Identifying the loss mechanisms of niobium cavities enables an accurate determination of applications for future accelerator projects and points to research topics required to mitigate current limitations. For several cavities an increasing surface resistance above a threshold field, saturating at higher field has been observed. Measurements on samples give evidence that this effect is caused by the surface electric field. The measured temperature and frequency dependence is consistent with a model that accounts for these losses by interface tunnel exchange between localized states in dielectric oxides and the adjacent superconductor.

Keywords: Superconducting cavities, niobium, Quadrupole Resonator, interface tunnel exchange, surface resistance

Superconducting cavities made of niobium are nowadays routinely reaching surface resistances $R_S$ as low as a few nΩ at surface magnetic fields above 100 mT corresponding to peak electric fields of over 50 MV/m, some performing close to the theoretical limit of the material. Nevertheless many open questions concerning the field dependence of $R_S$ exist. In the medium field region between a few and few tens of MV/m an increasing surface resistance is always observed. For some cavities this increase can be fitted with a polynomial of second order. These losses are described by models based on the surface magnetic field $B$. Magnetic flux entry is thought to give rise to the quadratic term, which is dependent on hysteresis losses and independent of temperature. Adding an additional term to account for a widely observed decrease of $R_S$ at fields below a few mT the total surface resistance for a cavity measured at a fixed temperature can be written as:

$$R_S = R_0 + R_1 \left( \frac{B}{B_c} \right) + R_2 \left( \frac{B}{B_c} \right)^2 + R_3 \left( \frac{1}{B} \right)^2,$$

where the critical thermodynamic field $B_c$ is 200 mT for niobium. Even if these losses constitute the major contribution for most cavities, it is important to identify other loss types in order to disentangle them correctly. In this spirit we present a different loss mechanism of electrical origin, already observed, though not further quantified, in prototypes of superconducting bulk niobium cavities for the Large Electron Positron Collider at CERN. These losses yield an $R_S$ increasing above a threshold field saturating at higher field and can be explained by the interface tunnel exchange model (ITE). ITE assumes that electrons are exchanged between states in the superconducting Nb and localized states in adjacent dielectric oxides (Nb$_2$O$_5$ and/or NbO$_2$). This exchange is caused by the surface electric field $\vec{E}$ penetrating only the oxide and not the superconductor, allowing for an exchange of electrons (i.e. a current) between the two materials within one RF period. Fig. 1 depicts the variation of the density of occupied electron states before and after an exposure of the surface to a stepwise increase or decrease of the electric field. The time after exposure is considered here long as compared to the relaxation time. Hence the occupation of states is in thermal equilibrium near the interface of superconducting niobium and dielectric surface oxides; (left) after exposure to a positive and (right) to a negative electric field $E_{\perp}$. Note that the population of occupied electron states in the oxide is modified after the exposure of the electric field which indicates current flow. In the superconducting niobium (sc Nb) the gray-scales indicate the density of states. $E_F$ is the Fermi energy and $\Delta$ is the energy gap of superconducting niobium.

Experimental evidence for electric surface resistance in niobium

on the thickness of the oxide $x$ and on $\Delta$, below which there is no current and hence no RF loss. In a quantitative analysis, Halbritter calculated the surface resistance for ITE losses as\(^7\):

$$R_S^E = R_{S, sat}^E[f(\text{GHz})\left|e^{-b/E} - e^{-b/E_0}\right|], \quad E \geq E_0,$$  (2)

where the parameters $R_{S, sat}^E$ (here normalized to 1 GHz), $b$ and $E_0$ are defined by

$$b = \frac{2\kappa \Delta \varepsilon_r}{\beta^* e}, \quad R_{S, sat}^E = \frac{2\pi \mu_0}{(2\kappa)^2 y}, \quad E_0 = \frac{\Delta \varepsilon_r}{\varepsilon x \beta^*}$$

with

$$\kappa = \sqrt{2m(E_c - E_F)/h}, \quad y^{-1} = \frac{\langle nx_T \rangle e^2}{\varepsilon_0 \varepsilon_r}.$$  

The meaning of the physical parameters is the following: $E_c$ and $E_F$ are the energies of the conduction band and the Fermi energy, respectively; $\langle nx_T \rangle$ is the averaged product of the density of trapped electron states $n_T$ and the thickness of the oxide $x$; $\varepsilon_r$ is the relative dielectric constant; $\beta^*$ is the geometric field enhancement factor of the metal due to surface roughness; $m$, $e$, $\varepsilon_0$, $\mu_0$ and $h$ are the usual physical constants, such as the electron mass and electric charge, vacuum permittivity, vacuum permeability and Planck constant, in this order.

