ABSTRACT

BACKGROUND
Dengue fever (DF) is caused by a flavivirus and is transmitted to humans by the vector Aedes aegypti. Industrialization and unplanned urbanization have led to an increase in incidence of DF. DF can lead to organ-specific complications especially in those with co-morbidities. The present study was done to estimate the prevalence of organ-specific complications in DF and determine the association of co-morbidities and development of organ-specific complications.

METHODS
This is a prospective cross-sectional observational study. 148 participants with DF as confirmed by NS1 antigen or dengue IgM presenting to medicine outpatient department of Government Medical College, Trivandrum were enrolled in the study after obtaining written informed consent and obtaining Institutional Ethics Committee approval. Examination findings, laboratory investigations [complete blood count (CBC), liver & renal function tests (RFT)], chest radiograph, ultrasonography (USG), magnetic resonance imaging (MRI), and cerebrospinal fluid (CSF) examination were done as routine procedures wherever necessary, and the details were collected in case record forms. Data was analysed using Rafter assessment of normality and homogeneity and chi square test was used to determine the association between parameters and organ specific complications. P < 0.05 was considered statistically significant.

RESULTS
Acalculous cholecystitis (29.1%), hepatitis (4.7%), aseptic meningitis (4.1%), encephalopathy (4.1%), myocarditis (3.4%), encephalitis (2.7%), acute kidney injury (2%), acute respiratory distress syndrome (2%), pericardial effusion (1.4%), pleural effusion (1.4%) and conduction anomalies of heart (0.7%) were the organ specific complications associated with DF. Participants with co-morbidities were at a higher risk of developing organ-specific complications when compared to the healthier individuals.

CONCLUSIONS
Acalculous cholecystitis was the most common complication associated with DF and the presence of co-morbidities was a significant risk for development of complications. Proper planning for vector control measures especially during high-risk seasons would reduce the transmission of the disease and reduce the healthcare burden, mortality and morbidity associated with dengue fever.

KEY WORDS
Dengue Fever, Organ Specific Complications, Acalculous Cholecystitis, Hepatitis, Meningitis
Dengue virus belongs to genus flavivirus and the family flaviviridae. The disease is arthropod-borne (spread by *Aedes aegypti*) and is fast spreading and depending on the antigenic subtypes, can be classified as dengue virus 1 to 4. Dengue fever is the most common arboviral infection globally. DF can be asymptomatic and self-limiting in some patients. According to World Health Organization (WHO) guidelines of 1997, dengue virus infections were classified into three categories as DF, dengue haemorrhagic fever (DHF), and dengue shock syndrome (DSS). Later this classification was revised, and patients were categorized based on the severity levels of the infection into DF without warning signs, DF with warning signs, and severe DF. The warning signs of DF include lethargy, persistent vomiting, abdominal tenderness or pain, mucosal bleeding, hepatomegaly, and thrombocytopenia with elevated hematocrit. DF is characterized by high-grade fever for 3 to 7 days, severe headache, myalgia, retro-orbital pain, and joint pain and is associated with transient flushing erythema in the initial 2 days of fever which changes to a maculopapular/morbilliform rash after 3-7 days of fever. DHF mostly develops as a secondary dengue infection in adults, however, in infants, it may occur as a primary infection. Symptoms include high-grade fever with ecchymosis, epistaxis, purpura, gingival and mucosal bleeding and platelet count of less than 1 lakh/mm$^3$ is usually associated with it. DSS is characterized by DHF along with cold clammy skin, intraoral cyanosis, and narrow pulse pressure (<20 mm of Hg). DSS can lead to complications such as disseminated intravascular coagulation (DIC), multi-organ dysfunction syndrome, and shock. Subsequent infection with a heterologous strain increases the risk of developing DHF. In tropical and subtropical countries, over 2.5 billion people are infected with DF which includes residents and travellers, and is considered an endemic more than 100 countries. Though India is considered as a hot spot for DF, the number of cases and complications are largely underestimated. Hence, an active and efficient surveillance system is essential for the detection, diagnosis, and prevention of DF.

