Abstract. In an undulant universe, cosmic expansion is characterized by alternating periods of acceleration and deceleration. We examine cosmologies in which the dark energy equation of state varies periodically with the number of e-foldings of the scale factor of the universe, and use observations to constrain the frequency of oscillation. We find a tension between a forceful response to the cosmic coincidence problem and the standard treatment of structure formation.

Keywords: dark energy theory, cosmological constant experiments, power spectrum

ArXiv ePrint: astro-ph/0510178
1. Introduction

Astronomical observations have led to the inference that the Universe is approximately flat, and that its complement of mass energy now consists of 5% ordinary matter, 22% nonbaryonic dark matter, and a dominant negative-pressure component that accelerates the Hubble expansion [1]–[3]. The discovery that the present Universe is expanding at an accelerating pace arose in measurements of distant supernova redshifts [4, 5]. Detailed studies of anisotropies in the cosmic microwave background radiation [6] and broad surveys of large scale structure [7, 8] have deepened and broadened the initial evidence. Remarkably, most of the stuff of the Universe appears to lie outside our quotidian experience, and has not yet been detected in the laboratory.

The spottiness of the fossil record that we read in distance–redshift correlations, microwave anisotropies, and large scale structure leaves much room for interpretation [9]. The most economical description of the cosmological parameters attributes the negative-pressure (‘dark energy’) component to a cosmological constant in Einstein’s equation—an omnipresent and invariable vacuum energy density that assumes a greater importance as the Universe expands [10]. On this picture, we are entering a final inflationary epoch in which the Universe will grow so quickly as to be essentially empty of matter. A dynamical alternative attributes the accelerated expansion to a cosmic scalar field that changes with time and varies across space, slowly approaching its ground state [11, 12]. Such quintessence models, as they are called, admit a broad variety of future Universes.

Neither the cosmological constant interpretation nor the cosmic scalar picture has a ready explanation for the rough balance between matter and vacuum energy at this moment in cosmic history. The cosmic coincidence problem—the ‘why now?’ question—has stimulated speculations that range from anthropic rationalizations [13] to cyclic cosmologies [14].
Recently, we investigated the possibility that the physical characteristics of the vacuum energy might vary with time, specifically with the number of e-foldings of the scale factor $a$ of the Universe [15]. We showed that the simple ansatz
\[ w_v(a) = -\cos(\ln a) \]  
for the vacuum energy equation of state is compatible with existing observations and offers an intriguing response to the ‘why now?’ problem. (We choose a phase implicit in the form (1) to match the inference that $w_{v0} \approx -1$ in the current Universe.) The cosmic expansion of the ensuing *undulant universe* is characterized by alternating eras of acceleration and deceleration. Because over one period the equation of state (1) averages to zero (the equation of state of pressureless matter), the vacuum energy density tracks the matter density on average. In this way, the cosmic coincidence problem is resolved. The future evolution of the undulant universe is similar in broad outline to that of a matter-dominated universe at critical density, for which $a \propto t^{2/3}$, where $t$ measures the age of the Universe.

The oscillatory equation of state (1) could represent, for instance, the effective description of a dynamical cosmic field (fluid) present since very early times. In that spirit, Barenboim and Lykken [16] have extended the undulant universe notion, taking a new approach to quintessential inflation that not only yields inflation but also offers a dark energy candidate. Both features emerge from the evolution of a single scalar field in a potential with oscillatory and exponential behaviour. (The potential of [16] resembles the motion of a Slinky® spring toy descending a staircase, so the paradigm is called slinky inflation.) The vacuum energy equation of state that emerges from their potential has the form
\[ w_v(a) = -\cos(b \ln a), \]  
(2)
a simple generalization of equation (1), in which the dimensionless parameter $b$ controls the frequency of inflationary epochs. They present an illustrative example with $b = \frac{1}{7}$ that reproduces measured energy densities in the present universe and produces the requisite inflation. After the end of the radiation-dominated era, indeed, back to $a \approx 10^{-8}$, the characteristics of slinky inflation are essentially identical to those of an undulant cosmology specified by the equation of state (2). At earlier times, it is necessary to solve the coupled differential equations for the radiation, matter, and vacuum energy densities given by equation (12) of [16].

It is interesting to observe that equations of state involving the functional form $\cos(\ln a)$ but passing through $w = -1$ have been explored, to a different end, in a number of recent papers [17]–[22]. Rippled evolution of the scale factor is examined in the context of a Brans–Dicke theory in [23].

