ABSTRACT

The angular momentum transfer associated with Vela-like glitches has never been calculated directly within a realistic scenario for the storage and release of superfluid vorticity; therefore, the explanation of giant glitches in terms of vortices has not yet been tested against observations. We present the first physically reasonable model, both at the microscopic and macroscopic level (spherical geometry, \( n = 1 \) polytropic density profile, density-dependent pinning forces compatible with vortex rigidity), to determine where in the star the vorticity is pinned, how much of it is pinned, and for how long. For standard neutron star parameters (\( M = 1.4 M_\odot \), \( R = 10 \) km, \( \Omega = \Omega_\text{Vela} = -10^{-10} \) Hz s\(^{-1}\)), we find that maximum pinning forces of order \( f_p \approx 10^{15} \) dyn cm\(^{-1}\) can accumulate \( \Delta L_{gl} \approx 10^{40} \) erg s of superfluid angular momentum, and release it to the crust at intervals \( \Delta t_{gl} \approx 3 \) years. This estimate of \( \Delta L_{gl} \) is one order of magnitude smaller than that implied indirectly by current models for post-glitch recovery, where the core and inner-crust vortices are taken as physically disconnected; yet, it successfully yields the magnitudes observed in recent Vela glitches for both jump parameters, \( \Delta \Omega_{gl} \) and \( \Delta \Omega_{gl} \), provided one assumes that only a small fraction (<10%) of the total star vorticity is coupled to the crust on the short timescale of a glitch. This is reasonable in our approach, where no layer of normal matter exists between the core and the inner-crust, as indicated by existing microscopic calculation. The new scenario presented here is nonetheless compatible with current post-glitch models.

Key words: dense matter – pulsars: general – pulsars: individual (PSR J0835-4510) – stars: neutron

1. INTRODUCTION

Glitches are sudden spin-ups observed in the otherwise decreasing rotational frequency of a pulsar (Lyne et al. 2000). Their origin is still debated: the giant spin-ups observed in the 20 known Vela-like glitchers (Espinoza et al. 2011) could indicate the presence of bulk superfluidity inside these stars. In this scenario, giant glitches would represent the natural macroscopic outcome of the interaction between quantized neutron vortex lines, which carry the angular momentum of the rotating chargeless superfluid, and the Coulomb lattice of neutron-rich nuclear clusters, which coexist with the neutron superfluid in the inner crust (Ngele & Vautherin 1973). Indeed, this interaction can pin vortices to the normal component of the star, thus freezing the superfluid vorticity and storing its angular momentum. Only when the hydrodynamical lift on a vortex (Magnus force), which increases as the pulsar slows down, equals the pinning force on a line, is the vortex unbound from the lattice; thus, free to move under the action of drag forces, it can transfer its angular momentum to the normal component of the star. According to Anderson & Itoh (1975), giant glitches are due to the sudden and simultaneous depinning of a large number of accumulated vortices, followed by the rapid transfer of their angular momentum to the observable normal crust (which consists of the outer crust plus all the other charged components in the star, electrons, protons, and nuclear clusters, strongly coupled together by the pulsar magnetic field). Such a storage and trigger mechanism would have a natural periodicity, as indeed observed in Vela (Dodson et al. 2007).

The vortex scenario for glitches was roughly compared to existing observations in a simple but instructive toy model, which assumed a cylindrical, uniform-density star with a cylindrical pinning shell (corresponding to the inner-crust) close to the surface (Pines et al. 1980; Alpar et al. 1981; Anderson et al. 1982). Although the naive treatment of the vortex–nucleus and vortex–lattice interactions gave pinning forces three orders of magnitude larger than that required to explain the average interval between glitches observed in Vela (\( \Delta t_{gl} \approx 3 \) years), the model predicted the correct orders of magnitude for the typical glitch parameters known at the time, namely the jump in angular velocity, \( \Delta \Omega_{gl} \approx 10^{-4} \Omega \), and the jump in angular acceleration, \( \Delta \Omega_{gl} \approx 10^{-2} \Omega \) (the pre-glitch, steady-state parameters for Vela being \( \Omega_{\text{Vela}} = 70 \) Hz and \( \dot{\Omega}_{\text{Vela}} = -9.8 \times 10^{-11} \) Hz s\(^{-1}\)). In spite of these positive preliminary results, Pines et al. (1980) carefully pointed out that the effects of some crucial corrections had to be taken into account before drawing any conclusion: the spherical geometry of the star, the radial density profile required by gravitational equilibrium, the density dependence of the pinning interaction, and the presence of different superfluid phases along the star profile. To date, however, this has not been done in any coherent and consistent model; thus, the explanation of giant glitches in terms of vortices is not yet tested against observations, leaving the origin of these spin-ups an open question.