Figure 2 shows $R_S$ as a function of the peak electric field $E_{pk}$ at 2 K of a 1.3 GHz elliptical TESLA shaped cavity. It was manufactured of fine grain bulk niobium (grain size of about 50 $\mu$m). The first measurement was performed after chemical polishing (BCP). Afterwards the cavity was in situ baked at 120 °C. Then several hydrofluoric (HF) rinsings were done to remove about 10 nm of the outer surface layer\(^8\). The dashed lines show fits to the ITE model with two additional parameters accounting for the low field losses. The total $R_S$ is assumed to be

$$R_S = R_{S, sat}^E(E) + R_0 + R_3 \left(\frac{1}{B}\right)^2$$  (3)

where $R_{S, sat}^E(E)$ is calculated according to Eq. 2. For comparison the data has also been fitted to Eq. (1). Note that the fit to Eq. (1) systematically overestimates the data in the low and high field region, while it systematically underestimates the data in the medium field region for the data obtained after baking (red curve). The measurement is not well represented by the fit even if a relative high coefficient of determination $R^2$ is obtained.

The ITE model however can explain the dependence of $R_S$ on $E_{pk}$ better and significantly higher $R^2$ values are found for these fits obtained for the two data sets before HF rinsing, see Tab. 1. The phenomenological fit parameters (also found in Tab. 1) correspond to physical meaningful parameters (compare with\(^10\) and quotations therein and\(^11,12\)) as $\beta^* = 1$, $\varepsilon_r = 10$, $E_c - E_F = 0.05$ eV, $\Delta = 1.18$ meV, $x = 1.65$ nm and $\langle n_T \rangle = 3.1 \times 10^{24}$ $1/(eV m^3)$, before and $\beta^* = 1$, $\varepsilon_r = 10$, $E_c - E_F = 0.05$ eV, $\Delta = 1.33$ meV, $x = 1.27$ nm and $\langle n_T \rangle = 4.9 \times 10^{24}$ $1/(eV m^3)$ after baking. The values of $E_c - E_F$ are inconsistent with the band gap of NbO\(_2\) (3.4-5.3 eV\(^13\)) but fit neatly the value of NbO\(_2\) (0.1 eV\(^13\)). Hence the localized states participating in the exchange are found the NbO\(_2\) for which the value of $\varepsilon_r = 10$ is consistent with\(^15\). Recent results show that after mild baking the total thickness of the oxide layer is reduced, but the thickness of the NbO\(_2\) layer enhanced\(^11\), which is consistent with an enhanced $R_{S, sat}^E$ and corresponding $\langle n_T \rangle$. After HF rinsing the threshold disappears and the polynomial fit yields a better representation of the data. ITE losses require localized states inside a sufficiently thick dielectric (in this case NbO\(_2\)). Vanishing ITE after HF rinsing might be explained by a regrowth of a thinner fresh oxide layer with reduced NbO\(_2\) content.

A cavity test performed at fixed temperature and frequency is obviously not suited to test how the losses depend on these two external parameters. The Quadrupole Resonator\(^17\) is a unique device enabling to test $R_S$ of superconducting samples over a wide parameter range. It features two excitable modes at 400 and 800 MHz with identical magnetic field configuration on the sample surface. The ratio between electric and magnetic field for these two modes is proportional to $f$. For example

### TABLE I. Parameters derived for a least squares fit to Eq. (3) and (1) of a bulk niobium cavity (cf. Fig. 2).

| Parameter | BCP | 120°C baking | HF rinsing |
|-----------|-----|--------------|-----------|
| $R_{S, sat}^E$ in nΩ | 18.4±0.8 | 22.3±0.9 | 14.0±1.4 |
| $E_0$ in MV/m | 7.1±1.2 | 10.5±0.5 | 4±250\(^16\) |
| $b$ in MV/m | 26.9±1.2 | 30±3 | 44±4 |
| $R_0$ in nΩ | 16.6±0.4 | 9.24±0.09 | 11.0±0.2 |
| $R_3$ in nΩ($mT$)$^2$ | 100±50 | 15±3 | 3±3 |
| $R^2$ for Eq. (3) | 0.9987 | 0.9988 | 0.9885 |
| $R_0$ in nΩ | 12.8±0.5 | 6.9±0.8 | 10.4±0.2 |
| $R_1$ in nΩ | 38±2 | 27±8 | 6.5±1.9 |
| $R_2$ in nΩ | 0 | 20±6 | 19±4 |
| $R_3$ in nΩ($mT$)$^2$ | 170±80 | 48±16 | 9±3 |
| $R^2$ for Eq. (1) | 0.9913 | 0.9821 | 0.9926 |
Experimental evidence for electric surface resistance in niobium

FIG. 3. Surface profile from the niobium film sample obtained from AFM. The lateral resolution of the image is 4 nm.

for a peak magnetic field $B_p=10 \, \text{mT}$, the peak electric fields are $E_p=0.52$ and 1.04 MV/m for 400 and 800 MHz, respectively$^{18}$. This feature allows for a separation of magnetic and electrical losses from measurement data by comparison with theoretical models.

To test the properties of ITE a sample is required for which these temperature independent losses remain dominant up to relatively large temperatures. This condition was obtained for a micrometer thin niobium film sample sputtered on a copper substrate, which was kept under normal air for 10 years. Using XPS the thickness of its surface layer was found be significantly larger as a reference bulk niobium sample prepared by BCP$^6$. The thin film has a grain size of a few nm as measured by atomic force microscopy, see Fig 3. This is several orders of magnitude smaller than typical values of fine grain bulk niobium surfaces prepared for accelerating cavities.