The multisystemic complications associated with DF include encephalitis, encephalopathy, cardiomyopathy, hepatic disorders, orchitis, oophoritis, and pneumonia. Published literature has also demonstrated the occurrence of opsdonous-myolcosus syndrome and brachial neuritis with DF in the Indian population. The cardiac manifestations associated with dengue are asymptomatic sinus bradycardia, transient AV blocks, transient ventricular arrhythmias, myocarditis, and pericardial effusion. But in reality, most of the cardiac manifestations are poorly investigated and are underreported. Signs of liver dysfunction such as elevated liver enzymes can be observed in severe DF and the common hepatic complications are direct liver damage, hypoprotenaemia, hypoalbunemia and coagulation anomalies. Myalgia, myositis, rhabdomyolysis, and hypokalaemic paralysis are the manifestations of muscle involvement in DF. Renal complications such as acute renal failure, glomerulonephritis, haematuria, and proteinuria can be associated with severe DF. Pneumonitis, pleural effusion, pulmonary haemorrhages, and acute respiratory distress syndrome (ARDS) are the commonly reported respiratory complications of DF. Involvement of the eyes in form of retinal haemorrhages, macular oedema, foveolitis, vasculitis, and optic neuropathy can be seen associated with DF.

The presence of co-morbidities such as cardiovascular diseases, endocrine diseases, haematological abnormalities, liver disorders, renal dysfunction, autoimmune disorders and solid organ transplantation increases the risk of severe infections. DF in patients with DM and DM with coexisting hypertension increases the chance of developing DHF/DSS. The presence of co-morbidities increase the risk of severity in dengue patients and increases incidence of organ-specific complications. Owing to the scarcity of published literature, the present study determines the association of co-morbidities and severity of DF and organ specific complications associated with it.

**METHODS**

The present prospective cross-sectional observational study enrolled 148 participants with DF admitted in General Medicine Department of Government Medical College, Thiruvananthapuram from 2019 to 2020. Study commenced after obtaining Institutional Ethics Committee and written informed consent was obtained from all study participants. Sample size was calculated assuming an α error of 0.05, β error of 0.2 and 80% power. All participants aged 18 years and above admitted in the ward or intensive care unit (ICU) with dengue NS1Ag/ Dengue IgM positive results were included in our study. The research study variables collected include age, gender, history of co-morbidities (Diabetes, hypertension, dyslipidaemia, chronic liver disease, chronic kidney disease, reactive airway disease), laboratory investigations such as platelet count, serum bilirubin, liver enzymes (SGOT and SGPT), blood urea, serum creatinine, electrocardiogram (ECG), chest x-ray. Computed tomography (CT) scan was performed in participants with neurological symptoms or headache. Data was collected in semi structured proforma in which age, sex, history of co-morbidities, symptoms of the patient were recorded. In addition to this laboratory investigation reports, previous reports of participants were also collected for analysis. Normality of data was assessed using the Shapiro-Wilk test and values are expressed as proportions and data is expressed as tables and bar diagrams. Chi square test was used to determine the association between parameters and a P < 0.05 was considered statistically significant.

**RESULTS**

64.2 % (n = 95) participants were males and 35.8 % (n = 53) were females. Baseline characteristics of the study participants are demonstrated in table 1. Co-morbidities of the study participants is demonstrated in figure 1. 45.9 % participants were in the age between 21 to 30 years. Prevalence was slightly higher in rural areas compared to urban areas. Abnormalities in ECG were observed in 4.7 % study participants and the causes of these abnormalities were myocarditis and conduction anomalies. Echocardiogram was done in nine participants who had chest pain as a presenting
symptom and 4.7% participants had detectable abnormalities in echocardiogram. Five participants had global left ventricular hypokinesia suggestive of myocarditis and two participants had pericardial effusion. Chest X-ray demonstrated pleural effusion in two participants and pericardial effusion in two participants and one participant had X-ray findings consistent with ARDS. 1.4% participants had regions of focal involvement of brain parenchyma suggestive of encephalitis in CT scan. 7.4% participants had CSF findings diagnostic of aseptic meningitis or encephalitis. Among the study participants, fever was the most common symptom (98.6%) followed by headache (50%), vomiting (45.4%), abdominal pain (32.4%). Other symptoms included altered sensorium (4.1%), breathlessness (4.1%), chest pain (3.4%), cough (3.4%), seizures (2.7%) and oliguria (2%).