In this paper we catalogue the observational tests to which we have subjected the undulant universe defined by the simple equation of state (1). We further explore the bounds that can be placed on the frequency parameter $b$ by requiring consistency with current observations. In the limit of small values of $b \to 0$, the equation of state (2) approaches the cosmological constant value, $w \approx -1$. In that limit, the periodic equation of state merely reproduces the success of the cosmological constant + cold dark matter ($\Lambda$CDM) hypothesis (and offers no insight into the ‘why now?’ problem). More to the point, we find that a periodic equation of state with $0.6 \lesssim b \lesssim 2$, which responds to
the cosmic coincidence problem, is in comfortable agreement with all observations, save for the demands of structure formation as expressed through linear evolution of density perturbations. We shall explore this vulnerability.

We examine ways in which future observations might further constrain, or rule out, variants of the undulant universe. The fact that an alternative so different from the \( \Lambda \)CDM hypothesis is compatible with observations makes it important to pursue the discovery of the accelerating expansion on multiple fronts. In addition to seeking to characterize the dark energy through its equation of state in the recent past, it is highly desirable to probe the state of the Universe at epochs for which we have not yet learned to read the fossil record. It is premature to converge on a single hypothesis.

2. The essence of the undulant universe

Let us recapitulate the main elements of an evolving universe. The expansion of the universe is determined by the Friedmann equation,

\[
H^2 \equiv \left( \frac{\dot{R}}{R} \right)^2 = 8\pi G_N \rho / 3 - k/R^2 + \Lambda / 3, \tag{3}
\]

where \( H \) is the Hubble parameter, \( R \) is the cosmological scale factor, \( G_N \) is Newton’s constant, \( \rho \) is the energy density, \( k = (+1, 0, -1) \) is the curvature constant, and \( \Lambda \) is a possible cosmological constant. If \( \Lambda = 0 \), the curvature constant determines cosmic destiny. For \( k = +1 \) (closed Universe), the Universe recollapses in finite time; for \( k = 0 \) (flat) and \( k = -1 \) (open), the Universe expands without limit. It is convenient to define the dimensionless scale factor, \( a = R/R_0 \), where the subscript 0 denotes the value at the current epoch. The critical density, defined from (3), is \( \rho_c = 3H^2/8\pi G_N \). The dimensionless cosmological density parameter is defined relative to the critical density as \( \Omega_{\text{tot}} = \rho / \rho_c \) at any epoch. We express the rate of change of the Hubble parameter through the deceleration parameter,

\[
q \equiv -\frac{1}{H^2} \frac{\ddot{R}}{R} = \frac{\Lambda}{3H^2} - \frac{4\pi G_N}{3H^2} (\rho + 3p), \tag{4}
\]

where \( p \) is the isotropic pressure. If we define \( \Lambda = 4\pi G_N \rho_\Lambda \) and introduce the equation of state \( w_i = p_i/\rho_i \) for any component of the universe, we can recast the deceleration parameter as

\[
q = \frac{1}{2} \sum_i \Omega_i (1 + 3w_i) = \frac{1}{2} \left( \Omega_{\text{tot}} + 3 \sum_i \Omega_i w_i \right). \tag{5}
\]

The equation of state of pressureless matter is \( w_m = 0 \), and that of radiation is \( w_r = \frac{1}{3} \). We see by inspection of (4) that \( w_\Lambda = -1 \). Note that the deceleration parameter is defined to be positive if the rate of expansion is slowing; for the reference case (SCDM) of a matter-dominated universe at critical density (\( \Omega_{\text{tot}} = 1, \Lambda = 0 \)), \( q = \frac{1}{2} \).

The \( \Lambda \)CDM proposal is attractive for its simplicity, and it agrees well with all observations. It does appear to bear a burden of unnaturalness, however. While \( \Lambda \)CDM predicts that \( \Omega_\Lambda \approx \Omega_m \) at some point during the evolution of the Universe, it offers no explanation for the curious circumstance that the balance occurs at the current epoch—and no other—in the history of the Universe.
Let us analyse what happens if the physical characteristics of the vacuum energy vary periodically with the number of e-foldings of the scale factor according to the equation of state (1) or the generalization (2). In the numerical examples that follow, we assign the vacuum energy a weight $\Omega_v = 0.7$, in line with observations, and take $\Omega_m = 0.3$ and $\Omega_r = 4.63 \times 10^{-5}$. The present-day expansion rate is $H_0 = 100 h \text{ km s}^{-1} \text{ Mpc}^{-1}$, with $h = 0.71^{+0.04}_{-0.03}$ [24].