The post-glitch recovery of pulsars, on the other hand, has been successfully interpreted in terms of vortex motion under drag forces. Early on, the phenomenological model of Baym et al. (1969) explained the slow relaxation to steady state following a glitch as due to the weak interaction between a normal and a superfluid component, each rotating rigidly. Following a glitch, the response of the model is linear in the initial perturbation, and relaxes back to steady-state conditions exponentially, with a relaxation time which is inversely proportional to the strength of the interaction between the two components. The simple two-component model was then reformulated in terms of vortex motion to allow for differential rotation of the superfluid (Pines et al. 1980). Eventually, two scenarios were developed to describe vortex dynamics between glitches: thermally activated creep of strongly pinned vortices (Alpar et al. 1984a, 1984b;
spin-down is reversed during a glitch led us to consider glitches as related to crust vorticity alone and thus to the assumption of disconnected neutron superfluids. This scenario, however, has direct implications on the glitch energetics. Indeed, since vortex lines in the core are strongly coupled to the normal component, being magnetized by entrainment effects (Alpar et al. 1984c), the normal crust comprises most of the star and \( I_c \approx I_{\text{tot}} \). This implies that the angular momentum transferred during the glitch is \( \Delta L_{gl} = I_c \Delta \Omega_{gl} \approx 10^{41} \text{erg s} \) and the corresponding glitch energy is \( \Delta E_{gl} = \Delta L_{gl} \Omega \approx 10^{45} \text{erg} \); both values appear too large. On the one hand, \( 10^{41} \text{erg s} \) corresponds to the difference in angular momentum of the entire inner crust between glitches, thus requiring some unlikely mechanism that freezes the vorticity everywhere in the crust for about 3 years, and then releases it simultaneously. On the other hand, observations of the power wind nebula surrounding Vela indicate an upper limit of \( \sim 10^{42} \text{erg} \) to the glitch energy (Helfand et al. 2001).

In this Letter, we present the first realistic (with several approximations, but still preserving the essential physics) and consistent model to determine where in the star the vorticity is pinned, how much of it is pinned, and for how long. The model has been tested against observations using realistic equations of state (EoSs) for dense matter and implementing general relativistic hydrostatic equilibrium (P. M. Pizzochero et al., in preparation). Moreover, initial dynamical simulations based on the multifluid formalism of Andersson & Comer (2006) confirm the main assumptions and predictions of the model (Haskell et al. 2011). Here, however, we will discuss a fully analytical, Newtonian version of the model: it yields the correct orders of magnitude for all relevant variables, but provides deeper insight than any numerical treatment.

2. THE MODEL

We now outline the main assumptions of the model and present the resulting equations; details and calculations, together with a parameter study of the solutions, will be given in a longer article (P. M. Pizzochero, in preparation; hereafter, Paper I).

We describe the core and inner crust as an \( n = 1 \) polytrope of mass \( M \) and radius \( R_c \). The actual radius of the star will be larger because of the overlying outer crust; its presence, however, can be ignored here since it contributes negligibly to the mass and moment of inertia of the normal component. The polytropic relation \( P \propto \rho^\gamma \) is a very soft EoS for dense matter; realistic soft EoSs yield \( R_9 \approx 10 \text{ km} \) for \( M = 1.4 \text{M}_\odot \).

The density profile is \( u = \sin(\pi \xi)/\pi \xi \), with a dimensionless radius \( \xi = r/R_c \) and density \( \rho = \rho_c/\rho_0 \), normalized to its central value \( \rho_c = M/(4R_c^3) \). The radius of the core, \( R_c \), corresponds to the density \( \rho_c = 0.6\rho_0 \) (in units of nuclear saturation density, \( \rho_0 = 2.8 \times 10^{14} \text{g cm}^{-3} \)), where nuclei merge into nuclear matter. The inner crust has \( \xi > x_c \), where \( x_c = R_c/R_9 > 0.9 \); for \( \xi > 0.9 \), the approximation \( u = 1-\xi \) is sufficiently accurate (Figure 1, left). The total momentum of inertia is

\[
I_{\text{tot}} = \frac{2(\pi^2 - 6)}{3\pi^2} M R_9^2 = 0.26 M R_9^2, \tag{1}
\]

while the inner crust has \( M_{ic} = 4.9(1 - x_c)^2 M \) and \( I_{ic} = 12.6(1 - x_c)^2 I_{\text{tot}} \).

