Thermodynamics of itinerant magnets is studied using a classical model with one parameter characterizing the degree of itinerancy. Monte Carlo simulations for bcc and fcc lattices are compared with the mean-field approximation and with the Onsager cavity field approximation extended to itinerant systems. The qualitative features of thermodynamics are similar to the known results of the functional integral method. It is found that magnetic short-range order is weak and almost independent on the degree of itinerancy, and the mean-field approximation describes the thermodynamics reasonably well. Ambiguity of the phase space measure for classical models is emphasized. The Onsager cavity field method is extended to itinerant systems, which involves the renormalization of both the Weiss field and the on-site exchange interaction. The predictions of this approximation are in excellent agreement with Monte Carlo results.

1. INTRODUCTION

The thermodynamics of magnetic materials is often described using the Heisenberg model in which the spins are attached to lattice sites. Real magnets are much more complicated because the magnetization is due to band electrons whose degree of localization varies between different materials. This so-called itinerancy manifests itself in the fluctuation of the magnitudes of the local moments, which may be defined in a muffin-tin sphere or using a projection in an appropriate basis. Thus, the degree of itinerancy may be characterized by the relative importance of longitudinal and transverse (rotational) fluctuations of the local moments. In the localized (Heisenberg) limit the longitudinal spin fluctuations (LSF) have a large energy scale and are suppressed. This limit is approached in some magnetic insulators. Metals, on the other hand, are often quite far from this limit because the exchange splitting, and the bandwidth are typically of the same order. Experimentally, itinerancy is most clearly revealed in the paramagnetic susceptibility by the deviation of the effective moment found from the Curie-Weiss law. In particular, itinerancy is most clearly revealed in the paramagnetic susceptibility by the deviation of the effective moment found from the Curie-Weiss law. (CW) constant from the true local moment, as well as by the deviations from the Curie-Weiss law.

A large amount of work has been devoted to the thermodynamics of itinerant magnets using phenomenological Ginzburg-Landau models for weak ferromagnets or the Hubbard model and the functional integral methods. These studies have clarified the role of LSF in thermodynamics and explained the observed behavior of the paramagnetic susceptibility. However, these methods are unsuitable for quantitative studies of realistic materials. Ginzburg-Landau expansions, as is well known, correctly describe only the contribution of long-wave fluctuations and must always be rigged with a wave vector cutoff. Such models are useful in the studies of critical phenomena, but they are irrelevant to the determination of the critical temperature itself, which is determined by short-range fluctuations. An unsatisfactory signature of Ginzburg-Landau models is the absence of any information on the short-wave components of the exchange interaction in the resulting expressions for the Curie temperature. In our opinion, the neglect of short-wave fluctuations in these models makes their predictions for magnetic short-range order (MSRO) also unreliable. The functional integral method, on the other hand, suffers from the necessity to make severe and ambiguous approximations.

Magnetic thermodynamics has also been studied using density functional theory (DFT) by treating spin fluctuations within the adiabatic approximation, assuming that the relevant fluctuations are well represented by constrained non-collinear ground states. The most widespread approach is the disordered local moment (DLM) approximation which relies on the single-site approximation and is designed to approximate the DFT ground state of a system with random directions of the local moments. The LSF have been neglected in all implementations of this approach so far, restricting its application to magnets which are close to the localized limit. In particular, the DLM method neglecting LSF fails for (strongly itinerant) nickel where it finds vanishing local moment in the paramagnetic phase.

Other authors studied itinerant thermodynamics by mapping the results of first-principles energies for various spin configurations (including both transverse and longitudinal fluctuations) to a classical Hamiltonian in which variable local moments play the role of dynamical variables, and then exploring the thermodynamics of this Hamiltonian using either the variational principle in reciprocal space or Monte Carlo (MC) simulations in real space. These calculations clearly show that LSF, as expected, are very important in nickel. Moreover, they revealed only weak MSRO above the Curie temperature for both Fe and Ni, which is similar to the Heisenberg model. These results are consistent with the fact that in any lattice model with no frustration, all correlation corrections to the mean-field approximation (outside of the critical region) should be small in the parameter 1/z, where z is the number of neighbors within the interaction range. On the other hand, very strong MSRO above Tc was found in Ni using the ab initio spin dynamics method, which, similar to DLM, is based on the adiabatic approximation and neglects LSF.