In the general case (2), these are given in terms of the present normalized densities as $\rho_m/\rho_c = \Omega_m a^3$, $\rho_r/\rho_c = \Omega_r a^4$, and $\rho_v/\rho_c = g(a) \Omega_v a^3$, where

$$g(a) = \exp \left( 3 \int_a^1 \frac{da'}{a'} w(a') a' \right) = \exp \left[ \frac{3}{b} \sin(b \ln a) \right].$$

(6)

We plot in figure 1 the normalized energy densities of matter, radiation, and vacuum energy as functions of the scale parameter $a$, for the undulant universe case of $b = 1$. Looking back in time to the epoch of big bang nucleosynthesis at $a \approx 10^{-10}$, and forward to $a = 10^{+10}$, we see that the vacuum energy density crosses the matter density every $\pi$ e-foldings of the scale factor. If we require the vacuum component to have negative pressure, a situation similar to the present occurs every $2\pi$ e-foldings. Periodically dominant dark energy is in the spirit of [25]–[28]. These regular crossings stand in sharp contrast to the $\Lambda$CDM cosmology, in which $\Omega_v \approx \Omega_m$ only in the current epoch.

The presence of the exponential factor $e^{3/b}$ in (6) raises the possibility that for small values of $b$, the excursions in the vacuum energy density about the matter density may be amplified to unacceptable—or at least highly nonstandard—levels. We plot in figure 2 the histories of the Universe that result from the choices $b = 2, 2.5, 1.4, 1$. For $b = 2$ (top left panel), the oscillations are more frequent, and smaller, than those for the canonical choice $b = 1$. For $b = 2.5$ (top right), the oscillations are larger, but less frequent, than
Figure 2. Evolution from $a = 10^{-10}$ to the present of the matter (straight cyan line), radiation (magenta, steepest line), and vacuum (undulating blue line) energy densities in the variants of the undulant universe, normalized to the critical density $\rho_i/\rho_{c0}$, for different frequency parameters $b$. Clockwise from top left, the plots correspond to $b = 2$, $b = \frac{3}{5}$, $b = \frac{1}{4}$, and $b = \frac{1}{7}$.

for the default undulant Universe. The radiation-dominated era ends a little earlier than in the standard cosmology, but nothing is overtly wrong. The case $b = \frac{1}{7}$ (bottom right) is highly problematic, however: the first positive excursion occurs in the era of big bang nucleosynthesis (BBN), and would imply a large vacuum energy component at that time. (The equation of state is $w_v = -0.86, -0.45, +0.11$ for $a = 10^{-10}, 10^{-9}, 10^{-8}$.) At still smaller values of $b$, including the case $b = \frac{1}{7}$ (bottom left), the first positive excursion occurs well before BBN, and would not raise any obvious problems.
Observational constraints on undulant cosmologies

Figure 3. Evolution of the matter fraction as a function of scale factor for the ΛCDM model (thick cyan curve) and for the undulant universe described by (1) (oscillatory curve). At different eras, the vacuum fluid emulates radiation (magenta), matter (cyan), small negative values of \( w \) (blue, dash–dotted), dark energy (black solid), and a scalar field in the kination regime (dotted). Top panel: undulant universe of (1); bottom panel: generalized undulant universe of (2), with frequency parameter \( b = \frac{2}{5} \).

Although the matter density in the Universe scales smoothly as \( a^{-3} \) with respect to today’s critical density, the matter fraction of mass energy at any moment, \( \rho_m(a)/\rho_{\text{tot}}(a) \), is influenced by the evolution of the rest of the portfolio. In the case of the ΛCDM picture, the matter density was dominant in the recent past and will be totally negligible in the near future, because the vacuum energy density due to the cosmological constant is independent of the scale factor. The resulting evolution is shown by the thick curve in figure 3: matter takes over from radiation as the dominant component as the scale factor increases through \( a = 10^{-4} \). At recent times, corresponding to \( a \gtrsim 10^{-1} \), matter is supplanted by vacuum energy once and for all, and quickly becomes a negligible fraction of the mass energy budget.

In the undulant cosmology implied by the equation of state (1), the matter fraction is periodically dominant, not only at the end of the radiation era, but also at regular intervals in the future. The approximate cycles repeat every \( 2\pi/b \) e-foldings, where \( b \) is the frequency parameter in (2). The changing equation of state of the vacuum energy is encoded in the colour and texture of the undulating curve in figure 3. The dotted black line corresponds to \( 1 > w > \frac{2}{3} \); magenta to \( \frac{2}{3} > w > \frac{1}{3} \); cyan to \( \frac{1}{3} > w > -\frac{1}{3} \); dash–dotted blue to \( -\frac{1}{3} > w > -\frac{2}{3} \); solid black to \( -\frac{2}{3} > w > -1 \).
Figure 4. Evolution of the scale factor $a(t)$ in three cosmologies: the canonical \( \Lambda \)CDM model (thin black line); a critical universe (SCDM model) with $\Omega_m = 1$ (dashed red line); and (left panel) the periodic equation of state (1) or (right panel) the periodic equation of state (2) with $b = 0.4$ (thick blue line).