| Parameter | Category | N (%) |
|-----------|----------|-------|
| Gender | Male | 95 (64.2) |
| | Female | 53 (35.8) |

CKD - chronic kidney disease, CLD - chronic liver disease, RAD - reactive airway disease, association was determined using chi square test
The most common symptom was fever followed by other symptoms such as headache, abdominal pain, and vomiting, retro-orbital pain, etc. Altered sensorium, chest pain, breathlessness, cough, and oliguria were also noted in addition to the above said typical symptoms. In this study, 42% of patients developed atypical manifestations such as acalculous cholecystitis, encephalitis, myocarditis, acute respiratory distress syndrome, acute kidney injury, pericardial effusion, pleural effusion, and conduction anomalies. This is supported by a previous study that investigated the atypical manifestations of dengue outbreaks which reported transverse myelitis as a rare manifestation of DF. In both of these studies, acalculous cholecystitis had the maximum occurrence. It was diagnosed by sonographic findings and laboratory values. In a previous study it was concluded that acalculous cholecystitis was developed in a significant number of patients and study showed that all the patients were improved with hydration and correction of thrombocytopenia. Transaminitis i.e. SGOT AND SGPT elevation is a common feature in dengue infection. In this study, it was 54.7% which is comparable to a previous study result.

The incidence of neurological complications was 10.8% and aseptic meningitis was the major complication among them. Even though meningitis is a rare presentation of dengue viral fever, a previous study concluded that in endemic areas, dengue should be considered as a probable aetiological agent for the development of meningitis. Another study conducted in Brazil suggested that simultaneous infection with multiple dengue strains is associated with a higher chance of developing meningitis. Patients with pleural and pericardial effusion were detected with chest X-ray findings. The plasma leakage into the pleural and pericardial cavities is considered as the aetiology for these symptoms and can be diagnosed with the help of a chest X-ray, ultrasound scan, and serum albumin level < 3.5 mg/dL. In our study, myocarditis and conduction anomalies developed as a result of dengue infection. The direct action of a virus on cardiomycocytes and the damage induced via the inflammatory mediators released are considered as the mechanism behind these cardiac complications of dengue. Cardiac arrhythmias are other manifestations of myocardial inflammation. Previous studies reported that dengue is associated with the development of atrial fibrillation, ventricular tachycardia, and atrioventricular block. Histopathological analysis of dengue-associated myocarditis revealed multifocal necrosis, interstitial oedema, and diffuse infiltration of inflammatory cells. In our study, 2% of patients had acute kidney injury with raised blood urea and serum creatinine levels. Acute renal failure affects the severity and complications of dengue infection. A previous study showed that acute renal failure is complication of severe dengue infection with a higher side mortality risk. The histopathology examination revealed mesangial proliferation and deposition of immune conjugate deposition in the renal cells. The direct injury by the released inflammatory mediators also could result in acute renal damage. In our study, most of the patients had platelet count in the range of 20000 - 50000/lakh/mm². There is evidence in the works of literature that coagulopathy, vasculopathy, and thrombocytopenia all were associated with severe dengue infection.

This study also found out the association between co-morbidities and the presence of organ-specific complications with dengue infection. Patients with DF and co-morbidities seem to be at higher risk of developing complications and/or severe dengue compared to healthier individuals. A previous meta-analysis showed that dengue infection in diabetes mellitus (DM) patients could lead to potentially life-threatening severe complications including organ-specific
CONCLUSIONS

Organ-specific complications in dengue are no longer a rare entity. In this study, many complications were noted such as acalculous cholecystitis (most common), hepatitis, encephalopathy, aseptic meningitis, myocarditis, acute kidney injury, acute respiratory syndrome, pleural effusion, and pericardial effusion. Knowledge of these complications is crucial for early recognition of cases, appropriate treatment and thereby reducing mortality. And also, the presence of co-morbidities in individuals with dengue is a subject underexplored in the scientific literature. Further research in regions with a high prevalence of dengue infection would contribute to a better understanding of the relevance of co-morbidities with severe forms of DF.

Limitations of the Study

The limitations of this study include lack of co-morbidities and organ-specific complications due to the small sample size and relatively younger age group. As majority of patients were in the young age group, number of patients with co-morbidities was less in the sample.