Classical models with variable local moments seem to capture the important qualitative features of the thermody-
namics of itinerant magnets which are similar to the predictions of the functional integral method. However, these models have been built and studied only for a few particular materials, and a general study of their thermodynamic properties has not been undertaken. Such a study is useful as a step to more refined models with the advantage that numerically exact results for a classical model are easily accessible through Monte Carlo simulations. Therefore, in this paper we explore the thermodynamics of a classical spin-fluctuation model as a function of the degree of itinerancy using MC simulations and simple analytic approximations. We emphasize that here we are not concerned with the "mapping" procedure (which can be quite challenging) but rather focus on the other separate part of the program, i.e., on the determination of thermodynamics once the Hamiltonian has been defined. We therefore restrict ourselves to the simplest possible realization of this model which includes only one free parameter characterizing the degree of itinerancy.

II. MODEL

Our model is a lattice version of the phenomenological model of Murata and Doniach\textsuperscript{2} written with a vector order parameter\textsuperscript{1}

\[
H = \frac{1}{2} \sum_q \chi^{-1}_q \mathbf{m}_q \cdot \mathbf{m}_q + \frac{B}{4} \sum_i m_i^4 \tag{1}
\]

Here \( \mathbf{m}_i \) denotes the magnetic moment at site \( i \) whose length is unrestricted, and \( I \) is the Stoner exchange-correlation parameter. We have separately written the local \( \chi^{-1}_q = \partial B / \partial m_i \) and nonlocal \( J_q = -\chi_j^+ \) parts of the unenhanced inverse susceptibility. This model involves a number of simplifying assumptions. (1) It is classical in the sense that \( \mathbf{m}_i \) are dynamical variables and not operators. (2) Both local and nonlocal parts of the inverse susceptibility are considered to be independent of the magnetic state and isotropic. In general, \( \chi^+_q \) is a Cartesian tensor which depends on the magnetic state and reduces to a scalar only in the paramagnetic state. (3) Nonlinear effects are included only through a local fourth-order term, similar to the Murata-Doniach model.

Model (1) is somewhat similar to that used to represent the unified spin-fluctuation theory\textsuperscript{7} classically (see Ref. 1, Ch. 7, and also Ref. 20), with an important difference: the energy of LSFs is included as a function of local dynamical variables \( \mathbf{m}_i \), rather than that of one global parameter \( m_i^4 \). This difference is similar to that between the Heisenberg model and the spherical approximation to it. In the ground state all local moments are parallel, and we recover the Stoner model which is ferromagnetic if \( \mathcal{N}(E_F) > 1 \), where \( \mathcal{N}(E_F) = \gamma(0) \) is the density of states at the Fermi level in the nonmagnetic state. This Stoner criterion can also be written as \( (1+J_0) > \chi_0^{-1} \), where \( J_0 = \sum_q J_q \). On the other hand, in the paramagnetic or nonmagnetic matrix, local moments exist in the Anderson sense only if \( I > \chi_0^{-1} \), which is stricter than the Stoner criterion. We will call this the Anderson criterion. (Note that \( \chi_0^{-1} \neq 1/\gamma(0) \).)

Introducing reduced local moments \( x_i = \mathbf{m}_i / m_0 \), where \( m_0 \) is the value of all \( m_i \) at \( T=0 \), the Hamiltonian (1) can be conveniently parametrized

\[
H' = \frac{H}{J_0 m_0^2} = \sum_i E(x_i) - \frac{1}{2} \sum_{i \neq j} J_{ij} x_i \cdot x_j, \tag{2}
\]

where \( E(x_i) = [ax^2 + 2bx^4 + 4]/J_0 \) with \( a = \chi_0^{-1} - 1 \) and \( b = Bm_0^2 = J_0 - a \). For the nearest-neighbor model with coordination number \( z \) we have \( J_n / J_0 = 1/z \), and for the given lattice \( H' \) contains only one parameter, which we define as \( \alpha = \arctan b/a \). Note that \( b > 0 \) is equivalent to the Stoner criterion, and \( \alpha < 0 \) is equivalent to the Anderson criterion.\textsuperscript{21}

