity of the formulation.
A second numerical test has been performed to assess the performance of the BEM formulation, developed in section 3.2 for inhomogeneous phantom profiles. The inhomogeneous head phantom we have used is shown in Figure 3. We have adopted an MRI based three layers head model which has a piecewise-constant dielectric profile. The reader should notice, however, that any other dielectric profile of arbitrary inhomogeneity could have been used as well. The electric field radiated by a mobile phone antenna in the presence of this inhomogeneous head phantom is shown in Figure 4a. The mobile antenna has been again enclosed in a parallelepiped’s equivalent surface that is also used as measurement surface. After applying the numerical procedure detailed in section 3.2, the electric field is reconstructed in Figure 4b. The reconstruction relative error is shown in Figure 2c, the maximum field relative error stays well below 1% confirming that also this formulation for inhomogeneous dielectric profiles is a valid one.

A final set of tests has been focused in validating the Calderón regularizations proposed in section 4. First we have considered two canonical cases (a cube and an hemisphere) to check the stability of the regularization to mesh refinement. To this purpose the measurement mesh has been kept constant, while the equivalent surface mesh density was increased. For the case of the cube, the condition numbers of the overall system matrix w.r.t to the average edge length is shown in Figure 5. It is clear that the regularized system matrix has a constant condition number when the mesh density increases whereas without

Figure 4: Inhomogeneous head model
regularization a steep condition number growth is observed. A similar behavior is observed in the case of the hemisphere as it is shown in Figure 6. The stability of the regularized system with respect to frequency has been tested as well. The condition numbers as a function of the frequency are shown in Figure 7. Also in this case the regularized formulation is stable, while standard operators show the expected frequency instability. A regularization in a real case scenario has been equally tested. To this purpose we have used the previous homogeneous head model. The relative tolerance of a CGS solver w.r.t. number of iterations to compute the dosimetry assessment can be seen in Figure 8. The tolerance curves show that the regularization proposed here can greatly improve the convergence behaviour and, as a consequence, the time necessary for the dosimetric assessment.

6. Conclusions

A Boundary Element Method (BEM) formulation for contactless electromagnetic field assessments has been presented. The new scheme, which is based on a regularized BEM approach, requires the use of electric field measurements only. The regularization, which is based on Calderon techniques, enables the use of highly discretized Huygens surfaces that can be consequently placed very near to the radiating source. An hybridization with both surfacic homogeneous and volumetric inhomogeneous forward BEM solvers has been proposed that allows the use of inhomogeneous and realistic head phantoms. Numerical results have been presented that corroborate the theory and confirms the practical effectiveness of all newly proposed formulations. Future investigations will include the extension of the new formulations presented here to the time domain as well as their application to an industrial-level measurement setting.