The Hubble parameter corresponding to scale factor $a$ is given by

$$H(a) = H_0 \sqrt{\frac{\Omega_m}{a^3} + \frac{g(a) \Omega_v}{a^3} + \frac{\Omega_r}{a^4}}.$$  

(7)

In the undulant universe (with $b = 1$), the current age of the universe, $t_0 = \int_0^1 \frac{da}{H(a)}a$, is 13.04 Gyr, to be compared with 13.46 Gyr in the \( \Lambda \)CDM model. By calculating the time to reach a given scale factor, we can determine the history and future of the universe. During the radiation-dominated era, which corresponds to $a \ll 10^{-5}$, $a(t) \propto t^{1/2}$; when matter dominates, $a(t) \propto t^{2/3}$.

We show the time dependence of the scale factor $a(t)$ for three cosmologies in figure 4. The dashed (red) line corresponds to the ‘standard cold dark matter’ (SCDM) cosmology that was canonical before the discovery of the accelerating universe. The thin solid (black) line shows the \( \Lambda \)CDM cosmology, in which the present epoch marks the beginning of a final inflationary period that leads to an empty universe in which matter is a negligible component. The heavy (blue) line shows the prediction that follows from equation (1). In the recent past, the periodic equation of state matches the behaviour of the \( \Lambda \)CDM cosmology, but in the future it undulates about the SCDM prediction.

The alternating periods of acceleration and deceleration that characterize the expansion of undulant universes are signalled by the deceleration parameter in figure 5. For scale factors $a$ between 0.1 and 1, the periodic equation of state (1) tracks the behaviour of the \( \Lambda \)CDM cosmology. For the generalized form (2), undulant cosmologies trace the \( \Lambda \)CDM curve over greater or smaller ranges of the scale factor for values of the frequency parameter $b$ that are smaller or greater than unity. In contrast to the \( \Lambda \)CDM
Observational constraints on undulant cosmologies

Figure 5. The deceleration parameter as defined in equation (5) for the undulant universe of (1) (thick blue line), ΛCDM model (thin black line) and SCDM model (dashed red line). Variants of the undulant universe given by the generalized equation of state (2) are shown as the dot–dashed line, for \( b = \frac{1}{2} \), and the dotted line, for \( b = 2 \).

The universe, which is about to enter a final inflationary era of sustained acceleration, the average behaviour of the undulant universes tracks that of SCDM.

Let us take a closer look at the ‘why now?’ problem. In the ΛCDM picture, there is literally no (other) time like the present, but in undulant cosmologies the matter–dark energy coincidence is a more or less typical circumstance. We will need to define a statistical measure to assess how typical is the present state of the Universe. It is informative to distribute a large number \( N \) of points randomly in \( \ln(a) \), excluding a slice that contains the present Universe, and to ask what fraction correspond to a balance between matter and dark energy similar to what we observe today. We define the current epoch by the condition \( 0.7 < a < 1.6 \), and say that the current situation is matched, provided that

\[
0.1 \leq \frac{\Omega_m}{\Omega_m + \Omega_v} \leq 0.5, \quad \text{and} \quad 0.5 \leq \frac{\Omega_v}{\Omega_m + \Omega_v} \leq 0.9, \quad \text{with } w_v < -0.7.
\]

(For scale factors \( a \gtrsim 10^{-5} \), radiation contributes negligibly to the energy portfolio of the Universe, so that \( \Omega_m + \Omega_v \approx 1 \).)

We examine two intervals in the scale factor. First, we consider responses to the cosmic coincidence question since the era of radiation dominance \( a > 10^{-5} \), when the Universe was about 94 years old, and a corresponding step into the future, extending to
Observational constraints on undulant cosmologies

Table 1. Probability, in per cent, that conditions approximate the current matter–dark energy balance of the Universe, according to the criteria explained in the text, for various values of the frequency parameter $b$ of (2).