To understand the meaning of the parameter \( \alpha \), consider the ground state of Hamiltonian \( H \) with a single-site excitation, i.e., the state with \( \mathbf{m}_i = \mathbf{m}_0 \) for all \( i \) except \( i = c \). The energy of this state has a minimum at \( \mathbf{m}_i = \mathbf{m}_0 \) and its curvature with respect to the longitudinal fluctuation of \( \mathbf{m}_i \) is \( K_i = J_i + 2b \), while the curvature with respect to transverse fluctuations is \( K_i = J_i \). Their ratio \( K_i / K_i = 1 + (2b/J_0) \) characterizes the relative importance of longitudinal and transverse fluctuations. If \( b \gg J_0 \), the fluctuations are mainly transverse, and we have the localized (Heisenberg) limit for which \( a = -b \) and \( \alpha = \mp \pi/2 \). If \( b \ll J_0 \), the transverse and longitudinal spin fluctuations are equally important; this limit corresponds to \( \alpha = 0 \). The Anderson criterion is equivalent to \( \alpha > \pi/2 \). Thus, the parameter \( \alpha \) characterizes the degree of itinerancy and is similar to those appearing in other theories.\textsuperscript{14} Note that we always have \( K_i / K_i > 1 \), even though the macroscopic longitudinal stiffness is proportional to \( b \) and tends to zero at \( \alpha = 0 \).

Evaluation of the thermodynamic properties involves taking a trace over the quantum states or a functional integral over the classical degrees of freedom. To our knowledge, in all classical models reported so far and based on \textit{ab initio} calculations, the uniform measure in the space of \( \mathbf{m}_i \) was used.\textsuperscript{14,17} However, our dynamical variables are not canonical, and therefore the phase space measure (PSM) is not known. In the case when LSF are important, the PSM has to be supplied along with the Hamiltonian as an additional phenomenological ingredient. Strictly speaking, it is not possible to disentangle the measure from quantum statistics; for example, in the atomic limit only integer moments with atomic multiplet degeneracies should be present. Ambiguity of PSM is intrinsic to all microscopic classical spin-fluctuation models including the classical version of the "unified theory" of Moriya and Takahashi (Ref. 1, Sec. VII) and its extensions,\textsuperscript{20} as well as the functional integral approach combined with the static approximation which destroys the correct quantum operator properties. In the latter case, the Hubbard-Stratonovich transformation can be applied with the interaction term written in different ways, which produce different results after the static approximation is made.\textsuperscript{5,9} Two particular choices discussed by Hubbard\textsuperscript{5} result in different measures in the space of fluctuating fields \( \psi; \) uniform in one case, and involving the weighting factor \( \Pi \nu_i^2 \) in another. To explore the influence of PSM on thermodynamics, we will consider these two measures in the space of the local moments \( \mathbf{m}_i \).
zation, the average square of the local moment and the paramagnetic susceptibility using the reduced variables according to Eq. (2). Results are shown for two values of $\alpha$: $0.48\pi$ and $0.69\pi$. In both cases the agreement between MC and MFA results is very good for all properties (MFA overestimates $T_c$ by 20% or less). The results strongly depend on PSM, especially in the more itinerant case $\alpha=0.48\pi$. In particular, for the uniform PSM a second-order phase transition occurs for both values of $\alpha$, but for the PSM with $g(x)=x^2$ the phase transition is of first order for $\alpha=0.48\pi$, and $T_c$ is nearly 2.8 times smaller compared to that for $g(x)=1$.

As seen in Fig. 1, below $T_c$ the average $(x^2)$ declines with temperature due to the decrease in the Weiss field, which causes the maximum of the distribution function to shift to smaller moments. This is in agreement with earlier results.\(^{1,5,6,14,15,17}\) The width of the distribution function increases with temperature, which counteracts the decrease in the local moment. The PSM with $g(x)=x^2$ puts less weight on the states with large moments, and hence $(x^2)$ drops much faster compared to the uniform PSM. If the Anderson criterion is not satisfied ($\alpha < \pi/2$) then the most probable moment in the paramagnetic state is zero. In this case, $(x^2)$ increases with temperature above $T_c$ as seen in Fig. 1(c). On the other hand, if the Anderson criterion is satisfied, the local moment may slightly decrease in a range of temperatures above $T_c$, as seen for $g(x)=x^3$ in Fig. 1(d).