The standard superfluid fraction, \( Q \), is introduced to describe the protons and nuclei of the normal crust, \( I_s = (1 - Q)I_{\text{tot}} \), and the neutron superfluid component, \( I_n = QI_{\text{tot}} \), of the star. Although the neutron fraction varies with density, a typical average value is \( Q \approx 0.95 \) (Zuo et al. 2004). Regarding proton
superfluidity in the core, here we choose the weak-drag limit. The model, however, also gives reasonable results for the jump parameters in the strong-drag limit; the decoupling of the core vorticity, pinned by flux-tubes, reduces both $\Delta L_{sl}$ and the moment of inertia responding at the glitch (cf. Paper I).

The density dependence of $f_{\text{pin}}(\rho)$, the (mesoscopic) pinning force per unit length, is taken as in Figure 1 (right panel). This is a reasonable first approximation for a parameter study in terms of the maximum value, $f_{m}$; indeed, pinning goes to zero at $\rho_c$, (no more nuclei) and at neutron drip $\rho_d = 0.0015 \rho_0$ (no more neutrons), while it is expected to be maximum around densities where the pairing gap peaks. Moreover, we have performed a numerical simulation to evaluate $f_{\text{pin}}(\rho)$ in a bcc lattice, with random crystal orientations and proper vortex rigidity. We obtain profiles compatible with Figure 1, with maximum values of order $f_{m} \approx 10^{15}$ dyn cm$^{-1}$ at densities $\rho_m \approx 0.2 \rho_0$.

We also find, as already noted by Link (2009), that attractive and repulsive vortex–nucleus interactions are equivalent for pinning vortices to the lattice (F. Grill & P. M. Pizzochero, in preparation).

The geometry of the model is shown in Figure 2. The star spins around the $z$-axis, and continuous vortex lines are assumed through the core. Following the results of Ruderman & Sutherland (1974), we can reduce the problem to axial symmetry by integrating the density-dependent quantities along the rotational axis. We distinguish two cylindrical zones, separated by $x_c = R_c / R_s$; the “crust” ($x > x_c$), with vortices lying entirely in the inner crust, and the “core” ($x < x_c$), with vortices crossing the star core. In particular, we can integrate the pinning and Magnus forces to obtain an estimate of their total values on a vortex. If $\omega(x) = \Omega_s(x) - \Omega$ indicates the lag between the local superfluid angular velocity and that of the rigid normal crust, the critical lag for depinning, $\omega_c(x)$, is obtained by equating these two forces

$$\int_V dz f_{\text{pin}}[\rho(x, z)] = x \omega_c(x) \kappa \int_V dz \rho(x, z),$$

where $\kappa = \pi \hbar / m_N$.

In Figure 3, we show the resulting profile: $\omega_c(x)$ presents a sharp peak in the “crust,” with maximum $\omega_{\text{max}}$ located very close to $x_m = 1 - u_m = 1 - \rho_m / \lambda$; we will take $\rho_m = 0.2 \rho_0$.

In most of the “core,” instead, $\omega_c(x)$ has a roughly uniform value $\omega_{\text{min}} \approx 10^{-2} \omega_{\text{max}}$ (as $x \to 0$ it diverges; similar to the outer crust, however, this region can be neglected). We find (cf. Paper I)

$$\omega_{\text{max}} = \omega_c(x_m) = \frac{4}{\kappa} \frac{R^2}{M} \frac{g_{\text{pin}}(x_m)}{g_{\text{mag}}(x_m)} f_m,$$  

where

$$g_{\text{pin}}(x) = \frac{1}{2(1-x)} \left[ \sqrt{1 - x^2} - x^2 \ln \left( \frac{1 + \sqrt{1 - x^2}}{x} \right) \right],$$

and

$$g_{\text{mag}}(x) = \pi x \left[ \ln \left( \frac{1 + \sqrt{1 - x^2}}{x} \right) - \sqrt{1 - x^2} \right].$$

In the “crust,” this estimate of $\omega_c(x)$ should be reasonable, since pinning is continuous along the vortices (Ruderman & Sutherland 1974; Jones 1990). In the “core,” instead, pinning is discontinuous: vortex lines are attached to the lattice only at their extremities, while most of their length lies in a pinning-free region (having selected the weak-drag limit). We can expect individual string-like excitations of the pinned vortices, which could detach them from the lattice well before $\omega_{\text{min}}$ is reached. Indeed, the collective rigidity of vortex bundles in coherent motion, which explains the axial symmetry predicted by the Taylor–Proudman theorem (Ruderman & Sutherland 1974), is actually not observed in laboratory experiments with superfluid vortices attached to the rotating vessel only at their ends (Adams et al. 1985).