| $b$   | $10^{-5} < a < 0.7$ | $1.6 < a < 10^5$ | $10^{-20} < a < 0.7$ | $1.6 < a < 10^{20}$ |
|-------|--------------------|-----------------|--------------------|--------------------|
| 0 (CDM) | 0                  | 0               | 0                  | 0                  |
| 0.1   | 0                  | 0               | 0                  | 0                  |
| 0.125 | 0                  | 0               | 0                  | 0                  |
| 1/7   | 0                  | 0               | 1.5                | 1.6                |
| 0.25  | 0                  | 0               | 1.6                | 1.6                |
| 0.4   | 0                  | 0               | 3.2                | 3.2                |
| 0.5   | 0                  | 0               | 4.8                | 4.8                |
| 0.6   | 6.4                | 6.4             | 6.4                | 6.4                |
| 0.7   | 6.4                | 6.4             | 7.8                | 8.0                |
| 0.9   | 6.5                | 6.5             | 9.8                | 9.8                |
| 1     | 6.6                | 6.7             | 11.3               | 11.5               |
| 2     | 18.2               | 18.2            | 21.1               | 21.2               |
| 5     | 24.9               | 24.9            | 24.8               | 25.3               |

$a = 10^5$. We tally the number of successful throws of $\ln(a)$, out of $N = 10^6$ trials, and report the probability of success in table 1. In the undulant universe defined by $b = 1$ [15], success comes about one time in sixteen, both in the past and in the future. The current conditions are in that sense typical of the undulant universe. This statistical conclusion squares with the behaviour we observed in figure 1. As the frequency of undulations increases, conditions like those in the current Universe become commonplace. On the other hand, for values of the frequency parameter $b \lesssim 0.6$, the present coincidence of mass and dark energy is the only one to occur in the range $10^{-5} \leq a \leq 10^5$. For the range $10^{-7} \leq a \leq 10^7$, values of $b \lesssim \frac{3}{8}$ yield only the present coincidence.

Expanding the range over which we look for cosmic coincidences to the interval $10^{-20} \leq a \leq 10^{20}$, we find that the undulant universe with $b = \frac{1}{7}$ implies one coincidence in the past and one in the future, but that models in which $b \lesssim \frac{1}{7}$ imply no coincidences other than the present one, which is included by design. It is fair to question whether a matter–dark energy coincidence in the radiation-dominated universe ($a \lesssim 10^{-5}$) is of any moment. The tracking behaviour of slinky inflation, in contrast, ensures that radiation is not uniformly dominant from the big bang to $a \approx 10^{-5}$, and opens the way to early coincidences that are more generally meaningful.

3. Tests of undulant cosmologies

The principal constraints on cosmological models arise from observational knowledge of the conditions that prevailed at the time of big bang nucleosynthesis, studies of the cosmic microwave background that look back to the surface of last scattering ($a \approx 10^{-3}$), and measurements of the deceleration parameter in supernova redshift surveys near the present epoch, extending to redshifts $z \approx 2$. The growth of large scale structure also exhibits some sensitivity to the cosmic equation of state, through a tension between the attraction of gravitational stability and the dynamical friction of the expansion, but the
Observational constraints on undulant cosmologies

standard treatment involves only linear perturbations [29]. We shall discuss these in turn.

3.1. Big bang nucleosynthesis

The presence of a dark energy field at early times alters the expansion rate of the Universe, changing the ratio of neutrons to protons at freeze-out and modifying the predicted abundances for light elements. At those early times \( a \lesssim 10^{-9} \) the vacuum energy density implied by the undulant universe (1) is utterly negligible in comparison to radiation, as we saw in figure 1, and so its influence on big bang nucleosynthesis will be imperceptible. We find, for example, \( \Omega_v(a = 10^{-10}) \approx 2 \times 10^{-5} \) and \( \Omega_v(a = 10^{-9}) \approx 10^{-6} \).

Bean et al [30] have reported that the \(^4\)He mass fraction and the deuterium-to-hydrogen ratio do not favour the presence of a dark energy component. In a class of quintessence models, they determine the bound \( \Omega_v < 0.045 \) at 2\( \sigma \). We can take the resulting bound as a reasonable upper limit for the more general case of the periodic equation of state (2). This bound is not threatened for \( 0.5 \lesssim b \lesssim 2 \). However, the exponential factor \( e^{3/b} \) in the expression (6) for \( g(a) \) can grow so large, for small values of the frequency parameter \( b \), that the energy budget of the Universe is altered dramatically just at the BBN era. We see this effect in the \( b = 1/4 \) (bottom right) panel of figure 2. The large value \( \Omega_v^{b=1/4}(a = 10^{-9}) \approx 0.4 \) is a clear cause for concern. Smaller values, including \( b = 1/7 \), for which a large positive excursion of the vacuum energy density occurs well before BBN, do not provoke any concern on this score.