The magnetic susceptibility above $T_c$ is shown in Figs. 1(e) and 1(f). In MC simulations it is calculated using fluctuation-dissipation theorem, while in MFA we directly consider the response of the system to the external magnetic field. Excellent agreement between MFA and MC is observed except for the small error in $T_c$. In MFA one obtains above $T_c$

$$\chi_{\text{MFA}} = \frac{1}{3} \left( \frac{1}{t} - \frac{1}{3} \right)^2.$$

This formula looks similar to the Curie-Weiss expression in the Heisenberg model, but here $(x^2)$ depends on temperature, which leads to a renormalization of the CW constant and deviations from the CW law. The CW constant $C = d\chi^{-1}/dt$ (for a second-order phase transition) is now given by

$$C = \frac{3}{\langle x^2(t_c) \rangle} \left[ 1 - \frac{d}{d\log t} \left( \log t \right) \right].$$

Thus, in addition to the usual Heisenberg term the Curie constant has a contribution due to the temperature dependence of $(x^2)$ [second term in square brackets in Eq. (5)]. As a result, the effective moment squared $x_{\text{eff}}^2 = 3/C$ deviates from $(x^2)$. As discussed above, $(x^2)$ usually increases with temperature above $T_c$, which, according to Eq. (5), reduces $C$ and increases $x_{\text{eff}}^2$. Moreover, for the uniform PSM $(x^2)$ increases faster with temperature compared to PSM with $g(x)=x^2$, and hence the CW constant is much smaller in this case [see Fig. 1(f) and also Fig. 1(e)], where the transition is however of first order].
The order parameter for the second-order transition is given by the equation
\[ E = \frac{1}{2} \sum_{ij} J_{ij} \langle \mathbf{m}_i \cdot \mathbf{m}_j \rangle \]
where the superscript \( x \) refers to the lattice with a cavity, i.e., with site 0 removed, and \( m \) is the magnitude of the magnetic moment.

In Fig. 2 some thermodynamic properties of the system are plotted as a function of the itinerancy parameter \( \alpha \). From Eq. (4) it follows that the MFA value of \( T_c \) for the second-order phase transition is found by solving the equation
\[ 3 \beta_c = \langle x^2(t_c) \rangle \]
where \( \langle x^2(t) \rangle \) is determined by the self-consistent renormalization theory for the Hubbard model. The cavity field method was successfully applied to Ising magnets which have permanent magnetic moments. Cyrot \(^{26} \) noted that Moriya-Kawabata’s self-consistent renormalization theory for the Hubbard model may be essentially reproduced by using Onsager-type arguments; more recently this method was implemented numerically. \(^{27} \) However, the actual physics there is very different; Cyrot’s approach seeks the correlation correction with respect to the Hartree-Fock solution, which is unrelated to short-range order. Onsager’s method was also applied to itinerant nickel, \(^{13} \) but, as we will see below, correct generalization to itinerant systems with LSF requires an additional ingredient which was missed in Ref. 13.

We now generalize Onsager’s method to magnets with LSF described by Hamiltonian (1). Consider model (1) above \( T_c \) in a small external collinear magnetic field \( H_{ext} \). We pick site 0 and integrate out the degrees of freedom from all the other sites in the partition function to obtain the effective Hamiltonian in the form of a generating functional for the lattice with a cavity.\(^ {18} \) Expanding this functional around the atomic limit to order \( 1/\alpha \) we obtain
\[ H_{cav} = E(m_0) - m_0 \langle H_{ext} + \sum_i J_{0i}(m_i^0) \rangle - \frac{m_0^2}{2} \sum_{ij} J_{0i}J_{0j} \chi_{ij}, \]
where the superscript \( c \) refers to the lattice with a cavity, i.e., with site 0 removed, and we used the fluctuation-dissipation