Although this issue requires and deserves further study, the crucial point is that vortices in the “core” are pinned very weakly. On the other hand, drag forces due to magnetization correspond to very short relaxation times and thus very small steady-state lags (Alpar et al. 1984c). Moreover, Link (2009) has shown that vortex repinning is dynamically possible if the lag falls below a critical value (smaller than the critical lag for depinning). These considerations and the profile in Figure 3 naturally suggest the following scenario: as the star slows down, vortices in the “core” are continuously depinned and then rapidly repinned;
The Astrophysical Journal Letters, 743:L20 (6pp), 2011 December 10

Pizzochero

Figure 2. Geometry of the model (not in scale): the star rotates around the $z$-axis, while the $x$-axis represents the dimensionless radius in cylindrical geometry. Two vortices are shown at $x_1$ and $x_2$, respectively, in the “core” and the “crust,” the two cylindrical regions separated by $x_c = R_c/R_s$.

Figure 3. Critical lag for depinning, $\omega_c(x)$, as a function of the dimensionless cylindrical radius $x$. At any given time, the lag $\omega(t)$ determines the position $x(t)$. The lags have been normalized to $\omega_{\text{max}}$.

this dynamical creep allows a steady removal of the excess vorticity on short effective timescales $\tau_c$. Although the value of $\tau_c$ is not relevant here, dynamical simulations of Vela glitches suggest $\tau_c \sim 10^3-10^4$ s (Haskell et al. 2011), compatible with mutual friction dominated by vortex magnetization. On timescales $\Delta t \lesssim \tau_c$ (e.g., during a glitch), the “core” vorticity is only partially coupled to the normal crust (the rest being pinned or responding on longer timescales), and only a detailed study of the dynamics can provide a direct estimate of the coupled fraction. On longer timescales $\Delta t \gg \tau_c$, however, the dynamical creep ensures full effective coupling of the two components with (average) lag of order $|\dot{\Omega}|\tau_c$; in steady state, this scenario is then equivalent to the corotation model.

The excess “core” vorticity will be repinned in the “crust,” where pinning increases rapidly by orders of magnitude. At any time $t$ after a glitch, the lag $\omega(t) = |\dot{\Omega}_\infty|/t$ defines a
radial distance \( x(t) \) as in Figure 3; here \( \Omega_{\infty} \) indicates the steady-state (pre-glitch) angular acceleration. We now assume that the excess vorticity, corresponding to the entire region \( x < x(t) \) and to the lag \( o(t) \), is accumulated in a thin vortex sheet at \( x(t) \); as the star slows down and \( o(t) \) increases, the sheet is pushed outward by the increasing Magnus force and moves with \( x(t) \). When \( o(t) \) reaches the value \( \omega_{\text{max}} \), the sheet is at the pinning peak, \( x_m \), and the vorticity accumulated in the sheet is finally released simultaneously, causing the glitch. This picture reminds one of a snowplow, pushing accumulated snow up an incline and eventually reaching its top edge. The interval between glitches is

\[
\Delta t_{\text{gl}} = \frac{\omega_{\text{max}}}{|\Omega_{\infty}|}. \tag{5}
\]

This scenario is compatible with post-glitch relaxation; indeed, after a glitch, the unpinned vortices in the “crust” are under the same conditions as those considered in current post-glitch models.

Although the “snowplow” model is quite schematic, it contains a plausible mechanism for storing and releasing vorticity, as actually confirmed by parallel dynamical simulations (Haskell et al. 2011). In particular, the model allows us to calculate directly the angular momentum \( L_v(x) \) of the vortex sheet at \( x \). In Figure 4, we show the reduction of angular momentum, \( \Delta L_{\text{gl}}(x) = L_v(x)/L_v(0) \), when uniformly distributed vorticity contained within \( x \) is accumulated in a sheet at \( x \); at the peak, \( x_m \), the reduction is of order \( 10^{-3} \). For comparison, we also show the significantly different results for a uniform-density, cylindrical or spherical star; we see how spherical symmetry and a realistic density profile are both crucial for obtaining the correct order of magnitude of \( \ell_v(x) \).