3.2. Power spectrum

To explore the implications of the periodic equation of state for anisotropies of the cosmic microwave background, we have made the appropriate modifications to the CMBFAST [31] code, assuming three massless neutrinos and fixing the helium mass fraction at \( y_{He} = 0.24 \). We show in figure 6 that the undulant universe describes the angular power spectrum, temperature–polarization cross-correlation, and matter power spectrum with the same degree of fidelity as the \( \Lambda \)CDM model. The structure at large scales \( (\ell \lesssim 10) \) in the \( T–E \) cross-correlation is a consequence of reionization [34]. Similar agreement can be expected for \( b \lesssim 2 \): small values of the frequency parameter resemble the \( \Lambda \)CDM picture, and values close to \( b = 1 \) yield similar averages of the vacuum energy equation of state.

3.3. SN Ia luminosity distance

Type Ia supernovae now constitute an incisive probe of the state of the Universe near the present epoch. Existing data provide good resolution in the redshift range \( 0 \lesssim z \lesssim 1.7 \). In the concordance (\( \Lambda \)CDM) model inferred from these and other recent data, this is the range in which dark energy works its influence on the cosmic expansion rate.

The observational technique consists in determining the apparent magnitude \( m \) (essentially the logarithm of the observed flux) and the redshift \( z \). The apparent magnitude is related to the absolute magnitude \( M \) of the supernova through the luminosity
Figure 6. Angular power spectrum (top panel) and T–E cross-correlation (middle panel) versus the multipole $\ell$, and matter power spectrum versus the wavenumber $k$ (bottom panel), for the periodic equation of state (1) (blue line) and for the $\Lambda$CDM model (black line). The top panel shows experimental data from the WMAP experiment (red) and from the combination of all CMB data (purple) [32]. The middle panel shows WMAP data. The data in the bottom panel are from an independent analysis of the 2dF survey [33].

The resolution hinges on establishing the absolute magnitude as a standard candle.

In figure 7, we compare the luminosity distance modulus of the Supernova Search Team’s gold and silver samples with the expectations of the $\Lambda$CDM picture and the undulant universe (1). For redshifts in the range $0 \lesssim z \lesssim 2$, the models cannot now be distinguished. To quantify the range of frequency parameters $b$ that adequately reproduce the existing data, we have modified Yun Wang’s supernova flux-averaging likelihood

$$d_L = c(1 + z) \int_0^z \frac{dz'}{H(z')}$$

as

$$\mu \equiv m - M = 5 \log_{10} \left( \frac{d_L}{1 \text{ Mpc}} \right) + 25.$$
The distance modulus $\mu = m - M$ for the $\Lambda$CDM model (black line) and for the undulant universe of equation (1) (blue line), compared with the luminosity modulus–redshift data from the SN gold and silver samples [35]. The periodic equation of state is plotted in the upper panel.

The most recent version of the code is at http://www.nhn.ou.edu/~wang/SNcode/index.html
Significant improvements are promised by candidates for the NASA/DOE Joint Dark Energy Mission\(^6\): DESTINY\(^7\), JEDI\(^8\), and SNAP\(^9\), alone and in combination with cosmic microwave background results from the European Space Agency’s Planck satellite\(^{10}\).

### 3.4. Galaxy clusters

Measurements of the apparent redshift dependence of the baryonic mass fraction of galaxy clusters can be used to constrain the geometry of the Universe and, hence, the amount and character of dark energy. The geometry enters in the dependence of the baryonic mass fraction on the assumed angular diameter distances, \(d_A = d_L/(1+z)^2\), to the clusters. The baryonic mass fraction in the largest clusters should be independent of the redshift, provided that the reference cosmology used in making the baryonic mass fraction measurements matches the true cosmology of the physical Universe.

Because galaxy clusters are so large, it is plausible that they represent a fair sample of the matter in the universe, so the relative amounts of hot gas and dark matter should be the same for every cluster. Moreover, the baryonic-to-total mass in the clusters should closely match the ratio of the cosmological parameters \(\Omega_b/\Omega_m\). By measuring the x-ray emissivity of 26 dynamically relaxed galaxy clusters in the redshift range \(0.07 < z < 0.9\)

\(^{10}\) The Planck Satellite, http://www.rssd.esa.int/index.php?project=PLANCK
Figure 9. The left panel displays the supernova luminosity distance versus redshift for the ΛCDM (black), undulant universe of equation (1) (solid blue), critical SCDM universe (red). Also shown are two variants of the undulant universe, defined by (2) with $b = 2$ (dot–dashed blue) and $b = 0.6$ (dashed blue). The right panel shows the correlation between the equation of state $w$ and its derivative $w' = dw/d\ln a$, for the periodic equation of state (2). The point at $(-1, 0)$ corresponds to zero redshift, $\ln a = 0$, and the step between points is $\Delta \ln a = -0.1/b$.

with the Chandra X-ray Observatory\textsuperscript{11}, Allen and collaborators have determined the x-ray gas mass fraction in these systems, using the SCDM reference cosmology [38]. The variation of the inferred gas fractions with the redshift, shown in the left panel of figure 10, indicates that the distance–redshift correlation of the SCDM reference cosmology does not correspond to our Universe.