FIG. 2. (Color online) (a) Reduced Curie temperature \( T_c \) and (b) MSRO parameter \( \langle \cos \theta_{m0} \rangle \) at \( T=1.1T_c \) as a function of the itinerancy parameter \( \alpha \) for the fcc lattice. Solid black line, red (gray) squares, and blue (dark gray) circles show the results of MFA, MC, and the generalized Onsager method for \( g(x)=1 \), respectively. Dashed black line and empty black squares depict MFA and MC results for \( g(x)=x^2 \). Green (light gray) triangles represent the incomplete Onsager reaction field correction with the on-site interaction left unrenormalized. The blue (gray) dashed-dotted line in the upper panel shows the effective magnetization \( x_{eff} \) found from the Curie constant for \( g(x)=1 \) in MFA. Very similar results were obtained for the bcc lattice (not shown).
This renormalization of the bare susceptibility is the essential feature in the definition of the effective field $\hat{W}$, which may be written as $\hat{W}=\hat{J}+\hat{\Pi}\hat{W}\hat{\Pi}$, and $\hat{\Pi}$ is the one-bond-irreducible “polarization operator” which may be shown to be local to first order in $1/z$.\textsuperscript{20} [All quantities in Eq. (7) are matrices in site indices.] Removal of site 0 may be formally represented by a perturbation $\Delta \hat{\Pi}=-\Pi_{00} \delta \Pi_{0j}$ to $\hat{\Pi}$. (The renormalization of $\Pi_{0j}$ for $j \neq 0$ due to removal of site 0 is at least of order $1/z^2$. Thus, denoting the effective interaction matrix for the cavity lattice as $\hat{W}_c$, we may write $\hat{W}_c=\hat{W}-\Delta \hat{\Pi}$. Using Eq. (7) and the fact that $\Pi$ is diagonal, we find

$$\chi_0 = \chi_{0j} - \frac{\chi_{00} \chi_{0j}}{\chi_{00}}. \quad (8)$$

The average local moments $M_i^f=\langle m_i \rangle$ for the lattice with a cavity are

$$M_i^f = \sum_j \chi_{ij} H_j^{ext} = M_i - \frac{\chi_{00}}{\chi_{00}} M_0, \quad (9)$$

where $M_i$ is the average local moments of the complete lattice without the cavity. The value of $H_0^{ext}$ does not affect $M_i^f$ (as expected), therefore in the right-hand side of Eq. (9) we may take $M_i$ for the actual field distribution.

From the effective Hamiltonian (6) we can find the magnetization at site 0

$$M_0 = \hat{\chi}^0 \hat{H}_0, \quad (10)$$

where

$$\hat{H}_0^{ext} = H_0^{ext} + \sum_i J_{0i} \left( M_i - \frac{\chi_{00}}{\chi_{00}} M_0 \right). \quad (11)$$

is the renormalized effective field (cavity field), and $\hat{\chi}^0$ is the renormalized bare (atomic-limit) susceptibility. The latter may be written as $\hat{\chi}^0=\langle m^2 \rangle / 3T$, where the average paramagnetic squared local moment $\langle m^2 \rangle$ is calculated using a renormalized on-site exchange $\tilde{T}=T+\lambda$, where $\lambda=\sum_j J_{0j} \chi_{0j}$. This renormalization of the bare susceptibility is the essential ingredient needed to extend Onsager’s theory to itinerant magnets. It has no effect in the localized limit where $m^2$ is constant.

As usual, we now obtain the Fourier transform of the susceptibility

$$\chi_q = \frac{\hat{\chi}^0}{1 - \hat{\chi}^0 (J_q - \lambda)}, \quad (12)$$

where $\lambda=\sum_j J_{0j} \chi_q / \chi_{00}$. We used the same symbol $\lambda$ as above in the definition of $\tilde{T}$ because these expressions are identical, as can now be shown with the help of Eqs. (12) and (8). Equation (12) with the definitions of $\lambda$, $\hat{\chi}^0$, and $\tilde{T}$ form a closed set of equations for the paramagnetic susceptibility. Note that Eq. (12) automatically leads to a sum rule $\chi_{00}=\chi^0$, which agrees with the fluctuation-dissipation theorem.

At the Curie temperature $T_c$ diverges at $q=0$. Therefore, from Eq. (12) we obtain $T_c = \frac{J_0}{\tilde{T}} (\lambda^2 J_0) / G$, where $G = \sum_q (1 - J_q / J_0)^{-1}$ is the diagonal element of the lattice Green’s function.\textsuperscript{25} Note that the value of $\lambda$ at $T_c$ is equal to $J_0 (1 - G^{-1})$ and independent of the degree of itinerancy $\alpha$.