The angular momentum stored during \( \Delta t_{\text{gl}} \) and released at the glitch, \( \Delta L_{\text{gl}} \), can be calculated from the number of vortices removed from the interior and accumulated at \( x_m \), namely, \( \Delta N_v(x_m) = 2\pi R_s^2 x_m^2 \omega_{\text{max}}/\kappa \). We find (cf. Paper I)

\[
\Delta L_{\text{gl}} = L_v(x_m)\omega_{\text{max}}. \tag{6}
\]

with an effective moment of inertia

\[
I_v(x) = \frac{3\pi^4}{2(\pi^2 - 6)}g_v(x)Q_{\text{int}} = \pi^2 g_v(x)QM^2R_s^2, \tag{7}
\]

where

\[
g_v(x) = \frac{x^2}{6} \left[ \frac{\sqrt{1 - x^2 (1 + 2x^2)} - 3x^2 \ln \left( \frac{1 + \sqrt{1 - x^2}}{x} \right)}{x} \right]. \tag{8}
\]

The glitch rise time is very short, \( \tau_{\text{gl}} < 40 \; \text{s} \) (Dodson et al. 2002); we introduce a new parameter, \( Y_{\text{gl}} \), which globally describes the fraction of vorticity coupled to the normal crust on timescales of order \( \tau_{\text{gl}} \) (the steady-state coupled fraction, corresponding to long timescales and to pre-glitch conditions, is \( Y_{\infty} = 1 \)). The value of \( Y_{\text{gl}} \) depends on the detailed short-time dynamics of the “core” vorticity; in order to get an estimate of the observables, only this quantity is needed. From angular momentum conservation and variation of the crust equation of motion we find the glitch jump parameters

\[
\Delta \Omega_{\text{gl}} = \frac{\Delta L_{\text{gl}}}{I_{\text{tot}}[1 - Q(1 - Y_{\text{gl}})]} \tag{9a}
\]

\[
\frac{\Delta \Omega_{\text{gl}}}{\Omega_{\infty}} = \frac{Q(1 - Y_{\text{gl}})}{1 - Q(1 - Y_{\text{gl}})}. \tag{9b}
\]

3. RESULTS AND OBSERVATIONS

After fixing the basic stellar parameters \( M, R_s, \) and \( Q \) (more generally, \( M \) and an EoS), the model has two free parameters, \( f_{\text{in}} \) and \( Y_{\text{gl}} \). It must predict three observables: the interval between glitches, the jump in angular velocity, and the jump in angular acceleration during a glitch. In the case of Vela, the average observed values are \( \Delta t_{\text{gl}} \approx 3 \; \text{years} \) and \( \Delta \Omega_{\text{gl}} = 1.2 \times 10^{-4} \; \text{Hz} \) (Lyne et al. 2000); we already mentioned that early observations gave \( \Delta \Omega_{\text{gl}}/\Omega_{\infty} \approx 10^{-2} \). More recent data, however, indicate
much larger values; in particular, the year 2000 glitch (Dodson et al. 2002) added to the already known short-, middle-, and long-time relaxation components (τi ≈ 104, 105, 106 s, with ∆Ωi/Ω∞ ≈ 0.44, 0.044, 0.009 for i = 1, 2, 3), a fourth and very short one, with τ4 = 1.2 ± 0.2 minutes and ∆Ω4/Ω∞ = 18 ± 6 (1σ errors). In the 2004 glitch, however, such a component was observed only barely above noise and no firm conclusion could be drawn from the weak data (Dodson et al. 2007). Waiting for future observations, there is nonetheless evidence that right after a glitch ∆Ωgl/Ω∞ is larger than unity.

In order to test the model against observations, we consider a standard neutron star with M = 1.4 M⊙, R = 10 km, and Q = 0.95. If we take fm = 1.1 × 1015 dyn cm−1, from Equations (3)–(8) we find that ∆Ω gl = 3.1 years and ∆L gl = 9.5 × 1039 erg s (also ∆E gl = 6.7 × 1041 erg). If we then take Y gl = 0.05, from Equation (9) we obtain ∆Ω gl = 1.3 × 10−4 Hz and ∆Ω gl/Ω∞ = 9.3, in good general agreement with observations. In Paper I, we analyze the parameter dependence of these results; we find that the model is quite robust under physically meaningful variations of all the basic parameters (M, R, Q, ρc, ρm, ρd).

In conclusion, assuming continuous vortices throughout the star, we find that maximum pinning forces of order fm ≈ 1015 dyn cm−1 can accumulate ≈1013 vortices in the inner crust of a standard neutron star, and release them every ≈3 years, transferring an angular momentum ∆L gl ≈ 1030 erg s. This is one order of magnitude smaller than that inferred from the (microscopically inconsistent) assumption of disconnected vortices, yet it yields the observed glitch parameters, provided one assumes a small coupled fraction Y gl < 10%. The model is compatible with post-glitch recovery and with the presently known microphysics; the numerical results follow from implementing both spherical geometry and a realistic density profile, and they are robust.