Using the Quadrupole Resonator it was measured at 400 and 800 MHz over a temperature range between 2 and 4.5 K. Figure 4 shows $R_S$ vs. the peak magnetic field $B_{pk}$ on the sample. Only about one fifth of the data is plotted. To calculate $R_S$, the measured dissipated RF power on the sample surface $P_{RF}$, is assumed as solely caused by the surface magnetic field using

$$R_S = \frac{2\mu_0 P_{RF}}{\int |\vec{B}|^2 dS}. \quad (4)$$

Curves for a different temperature and the same frequency are parallel. Therefore the field dependent part of $R_S$ can be assumed as independent of temperature. Between 0 and 35 mT $R_S$ increases by about 60 nΩ at 400 MHz and by about 600 nΩ at 800 MHz. These two features cannot be explained by any model predicting a linear or quadratic increase of the surface resistance with magnetic field, such as$^{2,3,19}$. In the following it is assumed that the field dependent contribution of $R_S$ is caused by the surface electric field to test whether the data is consistent with the ITE model. First, the field independent residual and BCS losses are subtracted from each curve individually. Then $R_S$ is derived assuming all other losses to be caused by the surface electric field using

$$R_S^E = \frac{2\mu_0 P_{RF}}{\varepsilon_0 \int |\vec{E}|^2 dS}. \quad (5)$$

From Fig. 5 the linear scaling of $R_S^E$ with frequency as predicted by the ITE model becomes apparent. It furthermore becomes more evident that these field dependent losses are independent on temperature. Note that due to the field configuration of the Quadrupole Resonator the ratio

$$\int |\vec{E}|^2 dS / \int |\vec{B}|^2 dS \propto f^2. \quad (6)$$

FIG. 4. Surface resistance $R_S$ of a niobium film sample tested with Quadrupole Resonator at 400 MHz (2.5 K (blue), 4 K (magenta)) and 800 MHz (2.5 K (black), 4 K (red)). $R_S$ was obtained under the assumption that all losses are solely caused by the surface magnetic field.

FIG. 5. Electric surface resistance at 400 MHz (2.5 K (blue), 4 K (magenta)) and 800 MHz (2.5 K (black), 4 K (red)) of a niobium film sample. The lines show predictions from a collective least squares multiparameter fit to a data set comprising 183 values $R_S(f,T,E)$. The data displayed is the same as in Fig 4. The losses independent on field strength have been subtracted from each curve. All field dependent losses are assumed to be caused by the surface electric field.
The complete data set consisting of 183 values $R_S(f,T,E)$ has been collectively fitted to Eq. (2). A $\chi^2=167.9$ was obtained for the fit parameter values of $R^E_{S,sat}=17000 \pm 500 \text{n}\Omega$, $b=1.06 \pm 0.10 \text{MV/m}$ and $E^0=0.610 \pm 0.015 \text{MV/m}$. The fact that $\chi^2$ is close to the number of data points indicates that the measurement is well represented by the model. For this sample $R^E_{S,sat}$ is three orders of magnitude larger than for the bulk niobium cavity, corresponding to higher density of trapped states. The onset field $E^0$ is one order of magnitude smaller for the sample, which might be correlated to the roughness of the sample in the nanometer scale, as measured by AFM, see Fig 3. For further surface analytic measurements on this sample in comparison to bulk niobium surfaces refer to\textsuperscript{9}.

Also here, the phenomenological fit parameters $R^E_{S,sat}$, $b$ and $E^0$ can be correlated to a set of physical parameters with meaningful values as $\beta^*=10$, $\varepsilon_r=10$, $E_c = E_F = 0.01 \text{eV}$, $\Delta=1.04 \text{meV}$, $x=1.7 \text{nm}$ and $\langle n_T \rangle=7 \times 10^{26} \text{1/(eVm}^3)$. A critical assessment of these numbers lies however beyond the scope of this paper.

In conclusion, the dependency of the surface resistance on the applied field strength is different for different cavities and/or surface preparations. This indicates a variety of different dominant field dependent loss mechanisms. Some cavities exhibit an $R_S$ increasing above a threshold field saturating at higher field. In this paper it has been shown that measurements on a state of the art bulk niobium cavity, showing this behavior of $R_S$ on the surface electric field, can be well described by the ITE model.

To further test the predictions of the ITE model a niobium thin film sample was tested with the Quadrupole Resonator. These measurements showed field dependent losses independent on temperature, which scale linearly with frequency, if one assumes that they are caused by the surface electric field. These findings are consistent with the predictions of the ITE model. They allow to better understand the field dependent surface resistance of superconducting niobium. This can be used for the development of future accelerating cavities. In particular a possible explanation for the larger field dependent surface resistance found in some cavities produced of niobium films on copper substrates, a technology widely used for cavity operation at 4.2 K\textsuperscript{23}, is given by the ITE model.