The reduced Curie temperature $t_c$ and MSRO parameter $\langle \cos \theta_0 \rangle = 1 + T_c$ calculated in this way are shown in Fig. 2 for the bcc lattice and the PSM with $\langle g(x) \rangle = 1$. The agreement with MC results is excellent in the whole range of $\alpha$. We repeated these calculations for the FCC lattice and found excellent agreement with MC as well. The accuracy of the predicted $t_c$ may be seen from Table I. Similar performance for bcc and fcc lattices suggests that this approximation is not very sensitive to the connectivity of the lattice. The paramagnetic susceptibility is also shown in Fig. 2 for bcc, fcc, and uniform PSM. The agreement with MC results is essentially perfect outside of the narrow critical region.

The first-order terms in the $1/z$ expansion derived above introduce two corrections to MFA. The first one is the subtracted mean reaction field; this correction reduces the magnetization. This is the only correction in Onsager’s method for systems with permanent moments. The second correction described by the last term in Eq. (6) adds back the fluctuating reaction field which is always parallel to the moment on the central site. For the Heisenberg (or Ising) model this second correction has no effect, but in itinerant systems it always increases the local moments and hence the Curie temperature. There is a strong cancellation between these two corrections in itinerant systems and improvement compared to MFA may be achieved only if both of them are included. Indeed, if the renormalization of the Stoner parameter is not taken into account [i.e., if the last term in Eq. (6) is dropped], we find a spurious strong suppression of $T_c$, for itinerant systems, as shown in Fig. 2(a).

It is interesting to compare the generalized Onsager method with the Horwitz-Callen (HC) approximation which is based on the “ring subset” of diagrams for the generating functional $\Phi$ in the linked-cluster technique.\textsuperscript{28,30} In this method, the second-order self-field $G_2$ is found by differentiating $\Phi$ with respect to the renormalized second cumulant $M_2$, while $M_2$ is represented by an integral containing $G_2$ as a parameter. This technique does not assume any particular form for the atomic limit, and therefore it can be used in our case including LSF as well. In the HC method, the on-site correlator may be found as $K_0=2M_2+G_2$, and the sum rule $K_0=1$ is not satisfied in the paramagnetic Heisenberg magnet. However, it is easy to check that the value of $K_0$ at $T_c$ is smaller than 1 by less than a percent in bcc and fcc lattices. In Onsager’s method for the Heisenberg model, the sum rule $K_0=1$ is used to fix $M_2$ instead of the integral representation as in the HC method. The results for $T_c$ are therefore very close. We found that this close similarity remains in the entire range of $\alpha$, as seen from Table I. The
generalized Onsager’s method is, however, technically much simpler.

V. CONCLUSIONS

We have studied the thermodynamics of a simple classical spin-fluctuation model allowing for a variable degree of itinerancy. This model is qualitatively similar to those used before to study the thermodynamics of Fe and Ni using first-principles data.\textsuperscript{14,15,17} It is worth emphasizing that the main drawback of using classical spin models of this type is the ambiguity of the phase space measure. As we showed above, the thermodynamics is very sensitive to this measure for systems with even intermediate degree of itinerancy. While the energetics of constrained spin configurations may, at least in principle, be accurately mapped using DFT calculations, it is not known (to our knowledge) how and whether the phase space measure can be supplied in a realistic way.

In the present work, we focused on the general features of the model rather than on the determination of its parameters from principles. We found that the thermodynamic properties are similar to the results of the functional integral approach.\textsuperscript{1,4–6} Further, we found that the mean-field approximation is qualitatively valid, and short-range order is weak and almost independent on the degree of itinerancy up to the strongly itinerant limit where the paramagnetic susceptibility is dominated by longitudinal fluctuations. This is in agreement with earlier results for the models of Fe and Ni (Refs. 15 and 17); it is clear that this is a general feature of the classical model with no frustration.

Further, we generalized the Onsager cavity field method to itinerant systems using an expansion around the atomic limit to first order in $1/z$. Both the interatomic exchange constant and the Stoner parameter are renormalized by short-range order. When both these corrections are included, the Curie temperature is in excellent agreement with Monte Carlo results. However, simple subtraction of the Onsager reaction field is a very poor approximation.