To compute the expectations of cosmologies that include vacuum energy, we evaluate the gas mass fraction,

$$f_{\text{gas}}(z) = \frac{B \Omega_b}{\left( 1 + 0.19\sqrt{h} \right) \Omega_m} \left( \frac{d_{\text{SCDM}}(z)}{d_{\text{vac}}(z)} \right)^{1.5}.$$ \hspace{1cm} (11)

The bias factor $B = 0.824 \pm 0.089$, for which we adopt a Gaussian prior [38, 39], accounts for the relatively small amount of baryonic material expelled from galaxy clusters as they form. The ΛCDM model (black curve) and the periodic equation of state (1) (blue curve) both reproduce the data faithfully.

The gas mass fraction is sensitive not only to the amount of vacuum energy, but also to its character, because the luminosity distance defined in (9) gives some sensitivity to the equation of state through $H(z)$. The right panel of figure 10 shows how the goodness of fit, as measured by $\chi^2$, depends on the frequency parameter $b$ of equation (2). The current gas mass fraction measurements disfavour values $b \gtrsim 2.2$, so are slightly less restrictive constraints than the supernova observations.

\textsuperscript{11} The Chandra X-ray Observatory, http://chandra.nasa.gov
Figure 10. Left panel: apparent variation of the x-ray gas mass fraction (with $1\sigma$ rms errors) as a function of the redshift for the reference SCDM. The expectation of the $\Lambda$CDM cosmology is plotted as the black curve. The blue curve shows the prediction of the undulant universe (1). The periodic equation of state is plotted in the upper panel. Right panel: $\Delta \chi^2$ results for the analysis of the x-ray mass fraction data as a function of the frequency parameter $b$ of (2).

3.5. Structure formation

The development of large scale structure in the universe is sensitive to the presence and character of dark energy. Vacuum energy influences the balance of attractive gravitational stability against the dynamical friction of the expansion. For an undulant universe, the equation of state of the vacuum energy affects the cosmic volume in which structures form, and rules the dynamical behaviour of the dark energy.

A simple, and useful, test is provided by the linear growth factor considered by Linder and Jenkins [29]. Considering linear evolution of the perturbations only, we may define the normalized growth factor (the ratio of the perturbation amplitude at scale factor $a$ to that at some initial scale factor $a_i$, divided by $a$)

$$G''(a) + \frac{3}{2} \left[ 7 - \frac{w(a)}{1 + X(a)} \right] \frac{G'(a)}{a} + \frac{3}{2} \cdot \frac{1 - w(a)}{1 + X(a)} \frac{G(a)}{a^2} = 0,$$

where a prime denotes a derivative with respect to the scale factor $a$ and

$$X(a) = \frac{\Omega_m}{1 - \Omega_m} \cdot \frac{1}{g(a)},$$

with $g(a)$ given by (6), is the ratio of matter density to dark energy density when radiation is negligible. Then, adopting the boundary condition $G(a_i) = 1$, $G'(a_i) = 0$, with $a_i = 10^{-4}$, we may solve for the normalized growth factor $G(a)$. The resulting values at the current epoch ($a = 1$) are shown in figure 11 for the undulant universe over the range of frequency parameters $0 \leq b \leq 1$.

In the limit as $b \to 0$, the periodic equation of state (2) approaches the $\Lambda$CDM cosmology, and so reproduces the canonical growth factor. The value of the growth factor
Figure 11. Linear growth factor in the present universe, \( G_0 \equiv G(a = 1) \), defined through equation (12) for an undulant universe characterized by the equation of state (2), as a function of the frequency parameter \( b \).

Figure 12. Dependence on the scale factor \( a \) of the linear growth factor \( G(a) \) for the \( \Lambda \) CDM cosmology (solid line) and for an undulant universe with frequency parameter \( b = 0.4 \) (dashed line).

In the present universe depends little on the frequency parameter for \( b \lesssim 0.4 \), then drops precipitously to small values. In particular, the case \( b = 0.4 \), the consequences of which are in excellent agreement with all the other constraints that we have examined, hardly differs from the \( \Lambda \) CDM result. Current determinations of \( \sigma_8 \) agree with the \( \Lambda \) CDM expectation within the uncertainties of about 20%. Indeed, the \( b \lesssim 0.4 \) undulant universes track the \( \Lambda \) CDM solution as a function of the scale factor \( a \). We display the \( b = 0.4 \) and \( \Lambda \) CDM solutions in figure 12.

The undulant universe characterized by frequency parameter \( b = 1 \) fails the test of the linear growth factor, as commented on by Linder [40,41]. In undulant cosmologies characterized by \( b \gtrsim 0.4 \), an early low-growth epoch persists too long to be compensated by the subsequent enhanced-growth epoch.

While taking note of this disagreement, we believe it is prudent to note that the strategy of considering linear evolution of the perturbations, while plausible, has not been
exhaustively validated. The undulant universe of equation (1) does reproduce the matter power spectrum determined by cosmic microwave background measurements imprinted at \(a \approx 10^{-3}\), so it is possible that a different treatment of structure formation might have a favourable outcome. Alternatively, it may be that frequency parameters \(b \gtrsim 0.4\) can be brought into agreement with structure formation constraints only by delaying the emergence of the vacuum energy component or, more generally, by introducing coupling between the vacuum energy and other components, as in the slinky inflation model.

4. Outlook

The undulant universe offers a new response to the cosmic coincidence problem: the current state of the Universe, with \(\Omega_m \approx \Omega_v\) and \(w_v \approx -1\), has happened before and will happen again, so long as the frequency parameter \(b \gtrsim 0.6\) in the undulant equation of state (2). No fine tuning is required, in the sense that \(0.5 \leq \Omega_v \leq 0.9\) with \(w_v \leq -0.7\) occurs with \(\sim 9\%\) probability for \(10^{-7} \leq a \leq 10^{+7}\) for the prototype undulant universe with \(b = 1\). The corresponding number is 4.5\% for the case \(b = 0.4\). (See the details in table 1.)

We find that periodic equations of state (2) reproduce the correct power spectrum and CMB temperature asymmetries as long as the frequency parameter \(b \lesssim 2\). Moreover, such models satisfy constraints on the matter density at the time of big bang nucleosynthesis, except for frequency parameters in the neighbourhood of \(b \approx \frac{1}{4}\). The undulant cosmologies fit very well with late-time geometry probes such as supernova luminosity distances; at 95\% C.L., frequency parameters as large as \(b = 2\) are acceptable. The one delicate issue is structure formation as embodied in the growth factor. A linear treatment of the evolution of density perturbations restricts the frequency parameter to \(b \lesssim 0.4\). The case of \(b = 0.4\) is in comfortable agreement with all observations, but entails only the present matter–dark energy coincidence since the radiation-dominated era ended.

We have postulated the periodic equation of state, not derived it from a dynamical principle, in the interest of exploring alternative implications of the discovery of the accelerating universe. The more ambitious programme of slinky inflation [16] gives an explicit construction of a periodic equation of state from a potential that governs the behaviour of a scalar field [42]–[44].

On the observational front, it is of clear interest to pin down the vacuum energy equation of state \(w(z)\) and to seek evidence that it varies with time, for redshifts \(z \approx 1\) [45, 46]. This observational challenge is an imperative for quintessence models in general, for the \(\Lambda\)CDM picture, and for the undulant universe and its extension, slinky inflation. The observational survival of periodic equations of state highlights the fact that, at present, we have telling observations at only a few epochs in the history of the universe. It is of clear interest to devise new observational tests that will explore new ranges in redshift, making new strata of the fossil record available for our scrutiny. The wide excursions in the deceleration parameter at different epochs, shown in figure 5, offer encouragement for probing deeper in redshift than is possible with supernovae.

While no finite set of astronomical measurements made over a finite time will ever allow us to determine the ultimate fate of our Universe [47], we can hope to look some distance into the future. Wang and collaborators have quantified [48] the limited reach of reliable extrapolations in the framework of the simplest doomsday model, in which
the universe collapses swiftly, once it ceases to expand. They reckon the collapse time $t_{\text{collapse}} \gtrsim 42(24)$ Gyr from today at 68% (95%) C.L. An interesting parameter in the undulant universe is the moment that marks the onset of the next period of deceleration, which we characterize as the moment at which the deceleration parameter next exceeds the value that obtains in a matter-critical universe, $q_{\text{SCDM}} = \frac{1}{2}$. That circumstance occurs at $(11, 23, 39, 153)$ Gyr in the future for frequency parameters $b = (3, 2, 1, 0.4)$. The cases with $b \lesssim 2$ all respect the doomsday bounds of [48].

The undulant universe explored here serves as a reminder that the range of possible destinies for the Universe, even in the short term, is very broad indeed. The universe need not necessarily evolve toward the cataclysm of terminal inflation or recollapse, but might steer a middle course not so different, on average, from a critical universe dominated by matter. The main lesson of the undulant universe is that it is premature to anoint the $\Lambda$CDM model as the sole candidate for the new standard cosmology.
